

# XXVIII Congress of the International Society of Biomechanics (ISB)

# Program & Abstracts

Digital Congress 25-29, July 2021

Congress sponsor

Major sponsors

Basic Sponsor

Qualisys Partners

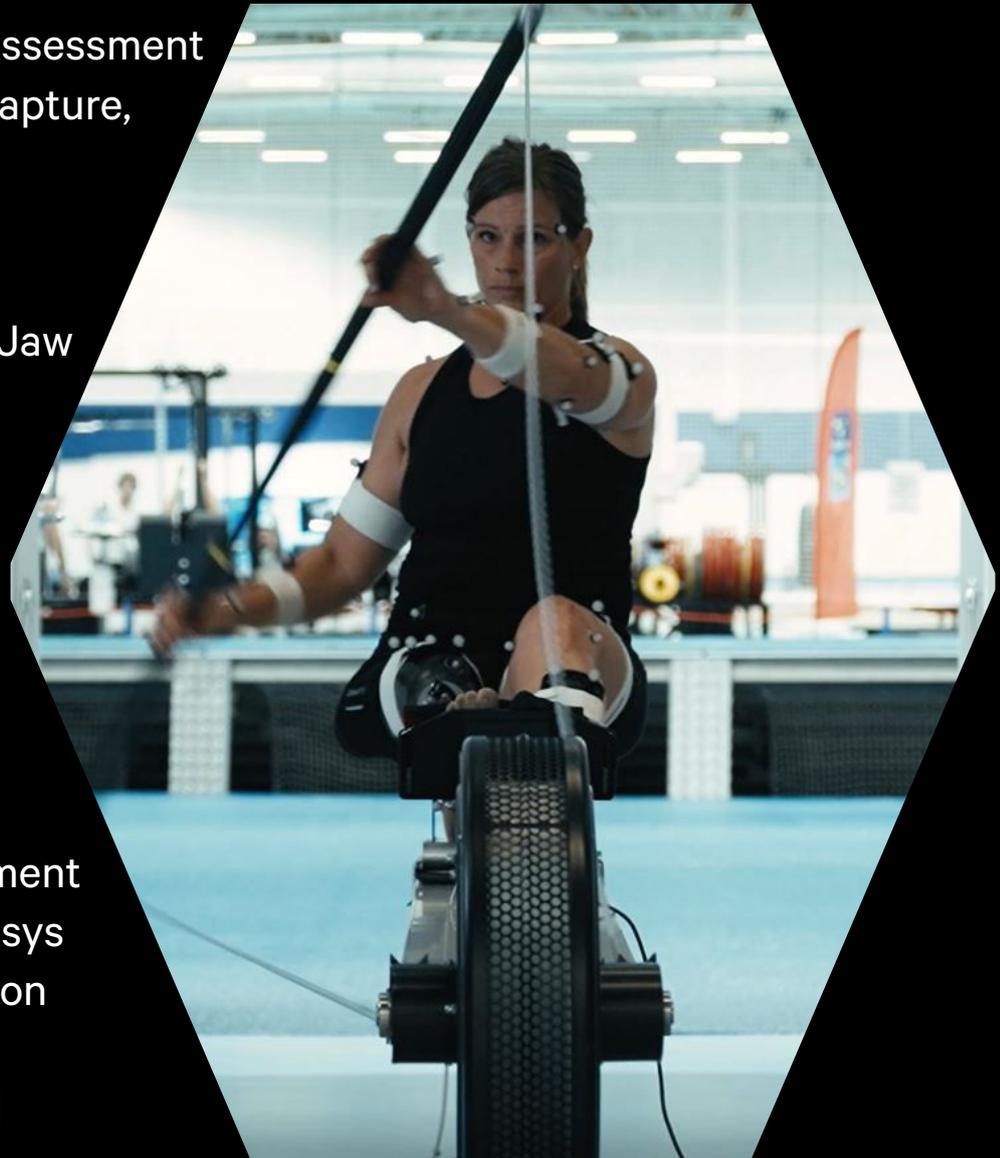

Arranged by

# QUALISYS

QUALISYS is proud to support the biomechanics community by being main congress sponsor of ISB 2021. For more than 30 years, we have been supplying motion capture systems for researchers, athletes, coaches, and clinicians. Together with our partners, we run daily live workshops from Qualisys ISB Studio. Check the congress program for the schedule. We are looking forward to seeing you!

- Objective Functional Assessment with Qualisys motion capture, Delsys EMG and AMTI force plates
- Innovative Analysis of Jaw Movement with Delsys EMG and Qualisys Motion Capture
- Qualisys and Theia Markerless workflows: hands-on session
- Fully Integrated Movement Assessment with Qualisys Motion Capture, Noraxon EMG and h/p/cosmos instrumented treadmill

*Helene Ripa, a World famous paralympic athlete, is practicing at Bosön, Sweden.*

# Welcome

to the XXVIII Congress of the International Society of Biomechanics!

For the first time ever this meeting will be held fully digitally and we are sure we will set a benchmark for successful digital meetings. Despite the financial, travel and personal difficulties imposed by the Covid-19 pandemic, we are excited to announce that over 1000 people have registered and that companies continue to be attracted to support the ISB.

The congress will start with the traditional educational tutorials with the highly relevant and stimulating topics of wearable sensors, imaging and modelling, deep learning and optimal control in biomechanics: <https://isb2021.com/program/tutorials/>. We are also extremely proud to have attracted such an eminent list of Award and Keynote lecturers: <https://isb2021.com/speakers/>. In order to promote discussion and insight into some cutting edge and controversial issues in biomechanics we have a strong focus on five panel debates with world experts on the topics: the distribution problem in biomechanics and motor control; markerless vs marker motion capture; scientific peer review; biorobotics; computational approaches on studying locomotion disorders. Please visit here to find details concerning these debates and the internationally renowned biomechanists leading them: <https://isb2021.com/program/debates/> Special sessions have been organised by the ISB Hand and Wrist Biomechanics International and Motor Control Technical Groups and also one on Computer Simulation.

The congress will also include student social events, student mentoring possibilities and Advancing Women in Biomechanics sessions. Also, a new format is being explored for exposing the fantastic sponsors, whom, despite the difficulties experienced during the Covid-19 pandemic have remained loyal to ISB. The congress sponsor (Qualisys and partners) and the major sponsors (Vicon, Xsens) will have special sessions in which to present their companies to all delegates – we are sure this will be a new level of digital exposure for congress sponsors!

Every effort has been made to make the congress as attractive as possible in the digital format. We have staggered the days so that material is available to different time zones on different days, all oral and plenary presentations will be live so that a discussion is possible and all material will be recorded and available to registered delegates for 30 days after the congress.

Many generous scientific awards will be presented including two new ISB awards: the Jaqueline Perry Emerging Female Scientist Award and the World Athletics Award for Biomechanics.

We are confident that ISB2021 will be a truly exciting event with an exceptional level of scientific content! We are happy to welcome you to ISB2021, the most gender equal ISB congress ever.

**Dr. Arndt**  
Professor in Biomechanics  
Swedish School of Sport and  
Health Sciences (GIH)

**Dr. Gutierrez Farewik**  
Professor in Biomechanics  
KTH Royal Institute of Technology

**Dr. Felländer-Tsai**  
Professor and senior consultant  
in Orthopaedics  
Karolinska Institutet

	Sunday 25 July	Monday 26 July	Tuesday 27 July	Wednesday 28 July	Thursday 29 July

## WELCOME

07:15 - 08:15

## KEYNOTE LECTURE: MUSIC PERFORMANCE BIOMECHANICS - USING BIOMECHANICAL PRINCIPLES TO GUIDE REHABILITATION OF INJURED MUSICIANS (BRONWEN ACKERMANN)

Location: Online

### BRONWEN ACKERMANN

Associate Professor Bronwen Ackermann is a specialist musicians' physiotherapist, musculoskeletal anatomist and medical science researcher focussing on musicians' health at the University of Sydney. Her research has focussed on interventions that can inform evidence-based approaches to optimising musical performance as well as preventing, assessing and managing performance-related injuries in musicians. Her research has utilised technologies including electromyography, 3D motion capture and fMRI imaging technology to better understand mechanisms underpinning healthy and pathological muscle usage patterns during musical performance. Additionally, she has worked extensively clinically with musicians using qualitative motion analysis, including video feedback and fine-motor coordination assessment, particularly for music-specific actions involving the upper limb, as well as orofacial and respiratory structures.

She was responsible for developing and leading the intensive Essentials of Performing Arts Medicine annual training course for the Performing Arts Medicine Association (PAMA) and American College of Sports Medicine (USA), authored an online e-health training program for musicians ([www.soundperformers.com](http://www.soundperformers.com)), led the first international occupational health and safety program for a national cohort of orchestral musicians (Sound Practice), and worked as the High Performance Consultant at the Australian National Academy of Music from 2012-2020. Internationally she collaborates extensively in research, teaches on a wide range of musicians' health topics, and has authored over 70 publications. Currently, she is a Humboldt Fellow in Germany, evaluating a clinical movement retraining program she designed to assess and treat task-specific movement dysfunctions, specifically embouchure (orofacial) dystonia and focal hand dystonia.

08:15 - 08:30

## BREAK

Location: Online

08:30 - 09:30

## OA1 - ARTIFICIAL INTELLIGENCE AND MACHINE LEARNING

Location: Online

Chair: Kim Duffy

Pres Time	Presentation title/Abstract title	Speakers/Authors
8:30	Generating 2D video frames from 3D motion capture data: a proof-of-concept study	Marion Mundt
8:42	Rib injury prediction using machine learning-based surrogate models	Shitij Malik
8:54	A machine learning approach for error detection in rowing	Oscar Sten
9:06	Validation of an AI assisted simple method to study muscle-tendon dynamics during running	Christoph Leitner
9:18	Optimal forefoot rocker parameter prediction using machine learning	Fredrik Olsson

08:30 - 09:30

## OA2 - BIOMEDICAL ENGINEERING

Location: Online

Chair: Elizabeth Clarke

Pres Time	Presentation title/Abstract title	Speakers/Authors
8:30	Does a prosthetic toe joint affect mechanics or preference when persons with limb loss walk over uneven terrain?	Kirsty McDonald
8:42	Influence of excipients and lesions on drug-coated balloon therapy	Karthic Anbalakan
8:54	Change in mechanical properties of cortical bone under voltage application for formation of mineral components	Fuki Ota
9:06	Production of micro-structured hollow fiber membranes for membrane oxygenators - mimicking nature to increase mass transport	Markus Pekovits
9:18	Passive ankle exoskeletons influence muscle behaviour during unexpected perturbations	James Williamson

08:30 - 09:30

## OA3 - CLINICAL BIOMECHANICS

Location: Online

Chair: Laura Diamond

Pres Time	Presentation title/Abstract title	Speakers/Authors
8:30	How does the prosthetic design affect muscle strength after knee arthroplasty surgery?	Iris Mittendorfer
8:42	Do bone defects of the greater trochanter affect the postoperative femoral fracture risk after total hip arthroplasty? A biomechanical study	Michael Saemann

8:54	Trunk kinematics during walking in adults receiving total knee arthroplasty: A systematic review	Tamaya Van Criekinge
9:06	Ambulatory knee mechanics after ACL repair with InternalBrace augmentation compared to healthy controls	Linda Bühl
9:18	Estimation and assessment of sagittal spinal curvature and thoracic muscle morphometry in different postures	Anoosha Pai S

08:30 - 09:30

## OA4 - IMAGING

Location: Online

Chair: Geoffrey Handsfield

Pres Time	Presentation title/Abstract title	Speakers/Authors
8:30	Pose and shape registration of ankle bones using statistical shape and intensity model during walking	Jeongseok Oh
8:42	Preliminary Micro-CT imaging of the human tibial plateau under load	Kieran Bennett
8:54	Can synchrotron phase contrast micro-tomography uncover how in vivo loading affects the achilles tendon structure?	Maria Pierantoni
9:06	A principal component analysis of infant gastrocnemius growth in the first two years of life	Ricardo Florez
9:18	Quantitative comparison of fascicle length in lower limb muscles using 3D freehand ultrasound and diffusion tensor imaging	Zhongzheng Wang

08:30 - 09:30

## OA5 - LOCOMOTION: GENERAL + CLINICAL GAIT

Location: Online

Chair: Rosemary Dubbeldam

Pres Time	Presentation title/Abstract title	Speakers/Authors
8:30	The feasibility and effectiveness of treadmill-based perturbations for assessing and improving walking stability in chronic obstructive pulmonary disease: a pilot study	Christopher McCrum
8:42	Simultaneous measurements of in vivo knee contact and tendon loading during walking	Colin Smith
8:54	Classification of spatiotemporal gait patterns in unilateral transfemoral amputees	Daisuke Ichimura
9:06	Series elasticity facilitates safe plantarflexor muscle-tendon shock absorption during perturbed human hopping	Taylor Dick
9:18	Musculoskeletal simulation of a gait for a person with unilateral transfemoral amputation: The cause of muscle atrophy	Isna Riski Safira

08:30 - 09:30

## OA6 - LOWER EXTREMITIES

Location: Online

Chair: Logan Wade

Pres Time	Presentation title/Abstract title	Speakers/Authors
8:30	Comparative effects of conservative and arthroscopic management of femoroacetabular impingement syndrome on lower limb angles and moments	Tamara Grant
8:42	Accuracy estimation of a MIMU-based functional calibration for ankle kinematics assessment	Paolo Brasiliano
8:54	Effects of 12 different heel rocker designs, configured with different rocker radii, apex positions and apex angles, on plantar pressure	Athra Malki
9:06	The effect of a foot strengthening exercise intervention on restoring foot strength in people with diabetic peripheral neuropathy	Karen Mickle
9:18	The energetic function of the human foot and its muscles during rapid accelerations and decelerations	Ross Smith

08:30 - 09:30

## OA7 - MUSCULOSKELETAL MODELLING

Location: Online

Chair: Sofia Brorsson

Pres Time	Presentation title/Abstract title	Speakers/Authors
8:30	Geometrical variations of the hind- and mid-foot and their associated functional consequences	Bryce A Killen
8:42	A mesh contact model for biomechanical simulations with automatic differentiation	Gil Serrancolí
8:54	A model of muscle mechanics elicits the important role of increased baseline tone in joint hyper-resistance in cerebral palsy	Jente Willaert
9:06	Wave propagation in muscles predicted by a Hill-type model with distributed mass	Jianqiao Guo
9:18	Accounting for vessel holes in finite element models of the femur affects strain prediction	Joeri Kok

08:30 - 09:30

## OA8 - ORTHOPAEDICS

Location: Online

Chair: Gustavo Orozco

Pres Time	Presentation title/Abstract title	Speakers/Authors
8:30	Cumulative joint damage from repeated mild knee injuries over time	Carina Blaker

8:42	Muscle-tendon morphomechanical properties of non-surgically treated Achilles tendon 1-year post-rupture	Raad Khair
8:54	Analysis of post-operative osteoblastic activity patterns in unicondylar knee arthroplasties slated for revision	Félix Dandois
9:06	Dynamic knee loading in the ACL deficient knee	Georgios Giarmatzis
9:18	Influence of implant alignment on joint laxity following medially-stabilized total knee arthroplasty	Orcun Taylan

09:30 - 09:45

## BREAK

Location: Online

09:45 - 10:15

## OBJECTIVE FUNCTIONAL ASSESSMENT WITH QUALISYS, DELSYS AND AMTI

Location: Online

Qualisys invites you to experience the Swedish concept of "Fika": taking a break with friends or colleagues to relax, talk and share information. In this first session, our partners Delsys and AMTI will join us to demonstrate a fully integrated, digital workflow to generate a Functional Assessment report.

Our software, QTM, supports a range of force plates and EMG systems which enables force data and EMG capture along with the motion capture. During the session, we will present our integration with AMTI and Delsys and live demos.

The data will be presented in our online report that contains graphs, metrics, video, and a 3D visualization. The interactive report is easy to use, all data are synchronized, and the different sessions can be compared easily.

10:15 - 11:45

## POSTER SESSION A

Location: Online

Pres Time	Presentation title/Abstract title	Speakers/Authors
	• Test test Running ISB 2021	Pärnilla Thompson
	• Analysis of biomechanical characteristics during the drop-landing phase with bionic shoes: A pilot study	Ukadike Chris Ugbohue
	• Can intraoperative intra-articular loads predict knee joint laxity? A Cadaveric Simulator Study	Darshan Shah
	• A proposal for the definition of anatomical reference systems for the bones of the foot and ankle complex	Michele Conconi
	• Muscle activity and fatigue in the context of musculoskeletal health complaints in high string musicians	Dirk Möller

- ACL injury prevention in high knee flexion conditions: a new musculoskeletal model Davide Pavan
- Design principles, mechanical testing and functional evaluation of a novel custom dynamic Ankle-Foot Orthosis for drop-foot patients Paolo Caravaggi
- Effects of Tai Chi exercise on postural stability among the elderly during stair descent under different levels of illumination Yaya Pang
- Quantification of arm swing during walking in healthy adults and patients with idiopathic Parkinson's disease Elke Warmerdam
- Meta-learning for personalized golf swing monitoring to overcome motion variability between users Myeongsub Kim
- Identifying the objective of human behavior using inverse reinforcement learning: A Case of human postural control SeongWoong Hong
- Classification of children with fragile X syndrome based on gait analysis: A supervised clustering approach Weronika Piatkowska
- FFH detection using SVM with SMOTE, normalization, and univariate feature selection Bummo Koo
- SEMG-based finger posture recognition considering the re-wearing of an armband sensor Jongman Kim
- Cerebral palsy gait classification based on 3D motion capture data using deep convolutional neural network Joongon Choi
- Upper Body Posture Monitoring Using Inertial Measurement Units and Recurrent Neural Network Hao-Yuan Tang
- A Biomechanical Testing Platform for the Stability and Mobility Assessment of Extracapsular Stabilization of Cranial Cruciate Ligament-Deficient Dogs Wei-Ru Hsu
- Acute effects of transcranial direct current stimulation on dynamic postural stability in healthy young adults Baofeng Wang
- Evaluation of Position and Variability of the Center of Pressure During Walking with Limited Knee Flexion Seobin Choi
- Visualising load distribution of the knee throughout kneeling tasks Simon Thwaites
- Effects of dual-task training on gait in stroke patients: a meta-analysis Xueyi Zhang
- Effects of transcranial direct current stimulation on dynamic postural control: A meta-analysis Changxiao Yu
- Evaluation of trunk muscles during horseback riding therapy on children with cerebral palsy Kenichi KANEKO
- Effects of different pressure lower-body compression garments on proprioception 思焱 王

- Comparison of foot kinematics of toe walking in the able-bodied to spastic equinus gait of cerebral palsy Beomki Yoo
- Systematic review of in vivo foot and ankle kinematics during gait measured using a dual fluoroscopic imaging system Dongqiang Ye
- Comfort assessments in a pneumatic cuff system Yejin Nam
- The differences between bonded and frictional contact settings in foot-sneaker finite element analysis Yi Yang
- Evaluation of muscle function by mechanomyography during dynamic contraction using microphone and accelerometer Yuki Haruta
- The functional role of collagen content in the human cartilage cell microenvironment Awuniji Linus
- Role of actin filament in dynamic changes of intranuclear strain induced by cyclic stretching Takumi Asakawa
- Dynamic responses of cells govern the boundary instability at the closing wound Jeong Hyuntae
- Hypoxic postconditioning on astrocyte activation in a 3D cortical stroke model Mong Lung Steve Poon
- Biophysical response of human bronchial epithelial cells to biocides Tae Yoon Kwon
- Arm Profile Score represents ability of activity using upper limb in individual with stroke. Dain Shim
- Lumbar and pelvis statistical shape model to characterize population shape variations Nikita Ghosh
- Evidence literature summary: Patellofemoral pain in adolescents and objective test routines for the movement analysis laboratory Beat Goepfert
- Kinematics Comparison of Two Posterior Stabilized Knee Implants During Daily Activities Chang Shu
- The effects of Joint Hypermobility Syndrome on the kinematics and kinetics of the vertical jump test Najla Alsiri
- Are biomechanics during gait associated with the structural onset and progression of lower limb osteoarthritis? A systematic review and meta-analysis Nicole D'Souza
- Influence of ankle joint angle on Achilles tendon stiffness Evan Crotty
- Assessment of role of iron in neural circuitry of motor intention on performance of Brain-Computer Interfaces Jagriti Natraj
- Imaging and image processing pipeline for enhanced connective tissue MRI Meeghage Randika Perera

- Detailed correlation between coronary artery disease and tissue speckle tracking Srisakul Chaichuum
- Differences in mechanical properties of hurdle bars Ryo Iwasaki
- Reliability of measuring ACL injury risk associated knee morphology in adolescent females Antonis Stylianou
- The effect of low back pain on plantar pressure during gait Clara Leyh
- Effects of different custom-made insoles on pressure-time integrals in cavus feet during running Mujia Ma
- Predictive simulation of walking with weak ankle plantar-flexor using an AI gait controller Young-Jun Koo
- ISB recommendations for skin-marker-based multi-segment foot kinematics Alberto Leardini
- Investigation of the function of walking shoes equipped with spring on the heel during gait Hayase Funakoshi
- The effect of functional biomechanics garment for walking Toshinori Miyashita
- Long-term Tai Chi practitioners performed better under dual-task condition during stair ascent Qipeng Song
- A longitudinal analysis of change of gait stability in older adults with dementia Sina Mehdizadeh
- Functional insoles improve plantar pressure distribution during race walking qipeng song
- Population etudy of kinematic gait parameters for biometric application Gunwoo Park
- A kinematic comparison of overground and treadmill walking using AI-based gait controllers Mingi Jung
- Developmental plasticity of locomotor economy in an avian bipedal model Talayah Johnson
- Plantar fascia stiffness is related to the foot arch deformability and performance in single-leg drop jump Hiroto Shiotani
- Adaptations of foot function when hopping on a damped surface Jonathon Birch
- Knee and ankle joint stiffness during running with different runaway surfaces Zihan Yang
- GaitSense: Estimation of knee joint angle for sit-to-stand (STS) movement activity in Osteoarthritis Gunjanbhai Patel
- Predictive tracking of the knee position for mobile x-ray imaging Seungwoo Yoon
- Identifying and comparing hip-knee coordination patterns in instep and punt kicking using functional data analysis Liwen Zhang

- Electromyography recordings of the tensor fascia lata muscle during dynamic tasks: A comparison of surface and fine-wire electrodes Manuela Besomi
- Removing artificial jumps from kinematic recordings with multiple cameras Charlotte Le Mouel
- Micro-biopsy fiber mechanics from the medial gastrocnemius of dancers Paige Rice
- Influence of intermittent blocking of visual information on corticomuscular coherence during walking Hitoshi Makabe
- Balance-dexterity task performance in and out of an episode of low back pain Jiaxi Tang
- The mechanical arrangement of the human semitendinosus muscle as assessed with shear wave elastography Adam Kositsky
- Surgical positioning of the hip joint center during total hip arthroplasty and its effects on muscle and hip joint reaction forces Jasvir Bahl
- Optimal Design of Elastic Ankle Exoskeleton Using Optimal Control of Musculoskeletal Model Karthick Ganesan
- Estimations of knee joint loading using generalized methods and muscle recruitment strategies Kieran Bennett
- Effect of sagittal alignment parameters on intervertebral compression forces in asymptomatic adolescent girls, during a pubertal growth spurt, using a thoracolumbar musculoskeletal model Mohammad Amin Shayestehpour
- Improving muscle geometry through via-point optimization Thomas Geijtenbeek
- The difference of bilateral tibial load in patients with unilateral anterior cruciate ligament reconstruction during jogging Ting Long
- The effect of functional knee alignment on the knee contact forces during execution of closed kinetic chain rehabilitation exercises Williane Bernardes
- Finite element solver based full-body musculoskeletal model for multiscale biomechanics Shihao Li
- Pre-operative planning of high tibial osteotomy using musculoskeletal and finite element models mousa kazemi
- Is hallux valgus responsible for metatarsus primus varus? Yuya Oishi
- Cartilage thickness is coupled to bone shape in healthy knees and varies with sex Marco Schneider
- How do Bone Measurements Change with Growth in a Paediatric Population? Laura Carman

- Increased Loading Rates During Gait Correlate with Morphology of Unaffected Hip in Juveniles with Treated Developmental Hip Dysplasia

WEI-CHUN LEE
- Whole-body sagittal plane angular momentum during running in unilateral transfemoral amputees

Genki Hisano
- Proprioceptive neuromuscular facilitation improves symptoms in older adults with knee osteoarthritis

Qipeng Song
- The effects of impaired foot plantar sensitivity on plantar pressure distribution during walking

Mengzi Sun
- Providing gravitational support using a direct-drive linear actuated assistive robot for shoulder rehabilitation

Soroosh Haji Hosseinejad
- Internal work could be used to estimate energy expenditure at various running intensities.

Bumjoon Kim
- Effects of training volume on lower limb kinematics in fast and slow running speed conditions in elite marathoners

Liqin Deng
- Shifts of tibiofemoral joint forces across the entire period of a half marathon

Tony Lin-Wei Chen
- Effects of running speeds and footwear on achilles tendon loading in elite marathoners with different training volumes

Xini Zhang
- Foot motion analysis using a stretch strain sensor during gait and running

Kodai Sakamoto
- Effects of training volume and running shoes on the patellofemoral joint loading in elite marathoners

Bin Shen
- Effects of the arch span of a carbon-plated midsole on running shoe energy transformation--a finite element study

Tony Lin-Wei Chen
- Influence of the functional foot supporter on the foot motion during locomotion

Shintarou Kudo
- FEM Driven plantar foot orthosis for diabetic foot prevention.

Alfredo Ciniglio
- Computational framework to perform parametric CFD studies from a patient-specific left atrium

Jorge Dueñas Pamplona
- Assigning trabecular bone material properties to total hip arthroplasty finite element models of the pelvis with peri-prosthetic osteolytic lesions

Thomas Grace
- Construction of subject-specific foot finite element model based on foot surface scan

Yinghu PENG
- Osteoporosis vertebral compression fracture finite element simulation and expendable bone implant system evaluation

Kit-leng Cheang

- Feasibility analysis of method for obtaining muscular data of forearm using musculoskeletal simulation TZU-LING CHEN
- An OpenSim-based musculoskeletal model controlled by neural oscillators that generates human gait patterns Makoto Yoshida
- Estimation of knee ligament forces during non-resisted and resisted pedaling using finite element analysis Yu-Ting Chen
- Simulating subject-specific spine mechanics: An integrated finite element and neuro-musculoskeletal modelling framework Laura Meszaros
- Biomechanical analysis of the stick handling in field hockey: kinematics and kinetics assessment Alfredo Ciniglio
- Intra-subject repeatability of joint angle measurement during skating on synthetic ice Aminreza Khandan
- Looking for the ideal sprint stride: how would sports results change if all strides were perfect Andrey Pomerantsev
- Grip socks reduce in-shoe sliding but not actual change of direction performance Charlotte Apps
- Reproducing the characteristics of muscle fatigue change through sEMG analysis based on joint mechanical work during upper limb repetitive rotation Jinsung Jung
- Feedback-based running retraining for impact reduction: The relationship between peak tibial acceleration and step frequency Pieter Van den Berghe
- The effect of cadences on lower extremity biomechanics during stair ascent and descent Qi Li
- Analysis flat service in tennis RAJINIKUMAR  
PALANIYAPPAN
- Kinematics Analysis of a Malaysian Female Elite Tenpin Bowler A Case Study Victoria Chin Quan Weoi
- Analysis of pacing strategy adopted by long-distance cross-country skiers XIANSHUANG YUAN
- Biomechanics of fast bowling in men's cricket using wearable sensors Ammar Waheed
- Combinations of release parameters for accurate baseball pitching Ayane Kusafuka
- The applied analysis of kayaking ergometer with different drag resistance in kayak training: a pilot study Jiaxiang Yan
- Gait velocity influence dynamic gait stability in a dual-task paradigm Jingwen Wang
- The effect of different illumination levels and Tai Chi exercise on the postural stability of the elderly during stair ascent Qipeng Song

- Optimization of the whole-body motion to minimize the muscle-tendon length of biceps femoris long head during the late swing phase of high-speed running

Terumitsu Miyazaki
- Does the canoe-kayak ergometer with the electromechanical drag force have a good performance during training?

Weilan He
- The biomechanical characteristics and rules could improve injury risks during race walking

Song Qipeng
- Long-term Tai Chi Practitioners were less influenced by the dual-task paradigm during stair descending

Xiaoli Ma
- Backpack weight influence postural control among children with obesity during stair descent

Xinheng Che
- Sex differences in foot kinematics and kinetics during drop-jump using a novel multi-segment foot model

Yuka Sekiguchi
- Acute effect of transcranial direct current stimulation on rowing endurance performance: a double-blind, randomized, crossover plot study

Zhiqiang Liang
- Proprioceptive neuromuscular facilitation improves descending mechanics among knee osteoarthritis patients

Qipeng Song
- Development of squat-exercise support system using kinect sensor for persons with intellectual disabilities

Kazuyuki Mito
- Directional Dependence of Uniaxial Response Characteristics of the Porcine Thoracic Aorta

Manoj Myneni
- Ventricle of terrestrial Anura is stiffer than that of aquatic Anura due to differences in collagen density

Megumi Ito
- The importance of inertial measurement unit placement in assessing upper limb motion

Fredrik Öhberg
- Comparing surface and intramuscular electromyography patterns of the brachialis muscle during the dynamic elbow movement.

Shota Date
- System identification to characterise shoulder stiffness in a functional posture at various levels of muscle contraction

Yahya Z. Yahya
- Assessing Upper Extremity Function by Applying Sensor-Embedded Device

Charlie C. Ma
- Quantify hand tremor of Parkinson's disease based on Channel State Information

Hui-Hsin Chen
- Positioning effects of GPS Sensors during running

Clint Hansen
- Evaluating The Validity Of An Inertial Measurement Unit For Determining Knee And Trunk Kinematics During Athletic Landing And Cutting Movements

Lionel Chia

- Is the Standing Long Jump Specific-Shoe really Necessary for Chinese Students? Yang Song
- Development of snowboard force measurement system Yun Chen
- Locomotor changes in knee osteoarthritis patients during a 6-minute walk test Dominic Thewlis
- A study on the hip joint mechanism of the exoskeletal robot to improve the assistance performance Mingoo Jeong
- The 3D CoM kinematic estimation using a simple machine learning for portable gait monitoring Myunghyun Lee
- Design and verification of bio-mimetic knee joint mechanism for exoskeletal robots Taeyeon Kim
- Relationship between A2 Pulley Venting and resultant Flexor Tendon Superficialis Slack Tyler Shipley
- Archery gesture segmentation with wearables in both able-bodied and Paralympic athletes Lorenzo Rum

11:45 - 12:00

## POSTER QUIZ

Location: Online

12:00 - 13:00

## OB1 - CLINICAL BIOMECHANICS

Location: Online

Chair: Felipe Carpes

Pres Time	Presentation title/Abstract title	Speakers/Authors
12:00	In vivo mechanoresponse of articular cartilage before and after load modifying surgery in patients with medial compartment knee osteoarthritis	Annegret Mündermann
12:12	Tibio-femoral kinematics of natural versus replaced knees - A comparison using dynamic videofluoroscopy	Barbara Postolka
12:24	High tibial osteotomy effectively redistributes compressive knee loads during walking	Enrico De Pieri
12:36	Effect of additional training weight on tibiofemoral contact forces during a forward lunge	Ilse Jonkers
12:48	Assessment of variations in scapular morphology and bone quality in patients with B glenoids	Nazanin Daneshvarhashjin

12:00 - 13:00

## OB2 - MUSCULOSKELETAL MODELLING

Location: Online

Chair: Taylor Dick

Pres Time	Presentation title/Abstract title	Speakers/Authors
12:00	Biomechanical analysis of industrial exoskeletons	Ulrich Glitsch
12:12	Impact of personalized geometry and motor control on musculoskeletal simulation results - How much detail is needed?	Hans Kainz
12:24	Predictive simulations of hemiparetic gait to explore the effects of muscle weakness on walking asymmetry and energetics	Tom Buurke
12:36	Altered triceps surae muscle dynamics and force demand at different stride frequencies	Wannes Swinnen
12:48	A multiscale constitutive description for load bearing soft biological tissue that incorporates the interfibrillar sliding of constituent collagen.	Christopher Miller

12:00 - 13:00

## OB3 - SPECIAL: HAND & WRIST BIOMECHANICS I

Location: Online

Chair: Verónica Gracia Ibáñez, Co-Chair: Zong-Ming Li

Pres Time	Presentation title/Abstract title	Speakers/Authors
12:00	Scan-driven fully automated pipeline for a personalized, 3D printed low-cost prosthetic hand	Yair Herbst
12:12	Complementary functions of the joint morphology and ligaments in providing stability to first the carpometacarpal joint	Wan Mohd Radzi Rusli
12:24	Uniformity of performance during the collection of maximum voluntary contraction tasks for the muscles of the wrist	Mercedes Aramayo Gomes Rezende
12:36	The effect of wrist posture on grip and muscle force capacities: comparison of a prehensile and a non-prehensile task	Mathieu Caumes
12:48	Characteristics of palmar and dorsal flexion muscle strength in college baseball players	Kazuhiro IKEDA

12:00 - 13:00

## OB4 - SPECIAL SESSION: MOTOR CONTROL IN IMPAIRED POPULATIONS

Location: Online

Chair: Paola Contessa, Co-Chair: James Richards

Pres Time	Presentation title/Abstract title	Speakers/Authors
12:00	Unrestricted age-related compensation in a daily life sit-to-walk task	Eline van der Kruk
12:12	Quantification of inter-limb coupling during bilateral stance in individuals with transtibial amputation	Peter Raffalt

12:24	Development of spontaneous motor activity with age in healthy infants and infants with infantile cerebral palsy	Catherine Disselhorst-Klug
12:36	Lumbar extensor muscle isometric torque steadiness and torque-HDsEMG coherence is altered in individuals with chronic low back pain	Michail Arvanitidis
12:48	Analysis of spectral attributes of surface electromyography during gait in children with Fragile X Syndrome	Weronika Piatkowska

12:00 - 13:00

## OB5 - SPORT BIOMECHANICS

Location: Online

Chair: Ton van den Bogert

Pres Time	Presentation title/Abstract title	Speakers/Authors
12:00	Drop-landing asymmetries are related to knee symptoms 6-months following ACL reconstruction	Katherine Collins
12:12	Elbow load variability in youth elite baseball pitchers	Bart van Trigt
12:24	Whole-body angular momentum and external torque during the block phase of the sprint start	Paul Sandamas
12:36	Injury and surgery are associated with shoulder external rotation during exam and baseball pitching	Hannah Stokes
12:48	How running biomechanics influence the occurrence of iliotibial band syndrome	Qipeng Song

12:00 - 13:00

## OB6 - SPINE & TRUNK

Location: Online

Chair: Veronique Feipel

Pres Time	Presentation title/Abstract title	Speakers/Authors
12:00	Cervical spine injuries observed in misdirected rugby tackles are not caused by a hyperflexion mechanism	Dario Cazzola
12:12	Spinal palpation error and its impact on marker-based spinal curvature estimation in adult spinal deformity	Pieter Severijns
12:24	Baricentricity of spinal alignment and posture in adolescent idiopathic scoliosis: Optical diagnosis	Saša Ćuković
12:36	Fear-avoidance beliefs are not related to stoop-squat-behavior during object lifting in healthy pain-free adults	Stefan Schmid
12:48	Subject-specific muscle forces in the lumbar spine are correlated to lumbar curvature	Jude Meakin

12:00 - 13:00

## OB7 - SIMULATION TECHNIQUES AND APPLICATIONS

Location: Online

Chair: Maria Pierantoni

Pres Time	Presentation title/Abstract title	Speakers/Authors
12:00	FEBio and ABAQUS with fibril-reinforced biphasic models of knee articular cartilage produce similar mechanical responses during gait	Alexander Paz
12:12	The effect of soft tissue modeling on tibiofemoral stress distribution in models of high tibial osteotomy and its importance for making simulation-based clinical decisions	Elaheh Elyasi
12:24	An agent based model of the vibration-induced arterial growth: feeding the model parameters by cellular tests	Maha Reda
12:36	Numerical discretization of trabecular bone based on Voronoi tessellation	Yijun Zhou
12:48	Rapid X-ray-based 3-D finite element modeling of knee joint cartilage biomechanics	sana Jahangir

12:00 - 13:00

## OB8 - POSTURE AND BALANCE

Location: Online

Chair: Andresa Germano

Pres Time	Presentation title/Abstract title	Speakers/Authors
12:00	Forefoot or ankle - which really affects balancing skills?	Rosemary Dubbeldam
12:12	How static and dynamic balance changes with age: the risk of sitting down	Lizeth Sloot
12:24	Concurrent assessment of posture and saccades -- connecting with cognitive function through immersive virtual reality	Yu Imaoka
12:36	Towards a new biomechanical model to explain upright postural control in unilateral transtibial prosthesis users	Cleveland Barnett T.
12:48	Sensitivity of biomechanical responses in path optimized follower loads considering the lumbosacral load sharing	Robin Remus

13:00 - 13:45

## LUNCH BREAK

Location: Online

13:45 - 14:45

**PANEL DEBATE: THE DISTRIBUTION PROBLEM IN BIOMECHANICS AND MOTOR CONTROL: HOW CAN WE MEASURE, PREDICT AND VALIDATE IN VIVO MUSCLE FORCES?**

Location: Online

SPEAKERS:

MODERATOR:

Ton van den Bogert,  
Cleveland State  
University (USA)

Friedl de Groote,  
Katholieke Universiteit  
Leuven (Belgium)

Walter Herzog,  
University of Calgary  
(Canada)

Lanie Gutierrez-  
Farewik, KTH  
MoveAbility Lab  
(Sweden)

– (experimental and  
theoretical)

– (theoretical)

– (experimental)

13:45 - 14:45

**PANEL DEBATE: MARKERLESS VS. MARKER-BASED MOTION CAPTURE**

Location: Online

SPEAKERS:

MODERATOR:

Julia Stebbins,  
PhD, Oxford Gait  
Laboratory, Nuffield  
Orthopaedic Centre  
(United Kingdom)

Kevin Deluzio,  
Professor, Queen's  
University, Ontario  
(Canada)

Michael Rainbow,  
Assoc. Professor,  
Skeletal Observation  
Laboratory,  
Queen's University,  
Ontario (Canada)

14:45 - 15:00

**BREAK**

Location: Online

15:00 - 16:00

---

## WARTENWEILER AWARD LECTURE: SUSAN S. MAGULIES

Location: Online

### SUSAN S. MAGULIES

The Wartenweiler Memorial Lecture is given to honour Prof. Jürg Wartenweiler (1915-1976), first President of the ISB, who organized the First International Seminar on Biomechanics in Zürich, Switzerland (1967).

Wallace H. Coulter Chair, Biomedical Engineering

Georgia Institute of Technology and Emory School of Medicine

GRA Eminent Scholar in Injury Biomechanics

Dr. Margulies is the Chair of the Wallace H. Coulter Department of Biomedical Engineering at Georgia Tech and Emory University, and the Georgia Research Alliance Eminent Scholar in Injury Biomechanics. She received her BSE in Mechanical and Aerospace Engineering at Princeton and PhD in Bioengineering from the University of Pennsylvania, and was a post-doctoral fellow at Mayo. With over 30 years of experience in the areas of traumatic brain injury research and pulmonary biomechanics, Dr. Margulies has secured over \$35 million in federal, private, and industry funding to discover injury mechanisms on the macro and micro scales, and translate basic research findings to improve clinical outcomes. Dr. Margulies is a Fellow of the American Society of Mechanical Engineers, Biomedical Engineering Society, and American Institute for Medical and Biological Engineering, and a Member of the National Academy of Engineering and National Academy of Medicine.

The Wallace H. Coulter Department of Biomedical Engineering at Emory University and Georgia Institute of Technology is the only public-private inter-institutional BME department in the nation and is a national leader in translational biomedical engineering research and education. Faculty research focuses on cell manufacturing technologies, biomaterials, imaging and instrumentation, informatics and systems modeling, biomedical robotics, cardiovascular engineering, immunoengineering, neuroengineering, cancer technologies and innovative engineering education methods. Coulter BME is top ranked in the nation (#2) for PhD and undergraduate programs, and graduates the largest number of female and under-represented biomedical engineers annually.

16:00 - 22:00

---

## SOCIAL MINGLE

Location: Online

# Tue 27 Jul 2021

10:45-11:45

## STUDENT HAPPY HOUR

Location: Online

11:45 - 12:00

## SHORT WELCOME

Location: Online

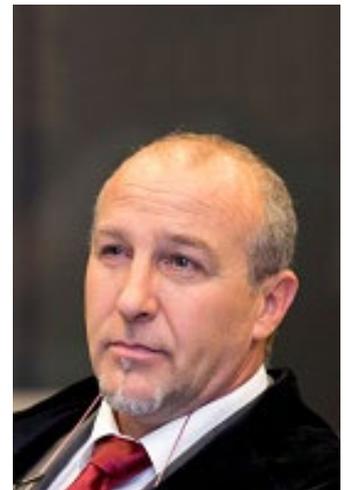

12:00 - 13:00

## KEYNOTE LECTURE: THE ROLE OF BIOMECHANICS IN EVIDENCE-BASED PARALYMPIC CLASSIFICATION (YVES C. VANLANDEWIJCK)

Location: Online

### YVES C. VANLANDEWIJCK

Yves C. Vanlandewijck is Professor in Rehabilitation Sciences at the Faculty of Kinesiology and Rehabilitation Sciences of the University of Leuven, Belgium, and guest-professor at the Swedish School of Sport and Health Sciences (GIH), Stockholm, Sweden. His research interests include exercise physiology, biomechanics and ergonomics, applied to individuals with locomotor impairment, in a rehabilitation to elite sports continuum. His main research applications focus on the development of evidence-based classification systems in Paralympic sports to ensure fairness in athletic competition categories. Since 2014, the research unit of Prof. Yves Vanlandewijck is recognized and funded by the International Paralympic Committee (IPC) as the Research & Development Centre for Classification in Athletes with Intellectual Impairment.

From 1997 to 2001, Prof. Yves Vanlandewijck was the vice-president of the International Federation of Adapted Physical Activity; he is the founding editor of the European Journal of Adapted Physical Activity and the editor of the IOC Series Books "The Paralympic Athlete" (2011) and "Training & Coaching the Paralympic Athlete" (2016). He was a member of the IOC Medical and Scientific Working Group and member of the Associations Board of the International Council of Sport Science and Physical Education. He is a member of the Sport Science Committee of the IPC since 1995 and Chairperson from 2003 to 2018. In 2017, Prof. Yves Vanlandewijck delivered the Joseph B. Wolffe Memorial Lecturer opening the ACSM Annual Meeting in Denver, Colorado, with a lecture entitled: "Crossroads and Conflicts – Olympics, Paralympics or Cyber Olympics". In 2019, he received the Paralympic Scientific Award for his lifetime contribution to Paralympic research and the Paralympic Movement.

13:00 - 13:30

## INNOVATIVE ANALYSIS OF JAW MOVEMENT WITH QUALISYS AND DELSYS

Location: Online

In the second part of our daily "Swedish Fika" breaks, Delsys joins Qualisys to demonstrate the latest EMG and Motion Capture innovations, using Delsys Quattro sensors and Arqus A26 cameras to perform an analysis of jaw movement.

Our software, QTM support Delsys Quattro digital integration which enables EMG data capture along with the motion capture. During the session, we will present our integration together with the Delsys team and do a live demo.

13:30 - 13:45

## BREAK

Location: Online

13:45 - 14:45

## OC1 - LOWER EXTREMITIES

Location: Online

Chair: Janet Dufek

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:45	Can electrical noise stimulation improve the perception of vibration stimuli in patients with diabetes mellitus?	Claudio Zippenfennig
13:57	Contraction intensity does not influence the elastic and contractile components of the muscle-tendon unit performance enhancement in stretch-shortening cycles	Denis Holzer
14:09	Comparing eight normalization methods for net joint moment data in the single-leg squat	Steven Hirsch
14:21	Is non-uniform achilles tendon displacement associated with calf muscle passive elastic modulus in young athletes?	Taija Finni
14:33	Modulating achilles tendon loading during gait with a resistive soft ankle exosuit	Dylan Schmitz

13:45 - 14:45

## OC2 - MEDICAL DEVICES

Location: Online

Chair: Annegret Mündermann

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:45	O2-enrichment device based on membrane separation for early phases of respiratory insufficiency	Christoph Janeczek
13:57	Fatigue resistance of nitinol stents subjected to walk-induced femoropopliteal artery motion	Ran He

14:09	Explicit and implicit FE-models capture the mechanical response of calcium phosphate-titanium cranial implants	Susanne Lewin
14:21	Experimental validation of the gross taper failure mechanism in total hip arthroplasty	Valerie Polster
14:33	Comparison of total ankle replacement designs using a dynamic computational model of the foot and ankle	Maria Ruiz

13:45 - 14:45

## OC3 - METHODOLOGIES AND DATA ANALYSIS

Location: Online

Chair: Gillian Weir

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:45	An open-source algorithm for automatic labelling of optical motion capture markers using deep learning	Allison Clouthier
13:57	The performance of open-source pose estimation algorithms during walking, running and jumping	Laurie Needham
14:09	Can leap motion controller replace conventional marker-based motion capture systems?	Amartya Ganguly
14:21	Under-shoe hydrodynamics correlate with film thickness predictions based on worn tread geometry	Sarah Hemler
14:33	Quantifying the hip-ankle synergy in short-term maximal cycling	Louise Burnie

13:45 - 14:45

## OC4 - MUSCULOSKELETAL MODELLING

Location: Online

Chair: Claudia Mazzà

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:45	Hill-type computational models of skeletal muscle-tendon actuators: a systematic review	Luca Modenese
13:57	Muscle-specific intramuscular passive properties are required to accurately scale passive muscle mechanics	Benjamin Binder-Markey
14:09	Motor-units matter: enriching continuum-mechanical skeletal muscle models with neuromuscular information	Harnoor Deep Singh Saini
14:21	A mechanistic model of muscle force and impedance	Matthew Millard
14:33	3D modeling of length and lever arm of sternocleidomastoid and scalenus muscles in respiratory movement	David Biteau

13:45 - 14:45

## OC5- ARTIFICIAL INTELLIGENCE AND MACHINE LEARNING

Location: Online

Chair: Anne Koelewijn

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:45	Automated and personalized pose registration from x-ray images using convolutional networks	Florian Vogl
13:57	Assessment of a novel deep learning-based marker-less motion capture system for clinical gait analysis	Laurent Gajny
14:09	Towards real-time estimation of joint moments during fast sidestepping	Sina David
14:21	Towards standardising a machine learning approach for automated and accurate event detection for human gait	Yong Kuk Kim
14:33	Muscle synergies enable accurate joint moment prediction using few EMGs	Yixing Liu

13:45 - 14:45

## OC6 - SPORT BIOMECHANICS

Location: Online

Chair: Michael Asmussen

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:45	The influence of bicycle lean on maximal power output during sprint cycling	Ross Wilkinson
13:57	Racing in the street -- Whole-body vibration during road cycling and the effect of different equipment choices to minimise it	Timothy Holsgrove
14:09	Sleep parameters and soccer kicking performance in youth players	Fabio Augusto Barbieri
14:21	Sagittal plane lower extremity joint demands of the golf swing in novice older adult golfers	Guanrong Cai
	Should major league baseball adjust the mound height?	Megan Stewart

13:45 - 14:45

## OC7 - SPECIAL: HAND & WRIST BIOMECHANICS II

Location: Online

Chair: Kai-Nan An, Co-Chair: Angela Kedgley

### MARC GARCIA-ELIAS

Dr. Garcia-Elias was born in Terrassa (Spain) the 6th of October of 1954.

He graduated in 1978 at the Universitat Autònoma Medical School, Barcelona, Spain. He obtained his certification as specialist in Orthopaedic Surgery in 1982, and his doctoral degree (PhD) by the University Autònoma of Barcelona, Spain in 1985. From 1986 to 1989, he worked as visiting scientist at the Orthopedic Biomechanics Laboratory of the Mayo Clinic. Since returning to his homeland, he has kept his interest in basic science of the upper limb. Since its foundation in 1994, Dr Garcia-Elias co-directs the Institut Kaplan for Hand Surgery in Barcelona, Spain. He is PhD coordinator of the Upper Limb Biomechanics laboratory of the Department of Anatomy of the Universitat Autònoma de Barcelona Medical School, in Bellaterra, Barcelona, Spain.

Since 2019, he is also President of the International Federation of Societies for Surgery of the Hand (see <https://www.ifssh.info/officers.php>). His areas of major interest are the anatomy and biomechanics of the wrist and the treatment of wrist and distal radioulnar instability. He has published 3 books, 74 chapters, and 168 peer reviewed (Pubmed indexed) articles, most of them on the anatomy and biomechanics of the wrist, or on surgery of the carpus and distal radioulnar joint instability.

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:45	My current understanding of wrist dynamics	Marc Garcia-Elias
14:09	Fused with motion: A biomechanical comparison of dart throw motions after partial wrist fusions	Frederick Werner
14:21	In vivo validation of musculoskeletal model of the wrist featuring a consistent anatomical data set	Oluwalogbon Akinnola
14:33	Palmar musculature and its role as a dynamic compressor of the carpal tunnel	Ronit Wollstein

13:45 - 14:45

## OC8 - CLINICAL BIOMECHANICS

Location: Online

Chair: Seong-won Han

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:45	Biomarkers of knee joint healing following anterior cruciate ligament reconstruction: a systematic review	Lisa Ek Orloff
13:57	Biomechanical simulation of lung-tumor motion based on surface imaging	Maida Ranjbar
14:09	In-vitro bi compartmental approach to assess intra-capsular pressure in the hip joint during movements: Is the acetabular cavity also presents pressure fluctuations as the capsular chamber?	Marc-Olivier St-Pierre
14:21	Closing the kinetic chain: Weight-bearing versus non-weight bearing maximal force generation and its relation to patient reported outcomes in ACL injured males and females	Michael Del Bel
14:33	Towards the usage of embedded prosthesis sensors for real-life gait analysis of amputee subjects	Sabina Manz

14:45 - 15:30

## LUNCH BREAK

Location: Online

## MAJOR SPONSOR WORKSHOPS

15:30 - 16:00

---

## **GENERATING AUTOMATED REPORTS WITH XSENS, BRIDGING THE GAP BETWEEN DATA AND ANALYSIS**

Location: Online

With MVN Reports you can easily generate automated reports for Health, Ergonomics and Sports. Powered by the new Xsens MotionCloud platform, MVN Reports instantly present complex movement data in an accessible, easy-to-read report. In this workshop we will show you how you can easily generate an automated Gait Analysis report with MVN Reports. In as little as a few minutes, a full standardized report with relevant data for that specific application is created. Also, the motion data is visualized as a 3D avatar. This report is automatically generated on the Xsens MotionCloud platform. The data is processed in the unique 'Xsens Sensor Fusion Engine, providing accurate and validated data. All that's required is an Xsens MVN motion capture setup and access to Xsens MotionCloud. During this workshop, we would like to give you an insight in the functionalities of MVN Reports and the reports roadmap. Also, we would like to give you an in-depth introduction to the Gait Analysis report specifically.

15:30 - 16:00

---

## **PANEL DISCUSSION ON HOW TECHNOLOGY IS USED IN RESEARCH AND WOMEN IN BIOMECHANICS.**

Location: Online

Hear what 5 top biomechanists have to say about their own research, how they use technology to help answer those research questions, and Women in Biomechanics.

16:00 - 17:00

---

## PANEL DEBATE: PEER REVIEW IN SCIENCE

Location: Online

SPEAKERS:

Benno Nigg  
Founder and Chief  
Science Officer

Walter Herzog,  
University of  
Calgary (Canada)

MODERATOR:

Katherine Boyer,  
University of  
Massachusetts  
Amherst (USA)

16:00 - 17:00

---

## PANEL DEBATE: BIROBOTICS - HOW BIOLOGY WILL INFORM THE NEXT-GEN MACHINES

Location: Online

SPEAKERS:

Auke Ijspeert,  
EPFL (Lausanne,  
Switzerland)

Yulia Sandamirskaya,  
University of Zurich and  
ETH (Switzerland)

MODERATOR:

Francisco Valero-Cuevas,  
University of Southern  
California (USA)

17:00 - 17:15

## **BREAK**

Location: Online

17:15 - 18:15

## **OD1 - WIRELESS SENSORS AND WEARABLE DEVICES**

Location: Online

Chair: Lauren Benson

<b>Pres Time</b>	<b>Presentation title/Abstract title</b>	<b>Speakers/Authors</b>
17:15	Development of a channel identification algorithm for an autonomously usable 16-channel sEMG sensor system	Elisa Romero Avila
17:27	Surface EMG-based AAC technology for recognition of silent prosodic speech	Jennifer Vojtech
17:39	An open-source workflow for IMU-based kinematics over long durations	Johanna O'Day
17:51	From feasible to practical: Progress in the development & validation of wearables for accurately monitoring tibial bone forces in the real-world	Laura Judson
18:03	Measuring trunk motion during on-site wheelchair propulsion using inertial measurement units	Marit van Dijk

17:15 - 18:15

## **OD2 - INJURIES AND REHABILITATION**

Location: Online

Chair: Hannah Rice

<b>Pres Time</b>	<b>Presentation title/Abstract title</b>	<b>Speakers/Authors</b>
17:15	Diffusion and advection of pro-inflammatory cytokines in injured articular cartilage under mechanical loading	Joonas Kosonen
17:27	Effects of functional resistance training on gait biomechanics following anterior cruciate ligament reconstruction	Alexa Johnson
17:39	A Prospective Study Linking Changes in Dynamic Center of Mass Motion With Lower-Limb Overuse Injuries Using a Single Trunk-Mounted Accelerometer	Gerard Aristizábal Pla
17:51	Consistency of athlete lower-limb work distribution across unilateral and bilateral tasks after ACL reconstruction	Holly Jones
18:03	A hierarchical clustering approach for examining potential risk factors for bone stress injury in runners	Jack Martin

17:15 - 18:15

### OD3 - SPORTS AND EXERCISE FOR PERSONS WITH IMPAIRMENT

Location: Online

Chair: Mary Rodgers

Pres Time	Presentation title/Abstract title	Speakers/Authors
17:15	Effect of seat configuration on joint power distribution and performance in an elite Paralympic rower: a case study	Jørgen Danielsen
17:27	Validation of a new sport specific trunk test battery for paracanoe	Anna Bjerkefors
17:39	The impact of leg impairment on strength and race performance in elite para-cyclists	Johanna Liljedahl
17:51	Kinematic and kinetic performance variables during paddling among para-kayak athletes with unilateral above or below knee amputation	Johanna Rosén
18:03	Towards a standardized and individualized lab-based protocol for wheelchair-specific exercise capacity testing of wheelchair athletes: a scoping review	Rowie Janssen

17:15 - 18:15

### OD4 - SPECIAL: HAND & WRIST BIOMECHANICS III

Location: Online

Chair: Frederick Werner, Co-Chair: Jennifer Nichols

Pres Time	Presentation title/Abstract title	Speakers/Authors
17:15	Biomechanical evaluation of a fracture fixation system for transverse fractures of the metacarpal neck	Rena Mathew
17:27	Reproducibility of Trapeziometacarpal Joint Angle Measurements Using Dynamic CT	Michael Kuczynski
17:39	Three-dimensional carpal tunnel reconstruction and analysis using multimodal co-registration of ultrasonography and computed tomography	Hui Zhang
17:51	Model of the Midcarpal Joint Accounting for Structural Difference	Ronit Wollstein
18:03	An implantable differential mechanism to restore individuated finger flexion following tendon transfer surgery	Suraj Chakravarthi Raja

17:15 - 18:15

### OD5 - DAVID WINTER YOUNG INVESTIGATOR ORAL SESSION

Location: Online

Chair: Timothy Derrick

Pres Time	Presentation title/Abstract title	Speakers/Authors
17:15	Development and validation of FootNet, a new kinematic and deep learning-based algorithm to detect foot-strike and toe-off in treadmill running	Adrian Rivadulla

17:27	Semi-automatic quantification of muscles deformations during controlled exercises: application to the abdominal wall	Arthur Jourdan
17:39	Biceps femoris long head fascicle length increases after 3 weeks of eccentric exercise training are due to sarcomere lengthening rather than serial sarcomere addition	Melissa Boswell
17:51	Development of a high-density EMG-driven Hill-type muscle model	Arnault H D Caillet
18:03	Fibril-reinforced poroelastic properties of normal and osteoarthritic human femoral, tibial, and patellar cartilage	Mohammadhossein Ebrahimi

17:15 - 18:15

## OD6 - SPECIAL: SIMULATION OF LOCOMOTION I

Location: Online

Chair: Friedl De Groot, Co-Chair: Tom Buurke

### KAREN LIU

C. Karen Liu is an associate professor in the Computer Science Department at Stanford University. Prior to joining Stanford, Liu was a faculty member at the School of Interactive Computing at Georgia Tech. She received her Ph.D. degree in Computer Science from the University of Washington. Liu's research interests are in computer graphics and robotics, including physics-based animation, character animation, optimal control, reinforcement learning, and computational biomechanics. She developed computational approaches to modeling realistic and natural human movements, learning complex control policies for humanoids and assistive robots, and advancing fundamental numerical simulation and optimal control algorithms. The algorithms and software developed in her lab have fostered interdisciplinary collaboration with researchers in robotics, computer graphics, mechanical engineering, biomechanics, neuroscience, and biology. Liu received a National Science Foundation CAREER Award, an Alfred P. Sloan Fellowship, and was named Young Innovators Under 35 by Technology Review. In 2012, Liu received the ACM SIGGRAPH Significant New Researcher Award for her contribution in the field of computer graphics.

Pres Time	Presentation title/Abstract title	Speakers/Authors
17:15	Simulating Human Movements for Assistive Robotics	Karen Liu
17:39	Evaluating and combining cost function criteria to predict healthy gait	Kirsten Veerkamp
17:51	Simulations of walking with an ankle-foot exoskeleton to evaluate the predictive capability of neuromechanical models	Maarten Afschrift
18:03	Three-dimensional knee reduces metabolic cost and joint loading in simulated running	Ross Miller

17:15 - 18:15

## OD7 - BIOMEDICAL ENGINEERING

Location: Online

Chair: Daniel Benoit

Pres Time	Presentation title/Abstract title	Speakers/Authors
17:15	Neck muscle network topology analysis in people with chronic neck pain	David Jimenez-Grande
17:27	Quantitative evaluation of hypomimia in Parkinson's disease: a face tracking approach	Elena Pegolo
17:39	A model for the biomechanical assessment of discoplasty in a laboratory setting	Salim Ghandour
17:51	Microfluidic integrated biosensor for the detection of osteoarthritis	Anupriya Singh
18:03	Micro- structured hollow fiber membranes - reducing the main transport resistance in membrane oxygenators	Paul Ecker

17:15 - 18:15

## OD8 - ANIMAL AND COMPARATIVE

Location: Online

Chair: Judith Meakin

Pres Time	Presentation title/Abstract title	Speakers/Authors
17:15	Morphological determinants of glenohumeral mobility in primates	Erin CS Lee
17:27	Lateral stability and the frontal shape of land animals	Neelima Sharma
17:39	How some insects adhere to underwater surfaces	Pranav Sudersan
17:51	Relatively shorter muscle lengths increase the metabolic rate of cyclic force production	Owen Beck
18:03	Cadaveric demonstration of a novel stretchable sensor to wirelessly measure musculoskeletal soft tissue strains during passive limb motion	Qiang Zhang

18:15 - 18:30

## BREAK

Location: Online

18:30 - 19:30

## MUYBRIDGE AWARD LECTURE: SCOTT L. DELP

Location: Online

Chair: Friedl De Groot

### SCOTT L. DELP

The Muybridge award is the most prestigious award of the Society. It is awarded for career achievements in biomechanics. The award is named after Eadward Muybridge (1830-1904), who was the first to use cinematography for the study of human and animal movement. Scott L. Delp, Ph.D., is the James H. Clark Professor of Bioengineering, Mechanical Engineering, and Orthopaedic Surgery at Stanford University. He is the Founding Chairman of the Department of Bioengineering at Stanford, Director of the RESTORE Center, a NIH national center focused on measuring real world rehabilitation outcomes, and Director of the Mobilize Center, a NIH National Center of Excellence focused on Big Data and Mobile Health. Scott is focused on developing technologies to advance movement science and human health.

Software tools developed in his lab, including OpenSim and Simtk.org, have become the basis of an international collaboration involving thousands of students and scientists who exchange simulations of human movement. Prior to joining the faculty at Stanford, Delp was on the faculty at Northwestern University and the Rehabilitation Institute of Chicago. He has published over 250 research articles in the field of biomechanics and has recently published a text from MIT Press entitled Biomechanics of Movement: The Science of Sports, Robotics, and Rehabilitation. Professor Delp has co-founded six health technology companies and is a member of the U.S. National Academy of Engineering.

19:30 - 20:30

## OE1 - TISSUE

Location: Online

Chair: Anna Gustavsson

Pres Time	Presentation title/Abstract title	Speakers/Authors
19:30	Endoprosthesis size optimizes impaction force and circumferential stress in transtibial intramedullary prostheses	Carolyn Taylor
19:42	Mechanical fatigue in spinal joints: Viscoelastic responses to altered rate and frequency of compression loading	Jackie Zehr
19:54	Effects of cyclic loading on the mechanical properties and failure of human patellar tendon	Colin Firminger
20:06	Determining the Relationship Between Skull Diploë Morphometry and Mechanical Properties In Four-Point Bending	Kevin Adanty
20:18	A one-dimensional viscoelastic model of collagenous tissues with damage	Jeff Barrett

19:30 - 20:30

## OE2 - ORTHOPAEDICS: BONE & CARTILAGE, SURGEON-GUIDED

Location: Online

Chair: Colin Smith

Pres Time	Presentation title/Abstract title	Speakers/Authors
19:30	Anterolateral versus medial plating for varus type pilon fractures	Ali Ammar
19:42	Quantification of 3-dimensional strength and pain in patients with shoulder osteoarthritis	Margaret Coats-Thomas
19:54	Mechanical fatigue of whole rabbit-tibiae under combined compression-torsional loading is better explained by strained volume than peak strain magnitude	Ifaz Haider
20:06	A biomechanical analysis of body mass index on frontal plane kinetics and kinematics between controls and total knee arthroplasty patients	Laura Linsley
20:18	The use of a wireless passive electronic strain sensor to measure hysteresis of sheep hindlimb tendons: A first step towards directly comparing in vitro and in vivo tendon properties	Fransiska M Bossuyt

19:30 - 20:30

## OE3 - EDUCATION AND OUTREACH

Location: Online

Chair: Sarah Breen

Pres Time	Presentation title/Abstract title	Speakers/Authors
19:30	What womxn want: Using the international womxn in biomechanics organization to help womxn in biomechanics thrive	Anahid Ebrahimi
19:42	Using a physical sarcomere model to demonstrate titin's contributions to residual force enhancement	Heron B O Medeiros
19:54	Visual detection on simulated electromyography signals with varying signal-to-noise ratios: A training tool to enhance onset identification	Mario Lamontagne
20:06	Using hula hooping as a discussion point for STEM education and outreach	Polly Blaikie
20:18	Finite element modelling of the abdomen in developing a robotic patient for palpation examination training	Florence Leong

19:30 - 20:30

## OE4 - LOCOMOTION: CLINICAL GAIT

Location: Online

Chair: Katherine Boyer

Pres Time	Presentation title/Abstract title	Speakers/Authors
19:30	Effect of low and high intensity strength training on muscle forces during walking in adults with knee osteoarthritis	Paul DeVita
19:42	Modular reorganization of gait in chronic but not in artificial knee joint constraint	Carlos Cruz
19:54	Lower back demands during load carriage with induced asymmetric gait	Jacob Banks
20:06	The use of the reference finite helical axis and high-speed biplanar videoradiography to characterize knee kinematics	Tomasz Bugajski
20:18	Gait asymmetries following ACL reconstruction differ based on sex and gait speed	Lindsay Slater

19:30 - 20:30

## OE5 - RUNNING: BIOMECHANICS

Location: Online

Chair: Hermann Schameder

Pres Time	Presentation title/Abstract title	Speakers/Authors
19:30	Effects of foot core strengthening protocol on plantar arch biomechanics	Alessandra Matias
19:42	Subgroups of foot-ankle running movement patterns influence the responsiveness to a foot-core exercise program	Ricky Watari
19:54	Internal tibial forces and moments during graded running	Michael Baggaley
20:06	Tibial damage and osteogenic effects of high intensity interval and prolonged running	Stacey Meardon
20:18	Achilles Tendon and Patellofemoral Kinetics Following A Long Hilly Run in Traditional and Maximal Cushioning Shoes	James Becker

19:30 - 20:30

## OE6 - SIMULATION TECHNIQUES AND APPLICATIONS

Location: Online

Chair: Dario Cazzola

Pres Time	Presentation title/Abstract title	Speakers/Authors
19:30	Hierarchical inverse kinematics via Bayesian inference	Andrew Pohl
19:42	The flow of tissue energy during whole muscle contraction in 3D	Stephanie Ross
19:54	Computational simulation of sideswipe collisions to predict head injury metrics	Shaun Jeffs
20:06	Inverse distance weighting to rapidly generate large simulation datasets	Kalyn Kearney
20:18	Kernel based modelling of intervertebral disc characteristics	Maria Hammer

19:30 - 20:30

## OE7 - IMPACT BIOMECHANICS

Location: Online

Chair: Helen Bayne

Pres Time	Presentation title/Abstract title	Speakers/Authors
19:30	Loss of consciousness in national football league players is associated with high strain rate in the cerebellum and brainstem	Karl Zimmerman
19:42	Quantification of upper limb loading behind a ballistic shield using an adapted ATD arm	Julia de Lange
19:54	Evaluation of design and concept verification of a new figure skating blade with integrated damping system for reducing impact related overuse injuries	Ondrej Spiegl
20:06	Modelling of the pelvis and lumbar spine in high-rate axial loading	Corina Espelien
20:18	Statistical prediction of spinal injury using CIREN data	Sean Shimada

19:30 - 20:30

## OE8 - LOWER EXTREMITIES

Location: Online

Chair: Victoria Chester

Pres Time	Presentation title/Abstract title	Speakers/Authors
19:30	Differences between loaded and unloaded bone kinematics of the foot and ankle complex	Michele Conconi
19:42	Patellofemoral contact forces after ACL reconstruction using statistical parametric mapping	Jack R. Williams

19:54	Out-of-plane motion reduces the knee extension moment arm	Mitchell Wheatley
20:06	Muscle-length dependence of residual force enhancement in the human patellar tendon during submaximal stretch-hold contractions	Patrick Bakenecker
20:18	The non-intuitive contributions of individual quadriceps muscles to patellar tracking	Seong-won Han

20:30 - 21:30

---

## **ADVANCING WOMEN IN BIOMECHANICS MEETING**

Location: Online

Becoming an Ally

The goal of this one-hour workshop is to provide practice in recognizing and addressing bias through specific scenarios and discussion of positive responses. There will be break-out rooms where scenarios will be enacted. Participants in small groups will work together to recognize biases taking place and how best to respond. This session is open to all, and men are especially encouraged to participate. Scenarios will include hiring, reviews and promotions, meeting dynamics, mentorship and sponsorship, and everyday interactions. Our aim is to provide a safe environment for meaningful discussions. This workshop is organized by “Advancing Women in Biomechanics” (AWB).

# Wed 28 Jul 2021

07:15 - 07:30

## SHORT WELCOME

Location: Online

07:30 - 08:30

## OF1 - ARTIFICIAL INTELLIGENCE AND MACHINE LEARNING

Location: Online

Chair: Julie Choisne

Pres Time	Presentation title/Abstract title	Speakers/Authors
7:30	Ground reaction force fusion for gait recognition	Kayne Duncanson
7:42	Data fusion of electromyography and motion data enhances locomotion intent recognition	Lin Meng
7:54	Predicting ground reaction force components from two-dimensional video using machine learning	Corey Morris
8:06	Estimation of knee flexion in knee arthroplasty patients using only shank mounted IMUs	Ted Yeung
8:18	Anomalous gait feature prediction using a neural network	Suil Jeon

07:30 - 08:30

## OF2 - CLINICAL BIOMECHANICS

Location: Online

Chair: Corina Nüesch

Pres Time	Presentation title/Abstract title	Speakers/Authors
7:30	Femoral offset shortening after nailing of Hip fractures does not correlate with pelvic control during gait	Arj Sivakumar
7:42	Relationships between hip muscle strength and running biomechanics in femoroacetabular impingement syndrome	Benjamin Mentiplay
7:54	Personalised hip load modification using real-time biofeedback in hip osteoarthritis: a feasibility study	Laura Diamond
8:06	Effect of functional weightbearing versus non-weightbearing quadriceps strengthening exercise on contact force in varus-malaligned medial knee osteoarthritis: A secondary analysis of a clinical trial	Scott Starkey
8:18	A finite element analysis of foot with hammer toe deformity during walking	Mohammad Moayed

07:30 - 08:30

## OF3 - MUSCLE TISSUE AND ARCHITECTURE

Location: Online

Chair: Hazel Screen

Pres Time	Presentation title/Abstract title	Speakers/Authors
7:30	Statistical shape and fibre models to determine the effect of strength training on vastus lateralis shape and architecture	Bart Bolsterlee
7:42	Triceps surae muscle fascicle dynamics as a function of walking speed in young and older adults	Lauri Stenroth
7:54	Gender difference in architectural and mechanical properties of medial gastrocnemius-achilles tendon unit	Liqin Deng
8:06	Influence of muscle stiffness and architecture on gastrocnemii shape during isometric plantarflexion contractions	Nicole Yvette Kelp
8:18	Three-dimensional architecture of the medial gastrocnemius muscle in human infants in vivo	Brian Chow

07:30 - 08:30

## OF4 - MUSCULOSKELETAL MODELLING

Location: Online

Chair: Glen Lichtwark

Pres Time	Presentation title/Abstract title	Speakers/Authors
7:30	Forward prediction of ankle joint moments using a generic feature set	Homayoon Zarshenas
7:42	Effect of meniscus material models on the mechanical responses of cartilage during walking: a finite element study	Tulashi Simkheada
7:54	A method to compare heterogeneous types of bone and cartilage meshes	Nynke Rooks
8:06	Free achilles tendon strain during common locomotor and rehabilitation tasks	Daniel Devaprakash
8:18	The deep hip stabilisers cannot stabilise	Evy Meinders

07:30 - 08:30

## OF5- ORTHOPAEDICS

Location: Online

Chair: Carina Blaker

Pres Time	Presentation title/Abstract title	Speakers/Authors
7:30	Morphological variation in paediatric lower limb bones	Laura Carman

7:42	A semi-automated method for quantifying total hip arthroplasty related acetabular bone loss from CT scans: lesion volume measurement accuracy and overall method reliability	Thomas Grace
7:54	The effects of decellularisation and sterilisation processing on kangaroo tendon strength	Dylan Ashton
8:06	The free achilles tendon is shorter, stiffer, and thicker in trained runners compared to healthy controls	Claudio Pizzolato
8:18	Prediction of ACL tunnels: a comparison between model and surgeon	Marco Schneider

07:30 - 08:30

## OF6 - REHABILITATION AND NEUROREHABILITATION

Location: Online

Chair: Polly McGuigan

Pres Time	Presentation title/Abstract title	Speakers/Authors
7:30	Does maintenance of whole-body balance take primacy over synchronization of footfalls to auditory beats during rhythm perturbed walking?	Deepak Ravi
7:42	The influence of a fatiguing wheelchair propulsion protocol on the neuromuscular activation of five shoulder muscles	Ursina Minder
7:54	Ankle kinematics during walking with a soft exoskeleton in people with dropfoot -- a case series	Eveline Graf
8:06	Influence of assistance timing on human gait biomechanics using a semi-passive ankle exoskeleton	Mahsa Momtahan
8:18	Real-time joint kinematics estimation in tele-rehabilitation	Marco Caruso

07:30 - 08:30

## OF7 - MOTOR CONTROL II: MOTOR CONTROL IN SPORT

Location: Online

Chair: Walter Herzog, Co-Chair: James Richards

Pres Time	Presentation title/Abstract title	Speakers/Authors
7:30	Altered knee mechanics during weight acceptance in stair descent for athletes with anterior cruciate ligament reconstruction compared to asymptomatic athletes	Jonas Markström
7:42	Muscle shortening velocities and joint-specific powers at different external power and cadence requirements during cycling	Cristian Riveros-Matthey
7:54	Corticospinal excitability during the preparatory phase of preloaded concentric and eccentric contractions	Daniel Hahn
8:06	Variability of muscle synergies across skateboarding tricks with different levels of complexity	Lorenz Zweier
8:18	An exploration of the motor unit behaviour during squatting tasks performed at different speeds	Eva Orantes-Gonzalez

07:30 - 08:30

## OF8 - RUNNING: BIOMECHANICS

Location: Online

Chair: Polly McGuigan; Antony Blazevich

Pres Time	Presentation title/Abstract title	Speakers/Authors
7:30	Changes in joint mechanics following repeated sprinting	Basilio Goncalves
7:42	The "spring-like" function of the subtalar joint in maintaining stability during running	Michael Asmussen
7:54	Increased segment coordination variability of the lower limb in runners accomplishing a half marathon	Tony Lin-Wei Chen
8:06	High-speed fluoroscopic imaging for investigation of 6 DOF knee kinematics during walking and running	Wenjin Wang
8:18	Mechanical energy transduction during running after unilateral transfemoral amputation	Hiroto Murata

08:30 - 09:00

## QUALISYS AND THEIA MARKERLESS WORKFLOWS: HANDS-ON SESSION

Location: Online

In the third "Swedish Fika" break we will focus on how Qualisys markerless processing workflows integrate Theia software and review the state of validation studies.

09:00 - 10:00

**PANEL DEBATE: COMPUTATIONAL APPROACHES TO STUDYING LOCOMOTION DISORDERS: NMSM VS. AI**

Location: Online

SPEAKERS:

MODERATOR:

David Lloyd,  
Griffith University  
(Australia)

Eni Halilaj, Carnegie  
Mellon University  
(USA)

Ilse Jonkers,  
University of  
Leuven (Belgium)

09:00 - 10:00

**SPECIAL ORAL: DEVELOPING COUNTRIES GRANT COMPETITION**

Location: Online

Chair: Daniel Hahn

Pres Time	Presentation title/Abstract title	Speakers/Authors
	Investigating the performance of neck exoskeleton in prevention and reduction of neck pain problems	Ganesh M. Bapat
	Massage and adapted posture for correction of the spinal curvatures of 360 adolescent yam growers	Gerard Doussou
	Effects of exercise intervention on the biomechanics of occupational-related tasks among nurses with low back pain	Shazlin Shaharudin
	Electrical Impedance Tomography combined with Transcranial Doppler ultrasonography on monitoring stroke recovery: Biomechanical application at North Western Part of China	Li Le
	Foot-ankle physiotherapy as preventive strategy for biomechanical dysfunctions in people with diabetes	Isabel C.N. Sacco

10:00 - 10:15

**BREAK**

Location: Online

10:15 - 11:15

## **KEYNOTE LECTURE: TENDON STRUCTURE-FUNCTION RELATIONSHIPS IN HEALTH AND DISEASE: EXPLORING THE INTERFASCICULAR MATRIX (HAZEL SCREEN)**

Location: Online

### **HAZEL SCREEN**

Hazel Screen is Professor of Biomedical Engineering and Head of the School of Engineering and Materials Science at Queen Mary University of London. Her research centres on healthy and pathological tissue structure-function behaviour and its interplay with mechanobiology.

She has a particular long-standing interest in tendon and ligament, and leads a highly multidisciplinary group which spans human and animal in vivo and in vitro studies of tendon function and injury, taking a multiscale approach to exploring tendon mechanobiology from the nano- to micro-scale. She has established and is now further exploring a new paradigm associated with the aetiology of tendon injury.

Screen also leads the UK Organ-on-a-Chip Technologies Network and co-directs the Centre for Predictive in vitro Models at QMUL, within which she leads a research group specifically focused on developing novel in vitro models of musculoskeletal tissues which integrates her expertise in mechanobiology and structure-function into new models to explore health and disease.

11:15 - 12:15

## **ISB AGM**

Location: Online

### **MAJOR SPONSOR WORKSHOPS**

12:15 - 12:45

## **SNEAK PEEK: ACL PATIENT TRACKING PLATFORM GENERATES IMMEDIATE OBJECTIVE RESULTS**

Location: Online

Objective measurements can now be visualized in automated reports as part of a new platform aimed at improving the rehabilitation phase of an ACL patient. Xsens MotionCloud generates a Knee Assessment Report which contains objective results of nine knee stability tests like 'single hop for distance' or a 'drop vertical jump'. Joint angles, distances, symmetries and automated LESS are visualized in the report.

The MotionCloud report is integrated into a patient tracking platform, where it is combined with the results of patient surveys (IKDC, Tegner, etc.) training specific programs and other measurement. This platform aids a physiotherapist to monitor a patient through the rehab phases, keeping the patient motivated. A dashboard displays the criteria that need to be met to elevate a patient to the next phase.

12:15 - 12:45

## **LIVE WORKSHOP: COMPARING TWO DIFFERENT SHOE TYPES WHILST HOPPING**

Location: Online

LIVE from KIH Lab, we will be streaming a demo comparing two different shoe types whilst hopping. See how quick you can process the data and see the results.

12:45 - 13:30

## LUNCH BREAK

Location: Online

13:30 - 14:30

## OG1- LOCOMOTION: GENERAL

Location: Online

Chair: Isabel Sacco

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:30	The effect of diabetic neuropathy progression on muscle fiber conduction velocity of proximal and distal leg muscles during isometric contractions at low level forces	Eneida Yuri Suda
13:42	Center of pressure control ensures mediolateral gait stability: Muscle driven foot placement and ankle moment control	Moira van Leeuwen
13:54	Tactical vest loading alters head-torso coordination in operational police officers during running	Matthew Ellison
14:06	Effects of unilateral swing leg resistance during walking on propulsion, braking and muscle activity	Sylvana Weiland
14:18	The effects of speed and footwear on 3D energy absorption during the braking phase of running: Distance matters	Steffen Willwacher

13:30 - 14:30

## OG2- MUSCULOSKELETAL MODELLING

Location: Online

Chair: Tiago Jacques

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:30	Sampling and modelling of motor unit-specific activation properties in the intact human in vivo	Antonio Gogeochea Hernandez
13:42	Estimating muscle and joint stiffness during plantar-dorsi flexion joint rotations via musculoskeletal modelling	Christopher P. Cop
13:54	Large-scale multi-channel electromyography and musculoskeletal modeling via wearable smart garments to support clinical decision-making	Donatella Simonetti
14:06	Voluntary control of a lower limb exoskeleton during walking using an EMG-driven biomechanical model	Guillaume Durandau
14:18	Predictive simulations of fixed-speed treadmill gait	Kayla Pariser

13:30 - 14:30

## OG3 -CLINICAL BIOMECHANICS

Location: Online

Chair: Marco Vaz

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:30	3D Body Landmark Detection for Markerless Motion Tracking	Alex Spencer
13:42	Neuromuscular activation patterns during challenged walking tasks in individuals with femoroacetabular impingement	Carson Halliwell
13:54	Eccentric training increases the cross-sectional area in different regions of the Achilles tendon after rupture	Emmanuel da Rocha
14:06	Is the side-stepping exercise effective on targeting gluteal muscles?	Heiliane de Brito Fontana
14:18	Biomechanical response of residual limb: combining shear-wave elastography and finite element analysis	Begum Zeybek

13:30 - 14:30

## OG4 - SPECIAL SESSION: UPPER EXTREMITY MOTOR CONTROL

Location: Online

Chair: Michael Twardowski, Co-Chair: Mark Latash

### MARK L. LATASH

Mark Latash is a Distinguished Professor of Kinesiology and Director of the Motor Control Laboratory at the Pennsylvania State University. His research interests are focused on the control and coordination of human voluntary movements, movement disorders in neurological disorders, and effects of rehabilitation. He is the author of "Control of Human Movement" (1993) "The Neurophysiological Basis of Movement" (1998, 2008), "Synergy" (2008), "Fundamentals of Motor Control" (2012), "Motor Control and Biomechanics: Defining Central Concepts" (with V.M. Zatsiorsky, 2016), and "Physics of Biological Action and Perception" (2019). In addition, he edited ten books and published over 400 papers in refereed journals. Mark Latash served as the Founding Editor of the journal "Motor Control" (1996-2007) and as President of the International Society of Motor Control (2001-2005). He has served as Director of the annual Motor Control Summer School series since 2004. He is a recipient of the Bernstein Prize in motor control.

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:30	Synergic control of individual muscles and agonist-antagonist muscle pairs	Mark L. Latash
13:54	Size and structure of joint angle variability in young and old adults performing a fatiguing repetitive reaching task	Christopher Bailey
14:06	Individual finger movement control and association to brain activity in healthy participants	Helena Grip
14:18	Mirror-system-like excitability to kinaesthetic stimuli in the human motor cortex	Marc de Lussanet

13:30 - 14:30

## OG5 - IMAGING

Location: Online

Chair: Arin Ellingson

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:30	Quantitative assessment of a treatment addressing hypomimia in Parkinson's disease	Zimi Sawacha
13:42	Intra-assessor reliability of intrinsic foot muscles' size in older and younger adults using a portable ultrasound device	Lydia Willemse
13:54	Automated analysis of medial gastrocnemius muscle-tendon junction displacement in healthy young adults using deep neural networks	Rebecca Krupenevich
14:06	Development of an in-vivo tibiotalar kinematic protocol to investigate activities of daily living	David Williams
14:18	Fixation of tibial components in cementless total knee replacement measured with RSA and MRI	Jordan Broberg

13:30 - 14:30

## OG6 - SPECIAL: HAND & WRIST BIOMECHANICS IV

Location: Online

Chair: Ronit Wollstein, Co-Chair: Benjamin Goislard de Monsabert

### VERONIQUE FEIPEL

Veronique Feipel is a Professor of Functional Anatomy at the Université Libre de Bruxelles (ULB), Belgium. She is currently Dean of the Faculty of Motor Sciences and coordinator of the Research Master in Motor Sciences at ULB. She completed her PhD at ULB in 1997 and was a postdoctoral fellow in the LIS-3D – Sainte-Justine Hospital, Montreal, in 2000. Veronique has been a member of the ISB since 1999, has been a council member of ISB and has enjoyed the ISB meetings since attending her first ISB meeting in Calgary in 1999. She is Fellow of the ISB.

Veronique's research interests include spine, wrist and knee kinematics, clinical applications of musculoskeletal modelling and gait analysis. Over the past few years, her personal interest in sports led her to broaden her research efforts on the prevention of running related injuries and its link to running biomechanics.

Veronique leads a group of researchers in the Laboratory of Functional Anatomy aiming to facilitate clinical penetration of biomechanics research. She will continue supporting with energy research in the field of her first love, wrist biomechanics.

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:30	Recent advances in wrist biomechanics	Veronique Feipel
13:54	A new radiographic index for early diagnosis of perilunate injuries	Fernando N Zambone Pinto

14:06	Force transmission via intertendinous linkages of the m flexor digitorum profundus	Guido Geusebroek
14:18	Monitoring development in children using hand function	Vasiliki Vardakastani

13:30 - 14:30

## OG7 - PROSTHETICS AND ORTHOTICS

Location: Online

Chair: Carolin Curtze

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:30	Knee implant wear predictions are altered by including fluoroscopy-measured kinematics in the boundary conditions	Michael J. Dreyer
13:42	Fuzzy-logic inference system for transfemoral socket rectification	Mike Karamousadakis
13:54	Plantar pressures in custom foot orthoses with and without heel plugs	Megan Balsdon
14:06	A case series of early swing perturbation recovery strategies in transfemoral prosthesis users	Shane King
14:18	Bi-linear Natural Ankle Quasi-Stiffness During Walking: Characterization and Implications for Orthosis Design	Luke Nigro

13:30 - 14:30

## OG8 - SPECIAL: SIMULATION OF LOCOMOTION II

Location: Online

Chair: Friedl De Groote, Co-Chair: Marten Afschrift

### PETER J. BISHOP

Originally from Australia, Peter has had a lifelong passion for palaeontology, geology and mathematics. He gained a BAppSc (Hons) in Geosciences from the Queensland University of Technology in 2012, completed his PhD in Evolutionary Biomechanics from Griffith University in 2017, and subsequently held post-doctoral research positions at Griffith University, the University of the Sunshine Coast and the Royal Veterinary College. Over this time he has studied many extinct animals including freshwater crustaceans, fish, stem tetrapods, lizards, early archosaurs and dinosaurs (avian and non-avian). Peter is particularly interested in integrating biomechanics with data from fossils and modern animals, using a rigorous, physics-based approach to examine the adaptive significance of evolutionary changes in the vertebrate skeleton. In his current role, his research focuses on the sprawling-to-erect postural transition that took place in synapsids on the line to mammals, where he is using biomechanical modelling and simulation to understand the anatomical and physical factors that influenced and constrained this transition. Since 2007, Peter has also been part of the Geosciences Program of the Queensland Museum, Brisbane, first as a student volunteer and more recently as an Honorary Research Fellow.

Pres Time	Presentation title/Abstract title	Speakers/Authors
13:30	Quo vadis, Tyrannosaurus? Predictive simulations of locomotor function and performance in modern and extinct animals	Peter J. Bishop
13:54	Trajectory optimization of a 3D musculoskeletal model with inertial sensors	Marlies Nitschke
14:06	Predictive simulation of human motion using SCONE	Thomas Geijtenbeek
14:18	Stochastic optimal control predicts features of sensorimotor control during walking	Tom Van Wouwe

14:45 - 15:45

## KEYNOTE LECTURE: LEARNING HOW TO MOVE LIMBS WITH SOFT WEARABLE ROBOTS (CONOR J. WALSH)

Location: Online

### CONOR J. WALSH

Conor Walsh is the Paul A. Maeder Professor of Engineering and Applied Sciences at the John A. Paulson Harvard School of Engineering and Applied Sciences. He is the founder of the Harvard Biodesign Lab, which brings together researchers from the engineering, industrial design, apparel, biomechanics, physical therapy and business communities to develop and translate new disruptive robotic technologies for augmenting and restoring human performance. Example application areas include, enhancing the mobility of healthy individuals, restoring the mobility of patients with gait deficits, assisting those with upper extremity weakness to perform activities of daily living and preventing injuries of workers performing physically strenuous tasks.

The soft exosuit technology is now commercially available in clinics for gait retraining through a collaboration with ReWalk Robotics and a lab spin-out, Verve, has launched a back assist product for workers performing physically strenuous tasks in industry. He is dedicated to training the next generation of biomedical engineering innovators and lab alumni have gone on to successful careers in academia, entrepreneurship, and high tech R&D positions in industry. Additionally, he co-founded the Soft Robotics Toolkit that serves as a platform the lab's extensive STEM outreach activities. He is the winner of multiple awards including the Presidential Early Career Award for Scientists and Engineers and the MIT Technology Review Innovator Under 35 Award.

15:45 - 17:15

## POSTER SESSION B

Location: Online

Pres Time	Presentation title/Abstract title	Speakers/Authors
	• DIC-based stress-shielding analysis in compression of CoCrMo porous structures for orthopedic implants	Paolo Caravaggi
	• A gait pattern comparison between healthy adults and neurological patients at different walking speeds	Elke Warmerdam

- Effect of fatigue on hip, knee and ankle proprioception during a golf specific fatigue protocol Ukadike Chris Ugbolue
- A procedure for measuring the kinematics of the foot and ankle complex through Weight-Bearing CT Michele Conconi
- The project reflatperform - development of a reference laboratory for the evaluation of playing- and performance-related dysfunctions of performing artists to derive individual prevention and rehabilitation strategies Dirk Möller
- Step length asymmetry is associated with fear of falling activity avoidance in persons with unilateral transtibial amputation Noah Rosenblatt
- Multi-digit Force Coordination in Patients with Trigger Digit using Machine Learning and Deep Learning Kien Tran
- Inter-session repeatability of markerless motion capture gait kinematics Robert Kanko
- Novel computer vision and deep learning approaches for tracking 3-D spine motion during dynamic trunk flexion using an RGB-D camera Kristen Beange
- A supervised classification of children with fragile X syndrome and controls based on kinematic and sEMG parameters Weronika Piatkowska
- Ankle Joint Quasi-Stiffness of Quiet Unperturbed Standing in Chiari Malformation: A Fast Fourier Transform Approach Brittany Sommers
- Ground reaction forces during anteriorly-loaded overground walking Jiyun Ahn
- Automatic identification and segmentation of balance-related tasks using markerless motion capture Kieran J. Eveleigh
- Improved balance control following distance learning of yoga in novice practitioners Pranavi Depur
- Functional calibration to improve kinematic analysis in the clinics using inertial measurement units Clint Hansen
- A preliminary study comparing the effects of concurrent and terminal visual feedback on standing balance in older adults Jamie Ferris
- Changes in postural dynamics can be captured by a Wii Balance Board during standing tasks Takashi Sado
- Evaluation of postural sway for remote monitoring of vestibular rehabilitation Timothy Zehnbauer
- Characterizing the feasibility of progressive gait perturbation protocol for individuals poststroke Hala E. Osman
- Multifractal analysis of quiet standing in the young and old John H Challis

- Simple model of arch support: relevance to Charcot Neuroarthropathy Shaye Tiell
- Do relaxed sarcomeres return to their original length following repeated activations? Meng LI
- Classification of autism gait patterns in children using multisegment and single segment foot kinematic data Ashirbad Pradhan
- Firefighter turnout gear limits the ability to lift while maintaining a neutral spine posture Danielle Carnegie
- Does the time of day influence the clinical assessment of muscle strength in men and women? Karine Josibel Velasques Stoelben
- Gluteal activation cues reduce peak acetabular contact pressure during squatting in persons with femoroacetabular impingement syndrome: A finite element analysis study Jordan Cannon
- Lower extremity kinetics following an achilles speedbridge: A case study Kevin Valenzuela
- Is the dissipative energetic behavior of the human heel associated with thermal changes? Nikolaos Papachatzis
- The effects of using a rehabilitation technology on foot muscles strength in people with diabetic neuropathy: A preliminary data analysis Jane Suelen Silva Pires Ferreira
- Effect of maturation and limb dominance on knee flexion and extension torque in adolescent athletes Joanna Geck
- Upper and lower body inter-segmental coordination during unsupervised gait of older adults with dementia Lina Musa
- Biomechanical improvement and timing for total knee arthroplasty surgery Chang Shu
- Sex and anterior cruciate ligament injury effects on isometric and isokinetic force production in a paediatric population Christine Smith
- Knee joint kinetics during stationary cycling for unilateral total knee arthroplasty patients Erik Hummer
- Evaluating Muscle Recruitment During Lower Trapezius Early-Stage Exercises Performed Below 90° Shoulder Elevation Maria Herrera
- National biomechanics day: Past, present, and future Lisa MacFadden
- Development of a hands-on, wearables course as an alternative for physiology labs Patrick Mayerhofer
- Pilot study: Performance benefit of young athletes using a video-based feedback and instrumented starting blocks in athletics sprint start Beat Goepfert

- Active learning strategies using surface electromyography improve the undergraduate student's understanding of neuromuscular human movement control

Carlos De la Fuente
- Micromovements, low back pain, and computer task performance during prolonged sedentary postures

Liana M. Tennant
- Sex-specific neuromuscular adaptations to fatigue in a repetitive pointing task while sitting on a sit-stand stool

Chen Yang
- Sex-specific effects of anti-fatigue lenses on discomfort, kinematics and performance during a seated computer task

Samuel Lamanuzzi
- Relationship between the global movement of the hand and the forearm muscles during typing

Takanori Ito
- Combining wearable sensors and machine learning to monitor low back loading and injury risks in material handling

Emily Matijevich
- Correlation between wear region of shoes and contact region during early gait

Kurt Beschorner
- A scoping review on the applications of machine learning for primary work-related musculoskeletal disorder prevention

Victor Chan
- Drift-free algorithm for estimating muscle fascicle length from ultrasound images

Tim van der Zee
- Patient and implant performance between satisfied and dissatisfied total knee replacement patients

Jordan Broberg
- Investigation of the biofidelity of the MIL-Lx foot

Julia de Lange
- Occupant kinematic prediction model during rear-end collisions

Shimada Sean
- Most severely injured body regions in near side motor vehicle collisions involving head impact

Sean Shimada
- High risk glenohumeral joint forces during three pull-up techniques

Caryn Urbanczyk
- Classification of ACL reconstructed running dynamics using common gait features

Yannis Halkiadakis
- Use of Pressure-Measuring Insoles to Characterize Center of Pressure Length and Width under Simulated Reduced Gravity Conditions

Christian Ison
- In vitro mechanical effects of a specific neurodynamic mobilizations of the superficial fibular nerve: a preliminary study

Felix-Antoine Lavoie
- Drop height and sex differences in anterior cruciate ligament force during unilateral drop landings

Jake Melaro

- Effects of ACL reconstruction on in vivo quadriceps contractile behavior and association with knee joint biomechanics Amanda Munsch
- Optimization vs unscented filtering for measuring walking motion using IMUs Andy Bhateja
- Eight-week individualized gait modification intervention to reduce knee adduction moment: Preliminary analysis of a randomized controlled trial Bryndan Lindsey
- Home-based foot-ankle exercises program oriented by a booklet changed positively foot motion during gait in people with diabetic neuropathy Érica Silva
- Evaluation of a clinical walking test among unilateral lower-limb amputees Hananeh Younesian
- Foot progression angle modifications that maximally reduce the knee adduction moment do not decrease medial knee contact force Kirsten Seagers
- Are medial and lateral tibiofemoral compressive forces different in uphill compared to level walking for patients following total knee arthroplasty? Tanner Thorsen
- Dynamic gait stability during anteriorly loaded treadmill walking Caroline Simpkins
- Danger ahead: Fatigued obstacle negotiation in an unpredictable environment Joshua Vicente
- Modeling spatial asymmetry in visuomotor coordination Kolby Brink
- Effectiveness of a speed control based on auditive feedback during metabolic cost trials Leonardo Lagos
- Differences in ground reaction forces between children, adults, and elder people during walking Mauricio Delgado
- Impact of foot progression angle and/or lateral trunk lean gait modifications on lower limb joints external moments Thomas Legrand
- Spinal reflexes can produce a variety of bipedal gaits Frans van der Helm

## POSTER QUIZ

Location: Online

17:30 - 19:00

---

## SOCIAL MINGLE

Location: Online

17:30 - 18:30

---

## STUDENT HAPPY HOUR

Location: Online

# Thu 29 Jul 2021

10:30 - 11:30

## ADVANCING WOMEN IN BIOMECHANICS MEETING

Location: Online

Becoming an Ally

The goal of this one-hour workshop is to provide practice in recognizing and addressing bias through specific scenarios and discussion of positive responses. There will be break-out rooms where scenarios will be enacted. Participants in small groups will work together to recognize biases taking place and how best to respond. This session is open to all, and men are especially encouraged to participate. Scenarios will include hiring, reviews and promotions, meeting dynamics, mentorship and sponsorship, and everyday interactions. Our aim is to provide a safe environment for meaningful discussions. This workshop is organized by "Advancing Women in Biomechanics" (AWB).

11:30 - 11:45

## SHORT WELCOME

Location: Online

11:45 - 12:45

## OH1 - CLINICAL BIOMECHANICS

Location: Online

Chair: Eva Andersson

Pres Time	Presentation title/Abstract title	Speakers/Authors
11:45	Biomechanical characterization of the primary fixation stability of different acetabular cups with respect to segmental acetabular bone defects	Christian Schulze
11:57	Superimposition of ground reaction force on tibial articular surface: a novel approach to support diagnosis and treatment of early knee osteoarthritis	Miriana Ruggeri
12:09	Supine versus weight-bearing computer tomography in surgically-treated patella instability: an investigation on ligament length change between two different loading conditions	Claudio Belvedere
12:21	Relationship between knee range of motion and gait function pre and post-total knee replacement	Marina De Vecchis
12:33	Recovery of weight-bearing symmetry after total hip arthroplasty depends on activity and pre-surgery values	Sónia A. Alves

11:45 - 12:45

## OH2 - LOCOMOTION: GENERAL

Location: Online

Chair: Lizeth Sloot

Pres Time	Presentation title/Abstract title	Speakers/Authors
11:45	Which metabolic cost models most accurately predict energetics at different speeds of walking?	Abraham Israel Luis Pena
11:57	Model-based closed-loop control of locomotion via muscle reflexes and spinal synergies: A direct collocation-based system identification approach	Huawei Wang
12:09	Inclination of talocrural joint axis: In vitro studies and morphological considerations not confirmed in walking condition	Peter Wolf
12:21	Do different activation patterns between the lateral and medial gastrocnemius translate into different fascicle behavior during walking?	Raphaël Hamard
12:33	Bracing Results in Immediate Improvements in Gait Mechanics for Patients with Adult Spinal Deformity	Ruth Higgins

11:45 - 12:45

## OH3 - MUSCULOSKELETAL MODELLING

Location: Online

Chair: Brian Umberger

Pres Time	Presentation title/Abstract title	Speakers/Authors
11:45	Bone alignments via weight-bearing CT scans and 3D reconstruction tools in the flat foot	Alberto Leardini
11:57	Computational modelling of proximal and distal epiphyseal and appositional growth of the femur in children	Andreas Lipphaus
12:09	Measuring knee joint laxity in four DOF in vivo using a robotics- and image-based technology	Hannah Katharina Fabro
12:21	Identification of optimal laxity tests to stretch individual parts of knee ligaments	Michael Skipper Andersen
12:33	Review of musculoskeletal modelling in a clinical setting: current use in rehabilitation design, surgical decision making and healthcare interventions	Samuel Smith

11:45 - 12:45

## OH4 - ORTHOPAEDICS: BONE & CARTILAGE, TENDON & LIGAMENT

Location: Online

Chair: Jennifer Shin

Pres Time	Presentation title/Abstract title	Speakers/Authors
11:45	Mathematical modeling of degradation process of biodegradable metallic biomaterials in immersion and perfusion setups	Mojtaba Barzegari

11:57	Changes in ankle and foot joint kinematics after fixed-bearing total ankle replacement	Paul-André Deleu
12:09	In vivo length-change patterns of the medial collateral ligament throughout complete cycles of level walking	Seyyed Hamed Hosseini Nasab
12:21	Characterization of collagen structural response to in situ loading of the rat Achilles tendon	Isabella Silva Barreto
12:33	Functional performance associated with triceps surae muscle and tendon morphology in patients with achilles tendinopathy	Kayla Seymore

11:45 - 12:45

## OH5 - MUSCULOSKELETAL MODELLING AND SIMULATION

Location: Online

Chair: Matthew Handford

Pres Time	Presentation title/Abstract title	Speakers/Authors
11:45	Sensitivity analysis of joint contact forces to individual muscles maximal isometric force using a Gaussian process emulator	Erica Montefiori
11:57	Musculoskeletal trunk model for simulation of scoliosis deformities	Hamed Shayestehpour
12:09	Hamstrings contraction regulates magnitude and timing of peak anterior cruciate ligament loading during drop vertical Jump in female athletes	Ryo Ueno
12:21	Application of a novel multiscale modeling toolbox to characterize knee joint mechanics during daily activities and rehabilitation exercises in knee osteoarthritis individuals	Amir Esrafilian
12:33	Applied biomechanics and computational modelling to prevent and manage upper extremity injuries in rowing	Caryn Urbanczyk

11:45 - 12:45

## OH6 - ARTIFICIAL INTELLIGENCE AND MACHINE LEARNING

Location: Online

Chair: Emma Tole

Pres Time	Presentation title/Abstract title	Speakers/Authors
11:45	Lower-limb joint torque prediction using multi-step deep learning approach	Longbin Zhang
11:57	Prediction of finger movements via a reservoir-computing neural network driven by electromyographical data	Frederik Thies
12:09	Frontal-parietal delta microstate-based Brain computer interface improves Knee Gait Trajectory and Phase Prediction	Sanya Varghese
12:21	High density and bipolar sEMG based ankle joint torque prediction using machine learning	Asta Danauskiene
12:33	Prediction of the shape of human lumbar vertebrae from adjacent ones by singular values decomposition	Marco Sensale

11:45 - 12:45

## OH7 - SPORTS BIOMECHANICS

Location: Online

Chair: Izzy Moore, Co-Chair: Molly McCarthyRyan

Pres Time	Presentation title/Abstract title	Speakers/Authors
11:45	Frontal plane knee control with regard to leg dominance in female adolescent competitive handball players during a drop vertical jump	Sabrina Erdrich
11:57	Anatomical predictors of sagittal hip kinematics during deep squat in adolescent males with and without CAM deformity	Dalia Al Otti
12:09	Development of a 3d musculoskeletal simulation model to estimate muscle and knee ligament forces during carved turns in alpine skiing	Dieter Heinrich
12:21	The validity of the GPS-based accelerometer to measure foot stance characteristics during running	Michael Lawson
12:33	Effects of 4-week transcranial direct current stimulation combined with foot core exercise on foot muscle strength and ankle kinesthesia	Songlin Xiao

11:45 - 12:45

## OH8 - MOTOR CONTROL

Location: Online

Chair: Paola Contessa, Co-Chair: Jennifer Vojtech

Pres Time	Presentation title/Abstract title	Speakers/Authors
11:45	Pain-induced adjustments in motor Unit discharge depend on contraction speed	Eduardo Martinez-Valdes
11:57	Impact of personality on postural control - a pilot study	Justyna Kędziorek
12:09	Corticospinal excitability during and after stretch-shortening cycle contractions compared with pure shortening contractions	Lea-Fedia Rissmann
12:21	Uncontrolled manifold analysis of effects of different fatigue locations on coordination during a repetitive pointing task	Matthew Slopecki
12:33	Inter-individual variation in coordination and control of countermovement jumps	Stuart McErlain-Naylor

12:45 - 14:15

## POSTER SESSION C

Location: Online

Pres Time	Presentation title/Abstract title	Speakers/Authors
	<ul style="list-style-type: none"> <li>Increased postural threat alters control of dynamic stability in response to external perturbations that induce a step</li> </ul>	Noah Rosenblatt

- The relationship between 2D and 3D sacropelvic measurements Nikita Ghosh
- Musculoskeletal simulations of high knee flexion tasks: knee ligaments geometry definition Davide Pavan
- Musculoskeletal modelling: relevance of model anatomical consistency Michele Conconi
- Cadaveric knee simulator in orthopaedic training to quantify joint kinematics for active functional motions Darshan Shah
- Assessing the mechanical properties and stress distribution in dynamic Ankle Foot Orthoses: bench testing and FEA Paolo Caravaggi
- Kinematic Analysis of the Human Body using Machine Learning Technique Usman Saleem
- BrokenPose: why we need custom models for markerless motion analysis Neil Cronin
- Improved balance analysis accuracy using a functional base of support model Matthew Millard
- Differences in single leg postural control when assessed over time in professional rugby union players Molly McCarthy-Ryan
- Foot and ankle joint coupling in balance and gait Rosemary Dubbeldam
- Intra and intersession reliability of centre of pressure measures in older adults during bipedal static postural tests Diana Soares
- The effect of feet position on standing balance in pediatric patients with flatfeet alina khodorovvskaya
- Limits of stability in cognitively healthy individuals and mild cognitive impairment Andresa MC Germano
- The vertical balance control system in children with cerebral palsy is more synchronized compared to healthy children Galina Ikoeva
- Energy dissipation while landing from a jump Thibaut Toussaint
- Anticipatory Postural Adjustments During Gait Initiation in People with Mild Chronic Low Back Pain Lorenzo Rum
- Video game based kinematic assessment using a leap motion controller Dominik Buchmann
- A novel method to assess soft tissue overloading within the sole of the foot Chockalingam Nachiappan
- Friction coefficients of cancellous bone densified with autologous bone-particles in uncemented fixation Sebastian Manuel Zobel
- A finite element investigation of the tunability of non-pneumatic tyres for wheelchair use Otis Wyatt

- Development of a sensor assembly to measure vertical, horizontal and tilt motion of the glenoid edge during the ASTM F2028 test Leanne Haworth
- Robot-based method for analysis of knee prostheses in human cadaveric knees Adrian Gomez
- Increased muscle activity in acoustic startle response among children with recurrent pain in the head, neck and abdomen due to chronic stress Eva Andersson
- Unraveling human-rollator-interaction using a robot rollator simulator device Frieder C. Krafft
- Thumb range of motion in osteoarthritis and effect on hand function Jarque-Bou Néstor J.
- Hiking with total knee arthroplasty: In field kinematics in sloped walking in relationship to muscle strength Judith Bleuel
- Can knee valgus kinematics be predicted by clinical assessments during a unilateral landing task? Karine JV Stoelben
- Influence of mandibular reconstruction employing iliac crest flap and fibula flap on the long-term gait of patients Sybele E. Williams
- Evaluation strategies for assessing finger motion in rheumatoid arthritis to estimate impaired hand function Uday Phutane
- Musculoskeletal alterations in children with fragile X syndrome Zimi Sawacha
- Knee Joint Biomechanics Following Total Knee Arthroplasty with Posterior Stabilized Implants Chang Shu
- The effect of diabetic peripheral neuropathy on lower limb biomechanics: a systematic review and meta-analysis Erica Bartolo
- Reliability of a portable system for motion analysis in children and young adults with treated obstetrical brachial plexus palsy Helena Grip
- Quadriceps muscle and pain during daily activities for total knee arthroplasty patients Fangjian Chen
- Comparison between two mobile applications measuring shoulder elevation angle - A validity study Fredrik Öhberg
- Introducing a test setup to measure the tribological behaviour of shoe-factory interactions under biomechanically relevant conditions Lasse Jakobsen
- Functional assessment for passive and active back supporting exoskeletons Jasper Johns
- Fracture behavior of a composite of bone and calcium sulfate/hydroxyapatite Joeri Kok

- Microscale compressive behavior of hydrated lamellar bone at high strain rates Cinzia Peruzzi
- A high-fidelity finite element model of the cerebrovasculature for brain injury simulation Harry Duckworth
- The axial impact response and plantar load distribution of the hybrid III and MIL-Lx under altered ankle postures Julia de Lange
- Knee biomechanics of single leg hop landings after primary anterior cruciate ligament repair and InternalBrace™ augmentation Birte Luise Coppers
- New home exercise program for the Swiss Box Lacrosse National Team Beat Goepfert

## **KEYNOTE LECTURE: HOW DO BIOMECHANICAL FACTORS INFLUENCE EXERCISE PRESCRIPTION ON THE INTERNATIONAL SPACE STATION (LORI PLOUTZ-SNYDER)**

Location: Online

### **LORI PLOUTZ-SNYDER**

Lori Ploutz-Snyder earned her B.S. and M.S. degrees in zoology (1989) and Ph.D. in biomedical sciences (1994) from Ohio University. She conducted post-doctoral research at Michigan State in physiology and radiology especially developing muscle functional MRI techniques. In 1996, she joined the faculty of Syracuse University as an assistant professor in Exercise Science and rose to professor in 2008, while serving as the chair of the Department of Exercise Science from 2004-2008. She worked collaboratively at Syracuse and held joint appointments in Physical Medicine and Rehabilitation, Physiology and Neuroscience, and the Center for Policy Research. In 2008, she joined the NASA Johnson Space Center and University Space Research Association as NASA's Lead Scientist for exercise physiology and countermeasures. In this role, she was responsible for NASA's research portfolio for the preservation of cardiovascular, skeletal muscle and bone health during long duration spaceflight. In 2013, she was appointed as a musculoskeletal alterations team leader at the National Space Biomedical Research Institute at Baylor College of Medicine. In July 2016, she was appointed Professor of Movement Science and Dean of the School of Kinesiology at the University of Michigan.

Professor Ploutz-Snyder's research focuses on skeletal muscle physiology, the development and optimization of exercise programs for special populations and the integrative effects of exercise. This includes identifying targets for exercise intervention such as functionally relevant thresholds of muscle strength or aerobic fitness. She has worked with diverse populations ranging from athletes and NASA astronauts to frail elderly, stroke survivors, children with cerebral palsy and adults with Down Syndrome.

16:15 - 16:45

## **FULLY INTEGRATED MOVEMENT ASSESSMENT WITH QUALISYS, NORAXON AND H/P/COSMOS**

Location: Online

h/p/cosmos and Noraxon join Qualisys to demonstrate how to create a fully integrated, digital workflow to analyse locomotion on an instrumented treadmill.

The session will be streamed live from German Sport University, Cologne

16:45 - 17:00

## **BREAK**

## **ISB PRESIDENT'S LECTURE: TONI ARNDT**

Location: Online

### **TONI ARNDT**

Toni Arndt performed his undergraduate studies in New Zealand and Australia in biology and Human Movement Sciences before receiving a scholarship for a PhD at the German Sport University, Köln. His PhD involved studies concerning asymmetrical loading of the Achilles tendon. This line of study continued at the Karolinska Institute in Sweden as a post-doc and he is still exploring new methods for investigating Achilles tendon function. At present Toni Arndt is a professor in biomechanics, specializing in lower extremity muscle-tendon function, athletic footwear and sports biomechanics, at The Swedish School of Sport and Health Sciences (GIH) in Stockholm. He was Dean of the Research and Doctoral Education Board at GIH for six years. He has published approximately 90 peer reviewed scientific articles and has supervised ten PhD students to completion. In 2020 Toni was awarded the Swedish senior prize for sport science research. He is President of the International Society of Biomechanics.

## Rib Injury Prediction using Machine Learning-based Surrogate Models

Shitij Malik<sup>1</sup>, Jobin D. John<sup>2</sup>, Johan Iraeus<sup>2</sup>, Mats Svensson<sup>2</sup>

<sup>1</sup>Indian Institute of Technology Delhi, New Delhi, India

<sup>2</sup>Vehicle Safety Division (Injury Prevention), Dept. Mechanics and Maritime Sciences, Chalmers University, Gothenburg, Sweden

Email: jobin.john@chalmers.se

### Summary

Although Finite Element (FE) Models of Human Body are extensively used in Vehicle Safety, they are computationally expensive for use in extensive investigations. In this paper, we explored the use of Machine Learning to build surrogate models as alternative fast models. Support Vector Regression and Decision-Tree based Ensemble Models were trained and validated for prediction of rib injury risk. Important variables influencing rib injury risk were evaluated from the surrogate models.

### Introduction

Rib injury is a major risk of injury for vehicle occupants. FE human body models (HBM) are widely used for evaluation of rib fracture. These models are, however, computationally expensive and time consuming. Cheap and fast models will be useful for quick evaluations and to investigate scenarios where further investigations are required using the detailed HBM. Towards this end, the aim of this study was to develop surrogate models to predict risk of rib fracture in a vehicle occupant during car crash.

### Methods

Rib injury risk data from FE simulations previously published, corresponding to a fracture of at least 3 ribs in a driver, was used as the training data for surrogate models [1], [2]. The training data had 25 variables (which included crash and vehicle features), which had been sampled using Latin Hypercube sampling to generate 1000 simulations. FE models of an average male along with a generic vehicle interior was used in these simulations. Details of the human body models and the simulation variables can be found in the cited studies.

In this study, the risk of rib injury was modeled using two methods: Support Vector Regression (SVR) with polynomial kernel and Decision-Tree based Ensemble Gradient Boosting Regression (GBR) with least squares loss function. The input variables were centered and scaled using Standard Scaler Transformation and the targets (risk values) were scaled using Quantile Transformation. Scikit-Learn was used to pre-process the data, train, and validate the surrogate models.

### Results and Discussion

Five-fold cross-validation of the models yielded maximum scores of 0.87 for SVR and 0.93 for GBR. The cross-validation curves for both the methods plateaued at approximately 500 samples (Fig. 1). Decision tree ensembles are versatile enough to handle nonlinear relationships and interactions between variables, and hence may explain the better performance of GBR.

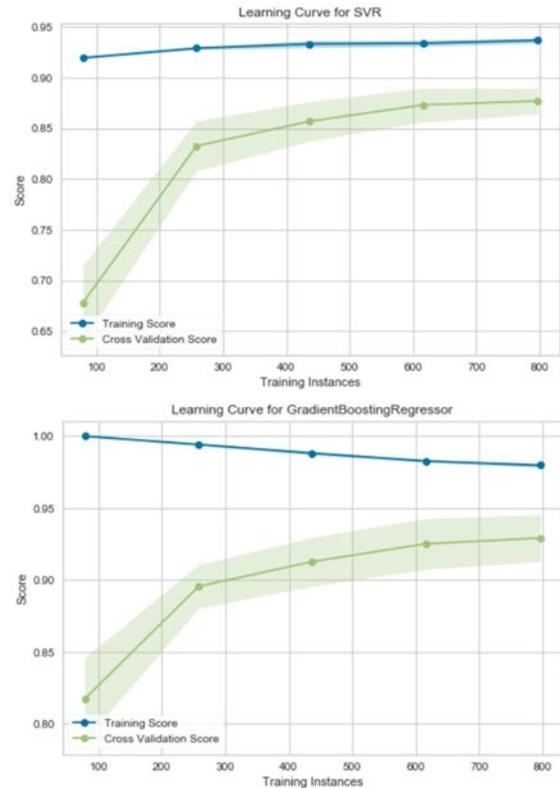

Figure 1: Learning curves for the two models.

The rib injury risks had a heavy right-skewed distribution, requiring transformation to obtain acceptable model accuracy. Quantile transformer, that converted the targets to an approximate uniform distribution, gave a better accuracy compared to other transformations like log.

The relative importance of the variables was evaluated on the GBR model. Change in velocity, airbag trigger time, and direction of impact influenced the risk of rib injury the most among the variables simulated in this study.

### Conclusions

We developed surrogate models as fast and cheap alternative to finite element models for injury prediction. For a set of 25 variables, approximately 500 simulations were required to get an accuracy of 0.9. From the surrogate models, change in velocity and airbag trigger time during a crash were found to have the most influence on the risk of rib fracture for a driver.

Email: marion.mundt@uwa.edu.au

### Summary

Applying machine learning techniques to video data for improving our understanding of biomechanics in the field is increasingly popular. Historically, the bulk of biomechanical research relied on marker-based optical motion capture systems to determine joint kinematics and kinetics. This study proposes a method to synthesize two-dimensional (2D) video frames from three-dimensional (3D) motion data, to create datasets of scale that can leverage machine learning approaches for biomechanical analysis. The results of this proof-of-concept study indicates that the proposed synthesized data method provides a feasible alternative to experimental data capture.

### Introduction

2D video data is becoming increasingly relevant for in-field biomechanical analysis. When coupled with pose-estimation (PE) algorithms, 2D video alone may be sufficient to determine joint kinematics and kinetics. Large datasets containing force plate, 2D video, 3D motion capture and/or inertial sensor data can be leveraged to improve the accuracy and validity of PE methods – especially for kinetic parameter estimations [1, 2]. Since such datasets are limited, this study presents a method to simulate 2D video frames and PE skeleton keypoints based on 3D motion capture data. In practice this method serves to facilitate the reuse of 3D motion capture databases by enlarging the available 2D video datasets for PE training, and also provides insight into the minimum number required, and optimal location of, 2D cameras.

### Methods

This proof-of-concept study used previously collected and synchronized 2D video and 3D motion capture data.

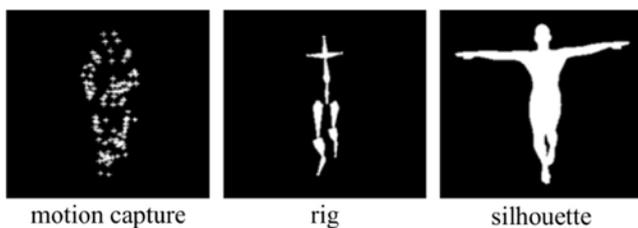

Figure 1: Workflow overview.

The motion capture data was used to create and drive a human silhouette in the open-source 3D computer graphics program blender (version 2.79). For this purpose, joint centers/locations of the bilateral ankle, knee, hip, shoulder and foot (endpoints), pelvis center, neck and head, were used to create a human skeleton rig. Using the MakeHuman plug-in for Blender, a

human silhouette was fitted to the rig and the marker data to model the participant's body shape (Figure 1). To validate the approach, the resulting model was screen captured in Blender software from the same camera view as the original 2D video. OpenPose [3] was used to determine keypoints in both the original video and the animated video. The Euclidean distance difference between the two associated keypoints over time was calculated to examine the accuracy of the method.

### Results and Discussion

Mean Euclidean distance difference between the original and animation derived keypoints was smaller than 10 pixels (Figure 2). Only lower limb and trunk keypoints are shown as the 3D motion capture data used did not include arms. The method was validated for a single, perfectly orthogonal sagittal camera view, although different camera views can be constructed in blender to create 2D videos of the animated model. The position of the camera will most likely influence the keypoint PE results in a similar way for both, original videos, and animations.

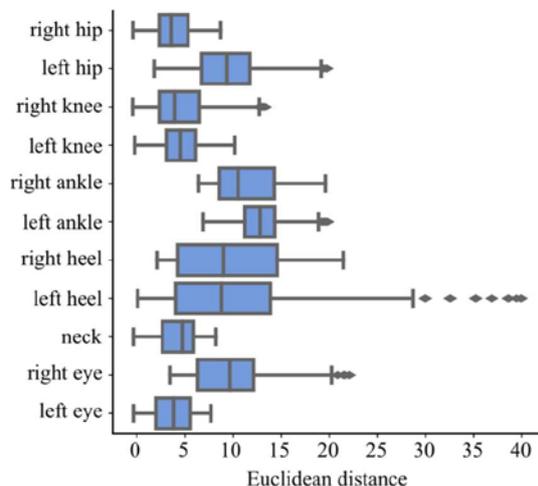

Figure 2: Euclidean distance between original video and animation.

### Conclusions

The Python plug-in for Blender enables the automated creation of videos from multi-view camera angles, facilitating the reuse of 3D motion capture datasets for 2D video-based machine learning applications.

## Summary

Our study extends previous research by proposing a lightweight, AI based method to assess muscle and tendons unit (MTU) behaviour during fast locomotion. We demonstrate that our method does not significantly differ from the current gold-standard.

## Introduction

Within the MTU, muscles and tendons have different properties, contribute differently to external loading and adapt dissimilar to training stimuli. Imbalances in muscle strength and tendon stiffness can lead to injuries or impede the interplay of muscles and tendons for efficient states of locomotion [1]. Investigations of muscle and tendon dynamics during locomotion involve several obtrusive sensors such as 3D motion capture, ultrasound (US), electromyography and force measurements [2]. This is complex, especially during fast movements like running due to high accelerations and skin perspiration. Therefore, simple methods overcoming these problems are desired. Kidzinski et al. [3] have demonstrated a quantitative movement analysis using single camera videos and deep neural networks. Our work aims to validate the estimation of MTU, muscle belly and Achilles tendon (AT) length changes using a lightweight laboratory setup consisting of an US probe and a single camera video during running.

**Figure 1:** AI tracked landmarks. Red arrows in hip, knee and ankle indicate the joint angle. White markers with orange cross are used to estimate US probe and MTJ positions.

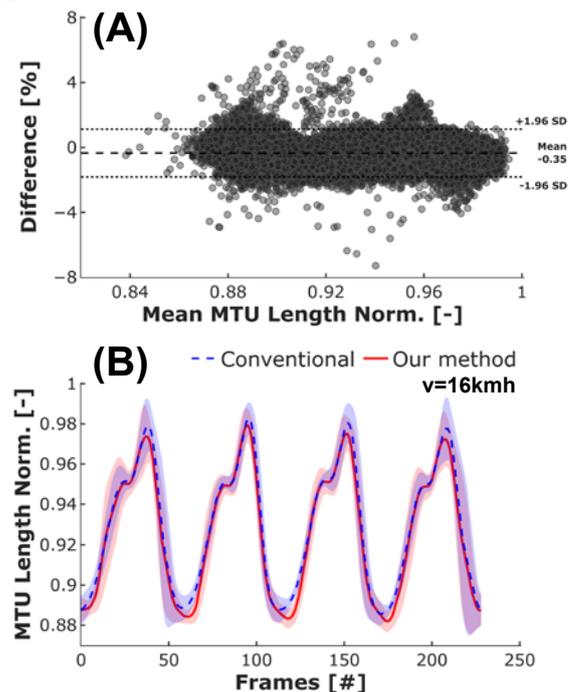

## Methods

Data were collected from 14 participants. Videos were captured with one Miquis (Qualisys, Göteborg, Sweden) camera from the lateral view while running on a treadmill at various speeds between 6-18 km/h (Fig. 1). US recordings were collected on the medial gastrocnemius (MG) using the ArtUs EXT-1H with the LV8-5N60-A2 transducer (Teled, Vilnius, Lithuania) operated at 7.5MHz (image-rate: 80Hz). The US probe was tightly connected to the lower limb using a custom made cast. In 3 subjects we synchronously captured recordings using a Miquis 3D motion system. For the AI pose estimation we used an open-source deeplearning toolbox [4]. We re-trained provided networks to extract joint markers in our collected 2D video files. For the calculation of MTU lengths we used the estimation method by

Hawkins et al. [5]. The automated tracking of the muscle tendon junction (MTJ) in US images using deepMTJ [6] and markers on knee and calcaneus allowed the estimation of muscle and AT lengths. Subsequently, we compared MTU lengths calculated from joint angles of the 3D motion system with the 2D camera view. We used Bland Altman plots and two sample paired t-tests in 1dSPM [7] to estimate differences in the methods and time series of MTU length, respectively.

## Results and Discussion

We observe that MTU lengths estimated with our proposed method (Fig. 2) do not significantly differ to the gold standard [ $t(1,46)=4.13301$ ,  $p < 0.05$ ] (Results for the AT and muscle belly use the same marker kinematics and are not shown). Thus, our work provides a lightweight and easily applicable setup for functional assessments of muscles and tendons during fast locomotion.

**Figure 2:** (A) The Bland Altman plot compares MTU length estimates using a conventional setup to our proposed AI based method (32.800 samples, 47 videos, 3 participants, running speeds 6-16 km/h). Our method underestimates MTU length by a mean of  $-0.35 \pm 0.75\%$  to the current gold-standard. (B) Normalized MTU lengths over 4 gait cycles calculated with the regression equation by Hawkins et al. [5], captured in 10 recordings, of one representative participant, running at 16km/h.

### Summary

Whether machine learning methods can successfully be employed for optimal shoe midsole rocker parameter selection for peak pressure minimization was evaluated. The study is motivated by the demonstrated benefits of peak pressure reduction in preventing the development of diabetic foot ulcers in diabetic patients. Random Forests and Convolutional Neural Networks were trained on data gathered from 9 healthy subjects.

### Introduction

With the rise in diabetic cases, with estimated 422 million cases worldwide [1], related issues have garnered attention. One of such is diabetic foot ulcers, with a global prevalence of 6.3% [2]. If not successfully treated, these may result in amputation.

Previous research has shown that diabetic foot ulcers can be prevented by reducing plantar pressure. To achieve this, special shoes with varied midsole rocker profiles have been developed [3], with a goal to reduce maximum peak pressure to less than 200 kPa if possible, or if not, then by at least 30%. While such footwear shows promise, selecting and producing individualized shoes can be resource-intensive, and may rely on the intuition of orthopedic shoe technicians and trial-and-error. This study examines the possibility of using machine learning to predict individualized optimal rocker parameters that reduce peak plantar pressure.

### Methods

Nine able-bodied subjects with shoe size of 42 were recruited. Each subject was tested with 24 forefoot rockers with varying parameters, including 3 rocker apex positions, 2 apex angles (both with respect to shoe's long axis), 2 rocker radii and either stiff or flexible sole (along forefoot rocker apex). This was achieved using a "sneaker" type shoe with replaceable forefoot mid- and outsole (Table 1). With first their usual sneakers then with each rocker shoe (in randomized order), each subjects were asked to walk on a treadmill at 3 different speeds (randomized) – normal, faster

Table 1. Midsole rocker parameters in the 24 tested shoes

Parameter	Values
Apex pos. (% sl)	55, 60, 65
Apex angle (°)	65, 85
Radius (mm)	177, 208
Sole stiffness	Flexible, stiff

and slower, defined as mean  $\pm 1$  SD of reported comfortable walking speeds adjusted for age and height [4], resulting in 75 trials per subject, with at least 12 strides in each trial. Plantar pressure was measured with instrumented insoles (pedar, Novel) at 100 Hz.

The data was then processed with derived features for the classification task. For each subject features extracted included average of peak pressure values over the steps recorded, 2D coordinates of the peak pressure value over all steps, mean and variance modelling pressure distribution from peak pressure point as measured for the control shoe. To prepare labels, for each rocker setting the average of peak pressures was compared to 200 kPa, and noted as 1 – positive sample if the value was less and 0 if the value was greater, resulting in a multi-label dataset.

Random Forests and Convolutional Neural Networks were used for classification. The dataset was split with a 7:2 ratio for training and testing.

### Results and Discussion

The resulting accuracy was 0.76 for Random Forests, while CNN failed to converge with accuracy near to random guessing. The latter is likely caused due to insufficient number of samples. One possible way to amend the issue would be adding augmentation using gaussian noise to the training samples.

Another limitation is using only 2 data points for testing, which gives a limited idea of the generalizability of the model to the general population.

### Conclusions

Random Forests show some promise in achieving the stated objective, while the data recorded is not enough to train Convolutional Neural Networks. Further study is required to choose the best method for the approach and better estimate the generalizability.

Email: o.sten@santannapisa.it

### Summary

In this work, a system for automatic error detection in rowing technique is proposed, based on measurements from a single gyroscope. A machine learning method to classify correct vs incorrect strokes was cross-validated, based on motion capture data from nine subjects, obtaining a 79.5% accuracy.

### Introduction

Sequential movement of the legs and trunk during rowing strokes is crucial during the drive phase, allowing greater acceleration of the boat and preventing raising the hull in the water. The legs should be in near complete extension before the initialization of trunk extension. A common error occurs if this does not happen which shows up as a double “hump” in the trunk velocity graph that otherwise has a unique peak for correct gestures. A similar trend can be observed in the generated force, causing a less efficient stroke [1]. In this work we hypothesized that this error could be detected using an inertial measurement unit (IMU) mounted on the athlete’s trunk (at C7 level). In particular, a machine learning based method to recognize incorrect gestures was proposed based on the analysis of angular velocity measurements.

### Methods

Experimental data was collected involving nine male able-bodied participants, experienced rowers (17±3 years). The participants were asked to perform two trials of 15 rowing strokes on an ergometer (> 32 strokes/min). The participants wore: *a*) motion capture markers to track seat, trunk (C7 vertebra) and right hand wrists motion, and *b*) one IMU mounted on the trunk over the C7 vertebra, according to the experimental protocol already described in [2]. Data was automatically labelled in terms of correct/incorrect strokes using motion capture data according to the method proposed by Kleshnev et al. [1]. Labelling was obtained as follows: 1) single strokes were segmented by detecting peaks in the wrist position data, 2) trunk and seat position data were processed with a smoothing spline (smoothing parameter of 0.9999) and then differentiated to obtain a velocity estimation, and finally 3) the first peak of seat and trunk velocity from each individual stroke was detected. Strokes were labeled as correct if the first peak of the seat velocity preceded the peak of the trunk velocity, and as incorrect if the contrary took place [1]. After labelling the sequences, classification features were extracted from the segmented angular velocity data. In a correct stroke, during the initial part of the drive phase (marked as thick in fig 1), velocity should increase linearly and monotonically, therefore Pearson and Spearman correlation with time of this segment were proposed as

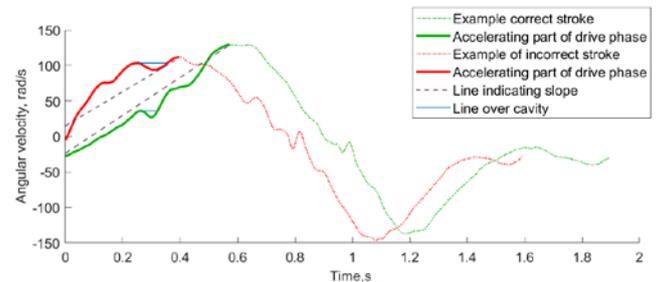

Figure 1: Two example strokes with features illustrated

discriminative features. In addition, the slope of the line between the start (median of the 10 first samples) and end (median of the 10 samples around the max) of this phase and the area of the main cavity in the graph (occurring if a non-monotonic behavior of the angular velocity was observed) were also proposed as features (fig. 1). Several machine learning models (Naïve Bayes, SVM, Random Forrest, and k-Nearest Neighbor) were compared, hyperparameters were selected through a grid search, and the models were cross validated by using Leave One Subject Out-Cross Validation (LOSO-CV). LOSO-CV was chosen since it allowed testing the inter-subject reliability of the method [3]. Processing was done using MatLab (vs2020a, The Mathworks, Natick, USA).

### Results and Discussion

In total 273 strokes were identified, 141 were labeled as correct and 132 as incorrect. The k-NN classifier showed, through LOSO-CV, a best accuracy of 79.5% in recognizing incorrect and correct strokes (80.9% sensitivity, 78% specificity, F<sub>1</sub> score 0.8). The use of LOSO-CV was crucial due to the relatively small number of participants. In future works, we plan to collect a larger pool of participants to increase the robustness of this preliminary, but promising system. Since the proposed solution only requires one gyroscope, it could be easily embedded in a smartphone, opening scenarios for a fully portable solution for sport practitioners.

### Acknowledgments

This study was funded by the Ministry of Defense under the WAVE project (Wearable Assistant for VEterans in sport).

# Change in Mechanical Properties of Cortical Bone under Voltage Application for Formation of Mineral Components

Fuki Ota, Kazuhiro Fujisaki, Keita Osanai, Kazuhiko Sasagawa, Takeshi Moriwaki  
 Graduate School of Science and Technology, Hirosaki University, Aomori, Japan  
 Email: h20ms503@hirosaki-u.ac.jp

## Summary

Mineral components relate to bone mechanical properties. We proposed a method to change the bone mineral configuration and mechanical properties by voltage application. In this study, hydroxyapatite formation of mineral components was confirmed in X-ray diffraction profiles. The change of bone elastic modulus in the voltage application process was obtained under bending test.

## Introduction

Bone mainly consists of type-1 collagen and minerals such as hydroxyapatite, and the mechanical properties of bone tissue depend on the alignment and amount of the mineral components. Shah et. al. showed that bending strength of bone samples decreased in demineralization process using ethylenediaminetetraacetic acid (EDTA) [1]. We previously observed apatite formation on titanium surface and on bone surface located at the cathode side of voltage application with direct current (DC) in synthetic apatite solution [2]. In this study, we attempt to control the formation of mineral components on bone tissue and to change the mechanical properties of the tissue by voltage application.

## Methods

Bone specimens cut out from the cortical region of a bovine femur were prepared to be 3×3 mm square area and more than 30 mm length for bending tests and wrapped by titanium wire used for electrode. Then, the specimens were immersed in phosphate buffered saline and respectively connected for both anode and cathode side of DC power supply. The specimens were applied constant voltage of 10 V for a day in 37°C. After that, they were observed by microscope and deposit on surface was analyzed with X-ray diffraction system. Finally, elastic modulus of the specimens was measured by 3-point bending test.

## Results and discussion

Mineral deposit appeared on the bone surface located at cathode side of the voltage application and the deposit had unique X-ray diffraction peaks that were (002), (211), (213) and (004) of hydroxyapatite, as shown in Figure 1. Figure 2 shows the elastic modulus change ( $\Delta E$ ) of each bone specimen located at cathode and anode sides, respectively. Here, EDTA samples were used to confirm the effect in the case of progressive demineralization. As a result, elastic modulus of the bone located cathode side decreased similar to EDTA and of the bone located anode side increased. The deposit having hydroxyapatite crystal structure was formed under the voltage application although the components of hydroxyapatite were not fully contained in the phosphate buffered saline. It was confirmed that the hydroxyapatite components transferred from bone samples located at anode

side to cathode side, thereby mineral formation and elastic modulus change were realized in this process.

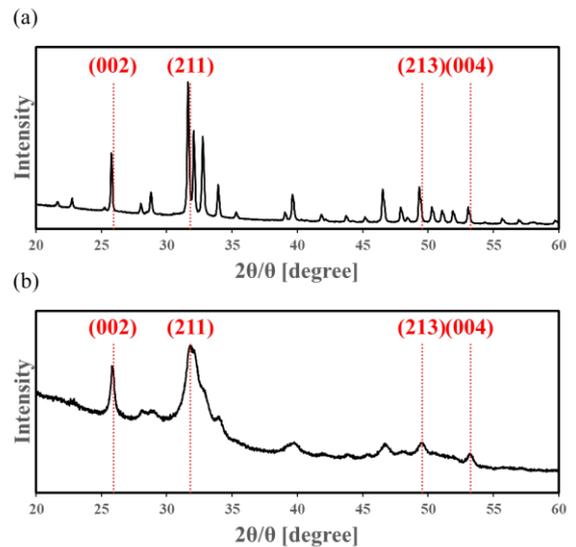

Figure 1: The X-ray diffraction pattern of (a)hydroxyapatite and (b)deposit.

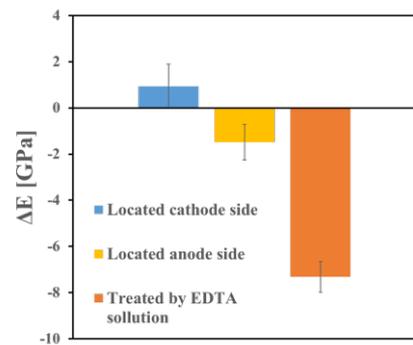

Figure 2: Comparison of elastic modulus change ( $\Delta E$ ).

## Conclusions

Mineral formation on the bone surface and the changes of elastic modulus of specimens were induced by voltage application. This method is available for improving bone mechanical properties.

## Influence of Excipients and Lesions on Drug-Coated Balloon Therapy

Karthic Anbalakan<sup>1</sup>, Toh Han Wei<sup>1,2</sup>, Ang Hui Ying<sup>1,2</sup>, Martin Lindsay Buist<sup>1</sup>, Leo Hwa Liang<sup>1</sup>

<sup>2</sup>National Heart Research Institute, Singapore

Email: [E0011515@u.nus.edu](mailto:E0011515@u.nus.edu)

### Summary

In this study, we evaluated the influence of different excipients on the efficacy of drug-coated balloon (DCB) therapy. We employed a previously established integrated model to quantify a variety of measures, associated with the treatment: tracking loss, vessel adhesion, drug release, uptake, and distribution. Moreover, we performed a parametric study to evaluate the potential influence different types of lesions would have on drug-coated balloon therapy. We found a strong correlation between the hydrophobicity of the excipient and its associated drug loss due to tracking and washout. In addition, we identified several key features of an atheroma that influences drug uptake and distribution.

### Introduction

Cardiovascular interventional therapies have seen marked improvements to their design and performance in the last decade. However, there is still much to be desired when it comes to our understanding of how different excipients and lesions influence the treatment's efficacy.

Correspondingly, in our study, we used an integrated approach to quantify the key differences between urea, a common hydrophilic excipient, and butyryl-trihexyl citrate (BTHC), a common hydrophobic excipient. Additionally, we performed a parametric study to evaluate how different lesions influence the efficacy of treatment.

### Methods

In this study, 60 percutaneous transluminal angioplasty balloon catheters were coated with sirolimus ( $3\mu\text{g}/\text{mm}^2$ ) and either urea or BTHC as the excipient. The tracking loss and vessel adhesion, associated with each excipient, was determined by navigating the samples through an in-vitro model adapted from the ASTM standard F2394-07 [1].

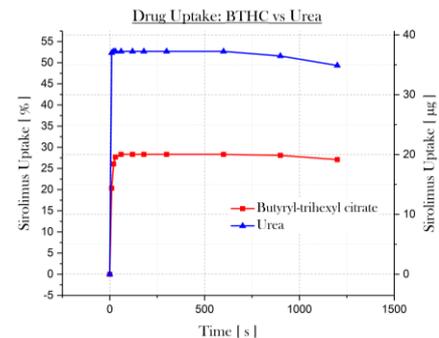

Additionally, the drug release profile was determined by inflating the balloons in citrated porcine blood, at sink conditions, at various time points. The residual amount of sirolimus was evaluated using high-pressure liquid chromatography (HPLC).

Subsequently, to determine the drug uptake, retention and distribution, a non-linear multi-layered diffusion advection reaction model was solved computationally using the FEniCS library [2]. This integrated approach is discussed in greater detail in our recent study [3].

### Results and Discussion

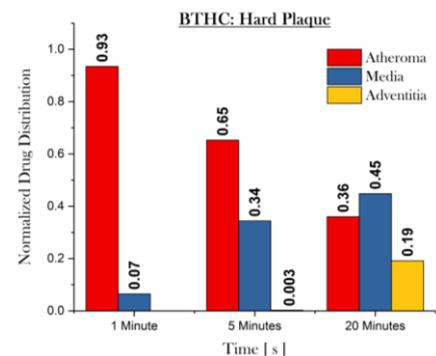

In this section, we summarize some of our key findings. Despite the significantly higher tracking loss (urea: 35.5% vs

BTHC: 8.13%) observed in the urea-based balloons, the drug uptake was almost two times greater than its hydrophobic counterpart: BTHC (Figure 1).

**Figure 1:** Sirolimus uptake over time observed with DCBs coated with different excipients: BTHC (red) against urea (blue)

Moreover, the distribution of drugs within the different layers of the tissue was found to vary most significantly between hard (Figure 2) and soft plaques.

**Figure 2:** Normalized sirolimus distribution within different layers of the vessel at three distinct time points post-DCB therapy.

### Conclusions

Ultimately, our results allude to a strong correlation between hydrophobicity of the excipients and tracking loss, which could potentially be a means of minimizing non-specific cytotoxic effects. Additionally, the porosity of the lesions and luminal calcification were found to be the chief contributors to drug distribution and uptake, respectively.

# PASSIVE ANKLE EXOSKELETONS INFLUENCE MUSCLE BEHAVIOUR DURING UNEXPECTED PERTURBATIONS

James L. Williamson<sup>1,2</sup>, Nicole Y. Kelp<sup>1</sup>, Glen A. Lichtwark<sup>2</sup>, Taylor J. M. Dick<sup>1</sup>

Email: [james.williamson@uq.net.au](mailto:james.williamson@uq.net.au)

## Summary

We present EMG and fascicle length data for the soleus (SOL) muscle during an unexpected drop task with and without passive ankle exoskeleton assistance. We find reduced SOL EMG and increased peak fascicle lengthening with exoskeleton assistance during unexpected perturbations. As passive exoskeleton devices move from the lab to the clinic – such important muscle level effects must be designed for.

## Introduction

The behaviour with which lower limbs store and return energy during steady gait has inspired the design of passive wearable devices to assist walking [1], running [2] and hopping [3]. However, we still lack an understanding of how devices influence movement and neuromuscular function in real world environments (i.e. an unexpected drop, uneven terrain, or variable walking speeds). This has limited our ability to design and implement wearable assistive technologies in real-life scenarios. The aim of this study is to determine the influence of passive ankle exoskeletons on neuromuscular control and muscle fascicle dynamics during unexpected vertical perturbations.

## Methods

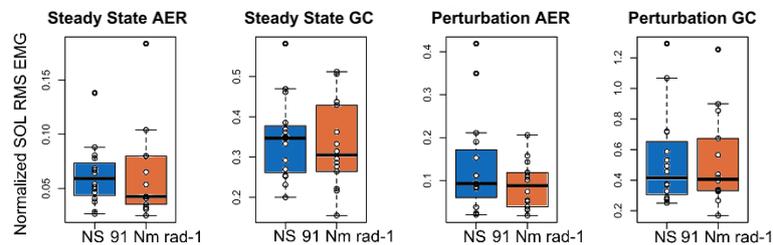

Fifteen participants (9M,6F, 23±3Y) completed an unexpected ‘falling-in-a-hole’ experimental paradigm. A vertical perturbation was elicited via the rapid removal of a ground platform (15cm) at an unknown time during hopping. B-mode ultrasound (125Hz, ArtUS, Teleded, Lithuania) was used to determine SOL fascicle length during the hopping perturbations with exoskeleton assistance (91 Nm rad<sup>-1</sup>) and without assistance.

Simultaneously, surface electromyography (sEMG) (2048Hz, Trigno EMG, Delsys Inc., USA) was used to measure muscle activity. sEMG signals were band-pass filtered (45-300Hz) and normalized to maximum jump trials. The RMS was calculated via a 20ms window over each ground contact (GC) and aerial (AER) hopping period for steady state hopping and the perturbation. Additionally, joint kinematics and kinetics were recorded using motion capture (100Hz, OptiTrack, USA) and bilateral force plates (2048Hz, Bertec, USA), respectively.

## Results and Discussion

### Exoskeletons Induce Altered Soleus Activation

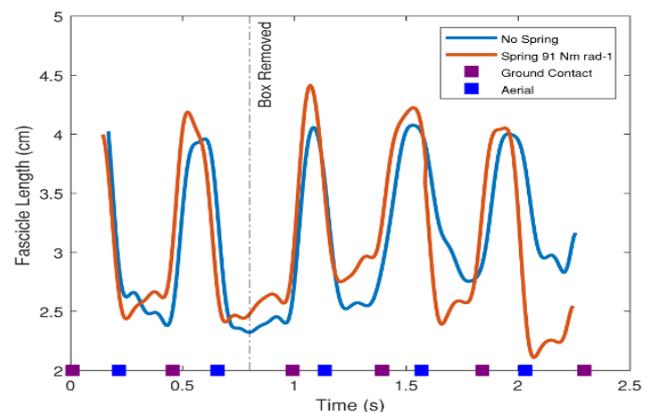

Consistent with previous studies [3], we found that SOL muscle activity decreased by 4.8±5.2% during the GC phase of steady state hopping with passive ankle exoskeleton assistance (Figure 1). During the unexpected perturbation, we found a 5.4±14.31% and 2.4%±8.84% reduction in SOL muscle activity during AER and GC phases, respectively.

**Figure 1:** Normalized SOL RMS EMG for GC and AER phases in both steady state hopping and the perturbation hop. Blue denotes the no spring case; orange denotes exoskeleton assistance.

### Exoskeletons Influence Soleus Fascicle Length Change

SOL fascicle length data from a subset of participants (N=4), showed that passive ankle exoskeletons use increased SOL fascicle lengths during both normal and perturbed hopping (Figure 2). Specifically, during steady state hopping, peak fascicle lengthening increased by ~8±3% with exoskeleton assistance compared to the no assistance case. During the perturbed hop, exoskeleton assistance increased peak SOL fascicle lengthening by ~9±5% more in comparison to the no assistance case.

**Figure 2:** Fascicle length data (N=1) for hops before, during and after the perturbation. The blue line denotes the no spring case; the orange denotes exoskeleton assistance. Average ground contact and aerial phases of the hopping cycle are marked by coloured squares.

## Conclusions

In summary we find reduced SOL EMG and increased peak fascicle lengthening with passive ankle exoskeleton assistance during unexpected vertical perturbations. However, further investigation is required to determine if these alterations impact capacity to respond to larger perturbations.

## Does a prosthetic toe joint affect mechanics or preference when persons with limb loss walk over uneven terrain?

Kirsty A. McDonald<sup>1</sup>, Rachel H. Teater<sup>2</sup>, Karl E. Zelik<sup>2</sup>

<sup>1</sup>School of Medical Sciences, University of New South Wales, Sydney, Australia

<sup>2</sup>School of Engineering, Vanderbilt University, Nashville, USA

Email: kirsty.mcdonald@unsw.edu.au

### Summary

Lower limb prosthesis users have previously indicated a preference for a compliant prosthetic forefoot region during uneven terrain locomotion. This feature likely attenuates the destabilizing effect of the surface and thus, may also reduce the mechanical work requirements of the remaining biological lower limb joints. Here, we added a Flexible toe joint to a passive prosthesis and found that 5 of 9 participants preferred this Flexible toe to a Locked out joint (i.e., rigid foot keel). Positive prosthesis work (which predominantly occurs during Push-off) decreased with a Flexible joint, but so did prosthetic and intact limb positive hip work. Despite producing more positive prosthesis work, the Locked toe configuration was associated with greater positive hip work from both limbs, possibly required to enhance locomotor stability in the absence of compliance at the toe or forefoot.

### Introduction

The challenges of walking over uneven terrain are exacerbated for people with lower limb loss [1]. Prosthetic device design modifications may improve user outcomes, e.g., prosthesis users (PUs) have been noted to prefer a more compliant forefoot region on uneven terrain [2], potentially because the compliance counteracts the destabilizing effects of the surface [3]. Thus, it is conceivable that mechanical work contributions of the remaining joints could decrease in response to the enhanced stability offered by a compliant forefoot on uneven terrain. Adding an articulating toe joint is a way to facilitate compliance of the keel in response to surface irregularities. Our group recently developed a prosthetic foot capable of switching between a Flexible (articulating) toe joint, and a Locked toe configuration [4]. We used this device to assess the effect of the two configurations on subjective preference and joint/prosthesis work when below-knee PUs walked over uneven terrain.

### Methods

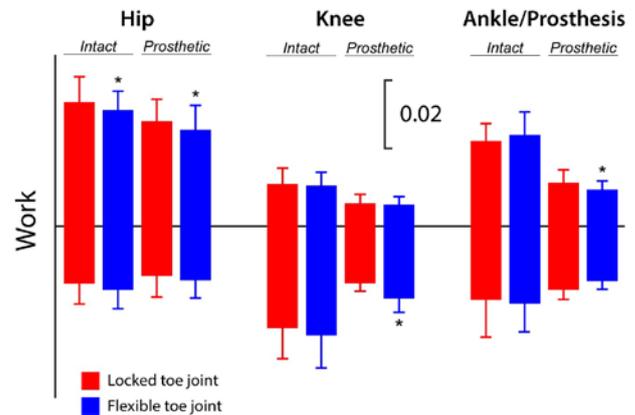

Active, below-knee PUs ( $N=9$ ) participated. As detailed in McDonald et al. [4], participants completed a series of locomotor tasks using an experimental prosthesis configured with a Flexible and a Locked toe joint. During training and testing sessions, participants walked over a continuous series of 10 uneven terrain platforms. Each platform consisted of 24 plywood and foam blocks of varying heights relative to the ground (16, 46 and 58 mm).

Participant preference was recorded. For biomechanical analyses, participants were required to traverse the walkway at a velocity of  $1 \text{ m s}^{-1}$ . A minimum of five strides per limb of 3D motion capture data (Vicon) and synchronized ground reaction forces (AMTI) were collected. T-tests were applied

with an alpha level of 0.05 to compare gait mechanics for the Flexible vs. Locked toe joint.

### Results and Discussion

Five participants preferred the Flexible configuration and four preferred the Locked configuration for walking over uneven terrain. Consistent with level walking, positive prosthesis work decreased for the Flexible toe configuration [4] (Fig. 1). However, positive hip work for both limbs also decreased. This is surprising because the positive prosthesis work occurs mostly during Push-off and therefore an increase in positive ipsilateral hip power in early stance is one method to overcome this reduction. Perhaps such a strategy did occur but was over-shadowed by inflated positive hip contributions in the Locked configuration that were required to offset the surface-level disturbances resulting from the non-compliant keel. Further research is required to explore or confirm.

**Figure 1:** Intact and prosthetic side joint/prosthesis positive and negative work during a walking stride. ( $N=8$  due to attrition).

### Conclusions

A Flexible prosthetic toe joint may serve as a useful design feature or option for PUs on uneven terrain. Slightly over half the participants preferred the Flexible toe joint over a Locked toe, and the hip work of both limbs was reduced when walking with the Flexible toe joint.

## Production of Micro-Structured Hollow Fiber Membranes for Membrane Oxygenators – Mimicking Nature to Increase Mass Transport

Markus Pekovits<sup>1,2</sup>, Paul Ecker<sup>1,2</sup>, Benjamin Lukitsch<sup>1</sup>, Bahram Haddadi<sup>1</sup>, Matthias Golda<sup>1,2</sup>, Michael Harasek<sup>1</sup>, Margit Gfoehler<sup>2</sup>

<sup>2</sup> Institute of Engineering Design and Product Development, TU Wien, Vienna, Austria

Email: markus.pekovits@tuwien.ac.at

### Summary

Microstructuring of hollow fiber membranes is a means to increase the gas exchange surface area of oxygenators, thereby increasing mass transport and making it more efficient. In this work, a method for fabricating micro-structured fibers is presented, process parameters are discussed, and feasibility in the size range of currently commercially available membranes is investigated.

### Introduction

Modern extracorporeal membrane oxygenation (ECMO) devices use gas-permeable cylindrical polymeric hollow fiber membranes that act as a barrier between the blood and the gas phase. Although approximately 2 m<sup>2</sup> of these membranes are used to achieve the required gas transfer rates to best support the weakened human lung in its function, the efficiency of lung support devices is still subject to limiting factors [1]. The cylindrical hollow fiber membrane bundles cannot accurately replicate the small physical structures in the human lung, resulting in an increase in mass transfer resistance [1].

Micro-notches in fish gills not only increase the respiratory surface area but also lead to transverse flows, resulting in a decreased mass transfer resistance [2]. Initial CFD analyses of micro-structured membrane surfaces confirmed a significant increase in mass transfer rate with no evidence of increased risk of blood damage [3].

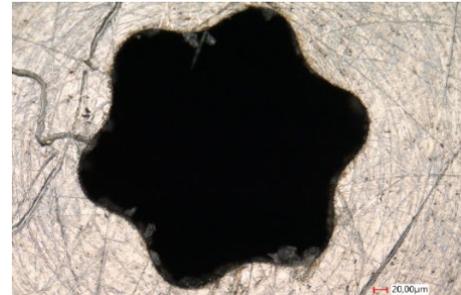

In this work the production of micro-structured hollow fiber membranes via the non-solvent induced phase separation (NIPS) technique is presented.

### Methods

A membrane spinning system based on the NIPS fabrication process, designed by our institutes at TU Wien, was used to spin the hollow fiber membranes patterned on the outer surface in combination with a sinusoidally designed spinneret (Figure 1). The developed membrane spinning system allowed to vary the process parameters which are crucial for the NIPS manufacturing process. This ensured that the morphological and geometrical structure and consequently the gas separation properties of the membrane could be influenced. The polymer used was a 31 wt.% polyethersulfone (PES) + *N*-Methyl-2-pyrrolidone (NMP) mixture.

Scanning electron microscope (SEM) images provided a first impression about the geometrical properties of the hollow fiber membranes. In order to quantify the increase in separation performance of the patterned fiber, bundles of fibers are assembled into modules and compared with

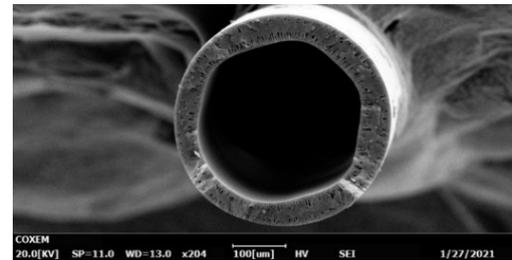

modules prepared from cylindrical fibers with respect to their gas permeance properties.

**Figure 1:** Sinusoidal outer shape of the spinneret ( $OD = 400 \mu\text{m} + 50 \mu\text{m} * \sin(6\phi)$ )

### Results and Discussion

The SEM images of the first spun fibers (Figure 2) show a centrally and circumferentially closed hollow fiber without holes in the membrane wall, whose lumen as well as outer wall are circular in shape. The double finger pore structure typical for the NIPS manufacturing process is present.

**Figure 2:** SEM picture of the preliminary spun PES hollow fiber membrane. OD and ID circularly shaped.

### Conclusions

The production of polymeric hollow fiber membranes in ranges of a few hundred micrometers is possible with our NIPS based spinning plant. Geometry optimization and comparison of gas permeances require further spinning tests and parameter settings.

# Estimation and Assessment of Sagittal Spinal Curvature and Thoracic Muscle Morphometry in Different Postures

Anoosha Pai S<sup>1</sup>, Honglin Zhang<sup>2</sup>, Nima Ashjaee<sup>1</sup>, Thomas R. Oxland<sup>2</sup>,

Email: toxland@icord.org

## Summary

Spine models are typically developed from supine imaging data, and hence do not fully replicate postures of subjects' clinical symptoms. A pipeline to estimate subject-specific sagittal spinal geometry in different postures (supine, flexion and sitting) from data (vertebral body center positions) in a reference posture (standing) was developed and validated. Dominant line-of-actions for two paraspinal muscles (erector spinae and transversospinalis) were computed in those postures. A correction factor (cosine between the MRI axial scan plane and fiber line-of-action) was computed and applied to the muscle parameters (CSA and moment-arm) computed from MR imaging. Overall, this work contributes to the growing literature of spine geometry and is a preliminary step in clinically relevant subject-specific modeling.

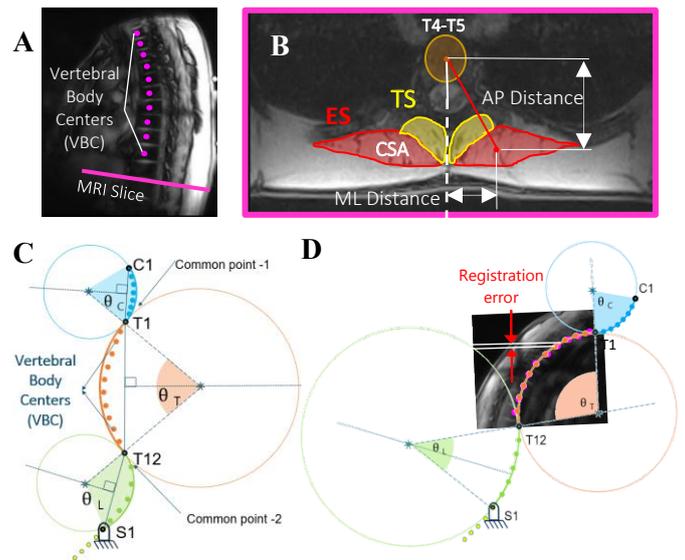

## Introduction

Clinical imaging for spinal deformity typically consists of a standing x-ray of the whole spine and a supine MRI of only the pathological spinal levels. This does offer coherent data for the development of subject-specific, biomechanical spine models that reflect actual clinical symptoms. Additionally, muscle parameters measured from MRI are not perpendicular to the scan slices and must be corrected to be appropriately used in models. Objectives: 1) To develop and validate a method for estimating of subject-specific sagittal spinal geometry in different postures from vertebral body center (VBC) data in a reference posture (standing). 2) To correct for the cosine between the MRI axial scan plane and dominant fiber line-of-action for muscle parameters (CSA and moment-arms) in these postures.

## Methods

Thoracic Spines of six healthy participants (age 26±6 y, BMI 24±3 kg/m<sup>2</sup>) were imaged (0.5T Open Upright MR scanner) in four postures (supine, standing, flexion, and sitting). VBCs from T1 to T10 were marked on sagittal MR images (Figure 1A). Muscle parameters, CSA, anterior-posterior (A-P) and medial-lateral (M-L) were computed for two muscles—erector spinae and transversospinalis on axial MR images (Figure. 1B). Sagittal spinal curvature was approximated using a circular spline parameterized with the segment angles (kyphosis or lordosis Cobb angle) and segment lengths (Figure 1C). The subject-spine geometry in any other posture was estimated by modification of these parameters and normalization with the reference posture. The estimated spine geometry was validated against the corresponding thoracic MRI data by rigid registration (Figure. 1D). The dominant muscle fiber line-of-action of erector spinae and

transversospinalis was computed for each posture. A correction factor based on published literature was then computed and applied to the muscle parameters [1].

**Figure 1:** A) Sagittal MR image. B) CSA, A-P and M-L distances of erector spinae (ES) and transversospinalis (TS) on Axial MR image. C) Geometric construct of sagittal spinal curvature (standing). D) Estimated spine geometry (flexion) rigidly registered to ground truth data (MRI in flexion) showing registration error.

## Results and Discussion

The maximum registration error between the estimated spine geometry and MRI data was small (average RMSE~1.2%). The correction factor reduced muscle parameters (~5% for erector spinae and ~25% for transversospinalis) when compared to raw, uncorrected MRI data. Compared to all existing methods for quantitative evaluation of sagittal spinal geometry [2], our method is simple, reliable, computationally inexpensive and easily digitizable for clinical images. Another novelty of this work is reporting trunk muscle properties for postures other than supine. Overall, our data contributes to the growing literature of trunk geometry evaluation and is preliminary step in clinically relevant subject-specific modelling.

## How does the prosthetic design affect muscle strength after knee arthroplasty surgery?

Iris Mittendorfer<sup>1</sup>, Igor Komnik<sup>2</sup>, Steffen Willwacher<sup>3</sup>, Björn Michel<sup>1</sup>, Judith Bleuel<sup>1</sup>

<sup>1</sup>Institute of Motion Analysis and Sports Medicine, Garmisch-Partenkirchen Medical Center, Garmisch-Partenkirchen, Germany

<sup>3</sup>Department of Mechanical and Process Engineering, Offenburg University of Applied Sciences, Offenburg, Germany

Email: iris.mittendorfer@klinikum-gap.de

### Summary

Muscle strength condition after knee arthroplasty (KA) is crucial for returning to an active lifestyle. We showed that 5-14 months after surgery the hamstrings to quadriceps (HQ) ratio was significantly different between patients with total knee arthroplasty (TKA) and unicompartmental knee arthroplasty (UKA). When creating rehabilitation or training plans, therapists and patients should consider that muscle adaptations after KA differ between prosthetic designs.

### Introduction

The number of KA, especially the UKA, increased significantly in the last 5 years in Germany [1], because of better function and higher patient satisfaction [2]. The muscular status of the knee surrounding muscles is one of the main factors for joint control after knee arthroplasty. It influences knee joint motion and loading. Different prosthetic designs aim to address the different anatomical and mechanical conditions of the arthritic joint. For instance, UKA only replaces one compartment of the knee and cruciate ligaments are preserved, while TKA replaces all articular surfaces at the knee [3]. The current data of recommendation after KA is mainly based on experts' expertise. Since return to sport with knee arthroplasty becomes increasingly important, we need a deeper understanding and scientific data of functional and biomechanical parameters of patients with UKA or TKA. The first specific aim of the study was therefore, to investigate if the muscle strength of the knee flexors and extensors 5-14 month after surgery is different in patients with UKA and TKA.

### Methods

TKA and UKA patients conducted tests of concentric and eccentric isokinetic muscle strength (Isomed2000, D. & R. Ferstl GmbH, Hemau, Germany) of the knee flexors and extensors at two angular velocities (50°/sec, 120°/sec) 5-14 months after surgery. Additionally, participants reported their perceived pain (Visual analog scale) during the measurements and their functional impairments in the daily life using the WOMAC questionnaire.

### Results and Discussion

Relative maximal muscle strength (maximal torque per body weight, MAX<sub>rel</sub>) was similar in TKA (n=19) and UKA (n=12) for both muscle groups under all testing conditions.

However, HQ ratio in the operated limb was lower in UKA in concentric (TKA 86,81 ± 21,84; UKA 66,28 ± 16,13, p < 0,01) and eccentric (TKA 79,98 ± 22, 78; UKA 60,33 ± 21,47; p < 0,05) condition at 50°/sec, indicating a more pronounced quadriceps weakness in relation to the hamstrings muscles in TKA.

Eccentric quadriceps MAX<sub>rel</sub> correlated with time post-op, showing higher torque values with more time after surgery. This was only quantifiable in TKA, but not in UKA. Similarly, multiple parameters of muscle strength (concentric hamstrings MAX<sub>rel</sub> at 50 & 120°/sec, concentric quadriceps MAX<sub>rel</sub> at 50°/sec, eccentric hamstrings MAX<sub>rel</sub> at 50°/sec) correlated with the total WOMAC score or subscales only in TKA. Here, strength was lower with higher scores, representing worse pain, stiffness, and functional limitations (p < 0,05).

### Conclusions

Although, patients with UKA and TKA have similar maximal strength (Nm/kg) in quadriceps and hamstrings muscles 5-14 months after KA, UKA patients show a more physiological muscular balance (closer to standard values) between agonist and antagonist. This may relate to a less invasive surgical approach, a better biomechanical performance of the prosthesis and a smaller preoperative damage in UKA. It indicates that factors like quadriceps weakness and proprioceptive impairment may be more present in TKA. This, in turn, can cause negative effects on gait patterns.

In an ongoing study, we are evaluating the effects of a specific training intervention on the deficits in muscle strength observed here in TKA and UKA patients. Furthermore, we are conducting kinematic analysis, to examine to what extent these muscular changes affect knee joint angles during different walking tasks in field.

## Ambulatory knee mechanics after ACL repair with InternalBrace™ augmentation compared to healthy controls

### Summary

In recent years, repair of the anterior cruciate ligament (ACL) with InternalBrace™ has been increasingly used to treat patients after ACL rupture. We provide first evidence of only little side-to-side differences in knee biomechanics during walking in patients 2 years after surgery and brief differences at the beginning of stance in ground reaction force and in tibia translation but not in knee kinetics in the operated leg compared to age-matched knee healthy controls.

### Introduction

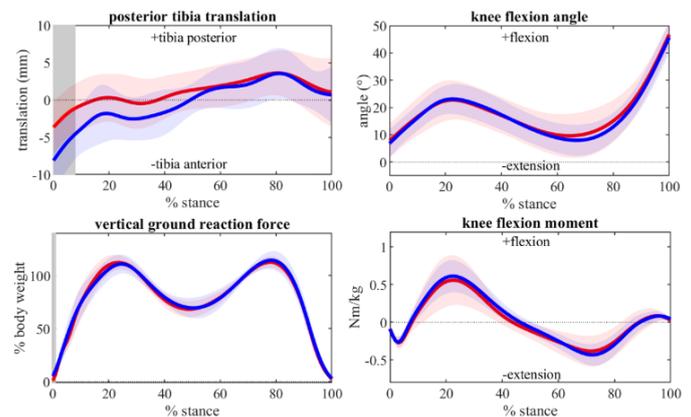

While clinical outcome and patient satisfaction after repair of the anterior cruciate ligament with augmentation have been investigated and compared to patients after ACL reconstruction, information or comparative studies on knee function recovery in dynamic tasks are scarce [1,2]. We compared knee ambulatory biomechanics of patients 2 years after unilateral primary proximal ACL repair with InternalBrace™ (Arthrex, USA) with knee healthy subjects.

### Methods

In 16 adult patients (6m/10f; 35.9±10.7 years; BMI 24.4±4.0 kg/m<sup>2</sup>; 25±2 months postoperatively) and 16 healthy control subjects (6m/10f; 36.0±11.1 years; BMI 22.6±3.9 kg/m<sup>2</sup>) bilateral 3D knee kinematics and kinetics during walking (stance phase) were measured with the Point Cluster Technique [3]. Differences in patients' operated leg compared with their healthy contralateral leg and with controls (non-dominant leg) were analyzed using statistical parametric mapping (t-tests, P<.05).

### Results and Discussion

Patients had lower lateral ground reaction force (GRF) in the operated than the contralateral leg between 5-7% of stance phase (SP) (P=.037; max. difference: -1.0% body weight (BW)). Compared to controls, the patients' knees had significantly more valgus (P=.021, max. difference: 3.8°) between 11-32%SP and a more posterior tibia position at the beginning of stance (0-8%SP; P=.038; max. difference: 2.7mm; Figure 1). At heel strike, patients exhibited lower anterior (P=.049; difference: -1.4%BW) and vertical (P=.048; difference: -4.3%BW; Figure 1) GRF followed by shortly lower lateral (0-3%SP; P=.031, max. difference: -1.5%BW) and greater anterior (2-3%SP; P=.044, max. difference: 2.4%BW) GRF than controls.

**Figure 1:** Mean values (solid line) and standard deviations (shaded color) of the operated leg in patients (red) and the non-dominant leg in controls (blue). The grey shaded area indicates significant differences.

### Conclusions

Overall, interlimb comparison in patients' knee kinematics and kinetics demonstrated neither a systematic asymmetry nor a stiffer gait strategy and – in contrast to results after ACL reconstruction [4,5] – no offset in knee rotation. Differences in GRF and less anterior tibia position after heel strike compared to controls indicate a compensatory mechanism possibly to lower the load on the repaired ACL.

The patients' compensation strategy might be successful in achieving normal knee biomechanics during weight bearing. These promising results should be further explored by investigating the ankle and hip joints, (pre-) activation of relevant leg muscles, and the role of proprioception and muscle strength in more demanding activities and in comparison to patients after ACL reconstruction.

## Trunk kinematica during walking in adults receiving total knee arthroplasty: a systematic review

T. Van Criekinge<sup>1</sup>, K. Claeys<sup>1</sup>

<sup>1</sup> Department of Rehabilitation Sciences, KU Leuven Campus Bruges, Bruges, Belgium

Email: [Tamaya.vancriekinge@kuleuven.be](mailto:Tamaya.vancriekinge@kuleuven.be)

### Summary

Since trunk control seems to be an important contributor in the recovery process after total knee arthroplasty (TKA), increasing our understanding on trunk motion could aid in setting accurate rehabilitation goals and treatment strategies to enhance mobility outcomes. A literature review was performed, including 21 studies of which 11 examined trunk movements during walking. Pre-operative trunk kinematics were characterized by increased movement amplitudes in all three planes. Although amplitudes decreased post-TKA, they still differed from healthy controls. Recovery was time-, speed- and technique-dependent as mediolateral amplitude reductions proceeded anteroposterior improvements and better outcomes were observed when assessing at comfortable walking speed and when using minimal invasive techniques.

### Introduction

Excessive trunk flexion has been related to a greater fall risk, while increased later trunk motion result in higher energy expenditures during walking in older adults.[1,2] Furthermore, it has been shown that enhanced trunk control improves mobility, balance and quality of life early after TKA. [3,4] As a result trunk control seems to be an important contributor to recovery after TKA. However, little is known about trunk motion in adults receiving TKA. By reviewing the available literature, we can increase our understanding on trunk deviations related to TKA, how they are altered due to surgery and which surgical technique is superior in the recovery process. This can aid in setting accurate rehabilitation goals and treatment strategies for improving mobility outcomes after TKA.

### Methods

Five scientific databases were searched until October 2020 (Pubmed, WOS, Cochrane Central, Sportsdiscus, and Science Direct). Eligibility criteria consisted of outcomes assessing trunk motion in a population of adults undergoing TKA. Two reviewers independently screened studies and risk of bias was assessed by the Mixed Methods Appraisal Tool (MMAT).

### Results and Discussion

Of the 341 studies retrieved from all databases, 21 studies were included (3 RCT and 18 cohorts). The cohort studies compared pre-post treatments (n=8 studies), case-control (n=11) and case-case (n=4). Mean MMAT score was 73%, which corresponds to an overall low score of risk of bias for the majority of studies.

In total 667 patients received TKA after OA and

were compared to 197 controls. The mean age of the participants in the TKA group was 70 years (range 58-76) and 69 years (range 55-76) in the control group. Time post-surgery varied from 68 days to 8 years. Eleven studies assessed trunk motion during walking or the relationship between trunk control and mobility. It was concluded that pre-operative trunk kinematics were characterized by increased three-dimensional movement amplitudes. After TKA, regardless of the technique, decreased movement amplitudes were observed but not all returned to normal, as compared to healthy adults. Minimal invasive TKA surgery lead to faster recovery by resulting in greater decreases in trunk movement amplitudes during walking within the first 3 months post-surgery, and afterwards these differences disappear when comparing to conventional methods. Recovery of trunk variability, on the other hand, seems to be both speed- and time-dependent in the frontal and transversal plane resulting in better outcomes when assessing at a normal comfortable walking speed (1.2 m/s) and leading to decreased variability with increasing time post-surgery, especially for TKA using computer-assisted navigation.

### Conclusion

Excessive trunk motion amplitudes, as seen pre-operatively, decreased after TKA. Truncal recovery seemed to be time-, speed- and technique-dependent. Suggesting that post-surgery rehabilitation might influence sagittal kinematics more than the surgery itself, assessment should be executed at comfortable walking speed and minimal invasive techniques result in faster recovery. However, differences with healthy adults did remain after TKA which could indicate that current rehabilitation approaches are not yet optimal to return the walking pattern to normal standards. Incorporating a full biomechanical chain approach, including trunk exercises, could lead to better results after TKA as seen in other knee pathologies.[5] Future research should focus on the relationship between trunk control and post-surgery outcomes after knee arthroplasty.

## Do bone defects of the greater trochanter affect the postoperative femoral fracture risk after total hip arthroplasty? A biomechanical study.

Email: michael.saemann@med.uni-rostock.de

### Summary

Bone defects can lead to substantially impaired musculoskeletal biomechanics. A common reason for bone defects of the greater trochanter are intraoperative periprosthetic femoral fractures (PFF), which are a severe complication during total hip arthroplasty (THA) using uncemented hip stems. The intraoperative PFF of the greater trochanter (Vancouver classification A<sub>G</sub>) is often treated with cerclage wire fixation or suturing and can result in a trochanteric bone defect. In our biomechanical study we analyzed, whether this bone defect affects the overall postoperative fracture risk of the femur equipped with an uncemented straight hip stem. We experimentally tested three cadaveric femurs without trochanteric defect and one fractured femur with a completely missing greater trochanter in a standing load case. Additionally, we conducted a corresponding Finite Element Analysis (FEA) of the three femurs with and without bone defect. Our preliminary results show that a defect of the greater trochanter did not significantly affect the postoperative fracture risk during standing or stumbling. Further research with a higher sample size is required.

### Introduction

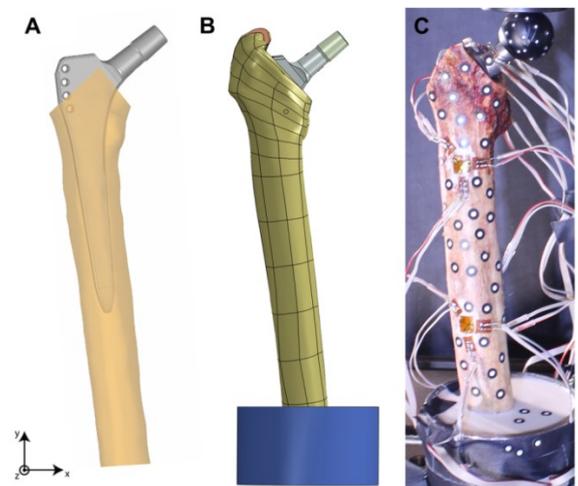

The intraoperative PFF of the greater trochanter (A<sub>G</sub>) makes up for around 25 % of all intraoperative PFF during primary THA and is often treated only with cerclage wires or sutures and in around 16 % of the cases no treatment was given [1]. Therefore, A<sub>G</sub> fractures resemble a common bone defect. Since intraoperative PFF are difficult to reproduce experimentally and an A<sub>G</sub> fracture occurred during our cadaveric trials, we used this femur to analyze the influence on the postoperative fracture risk after total hip arthroplasty.

### Methods

Experimental testing was conducted on three cadaveric human left unfractured femurs and one right fractured femur with trochanteric bone defect, each implanted with an uncemented straight hip stem. The femurs were distally embedded and axially loaded on the implant ball head to reproduce a standing or stumbling load scenario. The fracture load, load-displacement curves and stiffness at 1 mm axial displacement were compared. A FEA reproducing the experimental load scenario was conducted to compare the three left femurs without defect and with an artificially added A<sub>G</sub> fracture as defect. The approaches described by Kluess et al. [2] and Miles et al. [3] were used as basis for model generation and physical modeling, respectively.

### Results and Discussion

Experimentally and computationally, no significant differences between femurs with and without trochanteric defect could be shown. Nevertheless, the experimentally measured stiffness of the femur with defect was the lowest of the specimens, which, however, did not result in the lowest fracture load. Computationally, each femur showed a decrease in fracture load and stiffness with a trochanteric defect, although these were not significantly lower.

**Figure 1:** (A) Virtual positioning of the straight hip stem and added artificial A<sub>G</sub> fracture as defect, (B) FE model of an unfractured femur, (C) experimental setup of the one femur with defect and added marker points for displacement measurement and strain gauges at representative locations.

### Conclusions

From a biomechanical perspective it seems that a defect of the greater trochanter does not significantly affect the overall postoperative femoral fracture risk in a stumbling or standing load scenario, but further research with a higher sample size is necessary for confirmation.

## Pose and Shape Registration of Ankle Complex using Statistical Shape and Intensity Model

Jeongseok Oh<sup>1</sup>, Seungbum Koo<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea  
Email: skoo@kaist.ac.kr

### Summary

Accurate measurement of joint kinematics can help understand the pathomechanics of joint injuries. Recent development of bi-planar fluoroscopic imaging allows direct measurement of skeletal images but obtaining quantitative joint movements are laborious because of difficulties in the image processing and bone-to-image registration. We developed a method to find pose and shape of skeletons in the foot without patient's own bone geometry by using a statistical shape and intensity model (SSIM) and a digitally reconstructed radiograph specific to the SSIM. The accuracies in predicting three-dimensional pose were evaluated for the tibia, talus and calcaneus.

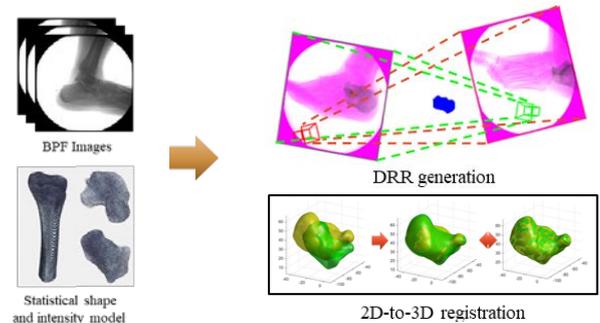

### Introduction

Bi-planar fluoroscopic (BPF) image analysis is one of the methods to measure the position and posture of a joint accurately. It is utilized to study joint kinematics in vivo without human invasion. The accurate 2D-to-3D registration was able to find the 6 degree-of-freedom (DOF) parameter with error of less than 1mm and 1° for the long bones such as tibia or femur [1]. However, registration of the bones consisting ankle complex is still challenging compared to the long bones due to overlapping between neighboring bones and the bones appearing smaller on the images. It is also a common way to prepare a bone model before the 2D-to-3D registration, and to find the bone models, obtaining computed tomography (CT) should be preceded. The objective of this study was to develop a CT-less 6-DOF bone pose estimation method through the 2D-to-3D registration. A statistical model is used to find the shape without this process. A DRR is required to directly compare with BPF images without post-processing, such as feature extraction, and the SSIM is used.

### Methods

The experiment was approved by the institutional review board and conducted by recruiting 18 healthy subjects with no abnormalities in walking. Bi-planar X-ray fluoroscopic images of the ankle were obtained. The positions of the two pairs of X-ray sources and image planes were obtained using a calibration phantom. Fluoroscopic images were taken at 60 fps and for about 2 seconds for each subject. The resolution of the images was 1024×1024. The ankle CT images were obtained and bone geometries were extracted to create a bone shape and intensity database to create a statistical model. The bone models were aligned, and the layers inside the volume were generated. The SPHARM-PDM [2] algorithm was used to find the corresponding points on the bone layers. The mean model and principal component (PC) were calculated using the principal component analysis. The

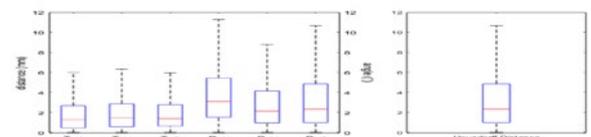

optimization proceeds by matching 6-DOF pose parameters and 10 PCs of shape parameters for each frame. The results of optimizations were compared with manually processed results.

**Figure 1:** Registration process using SSIM and BPF images

### Results and Discussion

The mean translation errors along the x-, y-, and z-axes were 1.35, 1.64, and 1.04 (mm), respectively. The mean rotational errors along the x-, y-, and z-axes were 3.31, 2.08, and 2.28 (°), respectively (Figure 1). The median Hausdorff distance of the registered model is 2.23 mm. The quality of registration is similar to the study using CT images to use the bone models [3], even the ground truth bone shape was estimated simultaneously.

**Figure 2:** Translational and rotational registration error

### Conclusions

The registration method using SSIM of bones that make up the ankle complex was developed, which shows an error of 1 -2 millimeters. We suggest that the procedures would be utilized for clinical applications and conducting studies comparing patients with foot disorders.

Kieran.Bennett@adelaide.edu.au

### Summary

In this preliminary study, we aim to use micro-CT analysis to determine the internal microstructural deformation of three tibial plateaus under physiological loading applied through their matching femur. Three cadaveric knees were scanned at 46  $\mu\text{m}$  isotropic pixel size under a representative physiological load representing peak loading during stance, reconstructed, and co-registered, with the aim to determine the deformation of the articular surfaces while under load. From these images, the internal deformations can be elucidated using digital volume correlation and used to validate computational models.

### Introduction

Micro-CT images of unloaded and loaded bones of entire articular surfaces, rather than excised biopsies, allows for investigation of the internal mechanics of bone and characterization of the responses of bone to external load [1, 2]. The aim of this study was to visualize bone the proximal tibia bone microstructure while under an inferior-superior load, using micro-CT imaging.

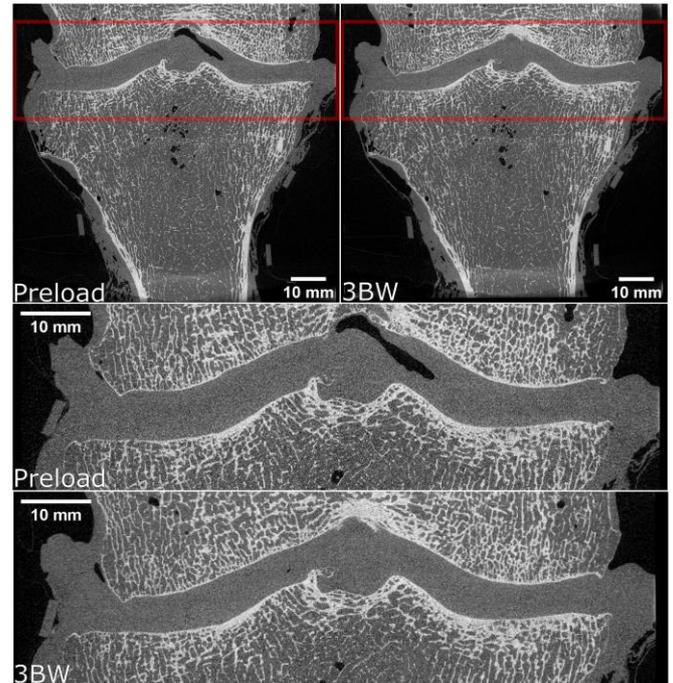

### Methods

Cadaveric knee specimens (N=3) were obtained. All soft tissues except for the articular cartilage and meniscus were removed. The patella was also removed. The bones were potted and mounted within the loading stage wrapped in saline soaked paper. A custom-made loading stage developed earlier [3] was modified, to adjust the loading direction. The loading rig containing the specimen was positioned within a large-volume micro-CT scanner (Nikon XT H 225, Nikon Metrology, UK). Scans were performed in unloaded and then in loaded conditions, with the proximal tibia and the distal femur contained in the field of view (86 x 86 mm, width x height). Axial loads equivalent to three bodyweights were applied to each specimen, based on the donor's mass at time of death. Load was measured using a six degree-of-freedom load cell. Scans were acquired at 46  $\mu\text{m}$  isotropic pixel size at a 0.18° rotation step over 360°. The time to take a single scan was 66 minutes. Cross-section images were reconstructed using CTPro3D software (Nikon Metrology) and saved as grey level images. The loaded dataset was then co-registered DataViewer software (Bruker) to the unloaded and examined.

### Results and Discussion

Three bodyweights of load was applied by displacing the femur vertically (1096-1563 N), with the angle of the femur altered to obtain a 60:40 medial:lateral loading ratio. Micro-

CT images (Figure 1) show the proximal tibial plateau in both preload and three bodyweight (3BW) loading conditions, with the joint space narrowing as the femur moves in the inferior direction. From this, the deformation of the articular surface will be evaluated.

**Figure 1:** Micro-CT scan reconstructions (coronal) of one human tibial plateau under preload and 3BW load conditions. The highlighted regions (red) of the joint are below.

### Conclusions

In this preliminary work, unloaded and loaded micro-CT scans of three human tibial plateaus were obtained. These data can be used to determine microstructural displacement due to joint loading within the tibial plateau. Future work will conduct digital volume correlation analysis to determine the internal deformations and strains. This will be used to inform computational models of bone mechanics.

## Can synchrotron phase contrast micro-tomography uncover how *in vivo* loading affects the Achilles tendon structure?

M. Pierantoni<sup>1</sup>, I. Silva Barreto<sup>1</sup>, M. Hammerman<sup>1,2</sup>, E. Törnquist<sup>1</sup>, V. Novak<sup>3</sup>, P. Eliasson<sup>2</sup>, H. Isaksson<sup>1</sup>

<sup>3</sup> Paul Scherrer Institute, Switzerland;

Email: [maria.pierantoni@bme.lth.se](mailto:maria.pierantoni@bme.lth.se)

### Summary

Achilles tendons are mechanoresponsive and actively adapt to their mechanical environment. Yet little is known about tendon microstructural response to loading. Here we use synchrotron phase contrast micro-tomography (SR-PhC- $\mu$ CT) to visualize the microstructure and to determine the effect of *in vivo* mechanical (un)loading on rat Achilles tendons.

### Introduction

Many studies consider the Achilles tendon as one homogenous tissue structure. Thus, less is known about tendons at the meso/microscale. Mechanical loading is believed to increase fiber orientation and packing density [1]. However, further investigation of the mechanobiological effects on the microstructure and mechanical properties is essential. Synchrotron X-ray tomography is a non-destructive method for 3D sub-micrometer visualization and quantitative analysis. In conventional X-ray tomography the contrast is given by the ability of the materials to absorb X-rays and imaging of soft biological materials is very challenging. Phase-contrast imaging was developed to image materials that weakly absorb X-rays, thus providing detailed visualization of soft tissues [2]. Our aim is to use SR-PhC- $\mu$ CT to investigate rat Achilles tendons to elucidate how different regimes of *in vivo* loading affect the microstructural properties.

### Methods

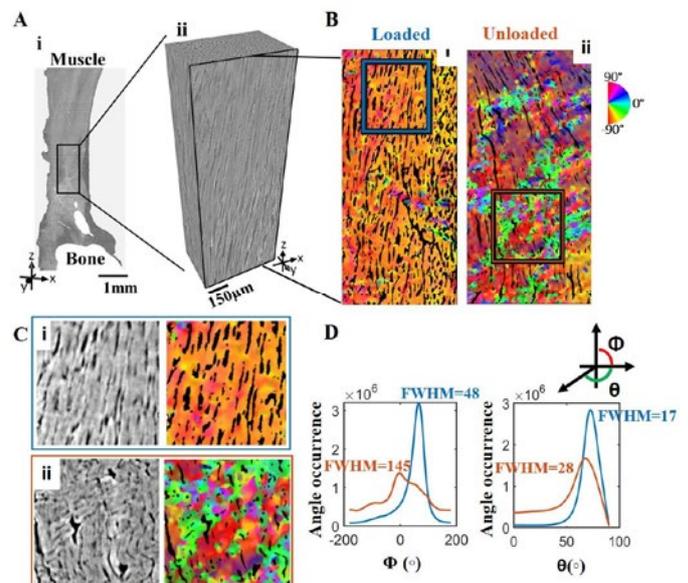

**Animal model:** 14 Sprague-Dawley rats were divided into 2 groups: normal cage activity and unloading by Botox injections plus cast immobilization, following Hammerman et al. [3]. The tendons were harvested and kept frozen in saline solution until imaging. Imaging was carried out at the X02DA TOMCAT beamline at the Swiss Light Source, Paul Scherrer Institute, using the High Numerical Aperture Microscope (magnification: 4x, FOV: 4.2mm x 3.5mm and pixel size: 1.63 $\mu$ m).

To determine the effect of *in vivo* loading on the microstructure, the 3D orientation distribution of the fibers was determined and compared. A structure tensor analysis was conducted adapting a MATLAB script by Krause et al. [4]. The analysis permits to directly visualize fibers orientations by computing azimuth and elevation angles and to statistically describe how the orientations are distributed.

### Results and Discussion

SR-PhC- $\mu$ CT imaging of fresh frozen Achilles tendons provides a comprehensive anatomical understanding of the complex internal fiber structure without invasive sample preparations (Fig. 1A). The 3D fiber orientation can be detected (Fig. 1B). The results indicate that angle

distributions depend on the *in vivo* loading regime and fibers are more organized along the main axis in the case of the loaded tendon and more crimped for the unloaded tendons (Fig. 1C and narrower Full Width at Half Maximum for both angles in Fig. 1D).

**Figure 1:** A) SR-PhC- $\mu$ CT of an Achilles tendon, i) the entire tendon, ii) magnification showing the collagen fibers. B) Colormap showing fiber orientations for *in vivo* loaded (i) and unloaded (ii) tendon orientations. C) Magnification of the areas indicated in B), showing straight fibers in the loaded tendon and crimped fibers in the unloaded tendon. D) Azimuth ( $\Phi$ ) and elevation ( $\theta$ ) angle distributions are narrower for the loaded tendon (blue curve) than the unloaded (red curve).

### Conclusions

SR-PhC- $\mu$ CT imaging of Achilles tendons provides a comprehensive understanding of the 3D microstructure. The microstructure is affected by altered *in vivo* loading. Fibers are more crimped and less organized when mechanical stimulation is lacking.

### Summary

The medial and lateral gastrocnemius exhibit extraordinary growth in the first two years of life. Using 3D ultrasound we have tracked the growth of the infant gastrocnemius from 3 to 24 months of age. A principal component analysis has revealed that the medial gastrocnemius starts to increase in volume, relative to the lateral side, about the time when infants show autonomous walking skills. This is consistent with changes in spatiotemporal parameters, joint kinematics and kinetics which start to approach adult characteristics by age 2 years. When age related muscle volume increases were removed from the analysis, principal component analysis revealed that muscle belly width was the primary shape change, with the medial side showing increased muscle belly width relative to the lateral side. Understanding typical infant muscle growth has implications for better identification of muscle pathology, including in cerebral palsy.

### Introduction

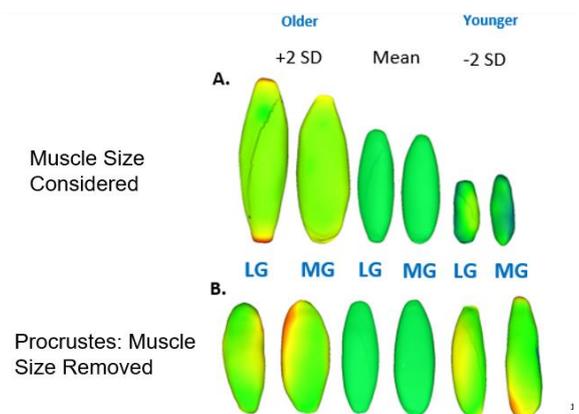

Infants experience rapid muscle changes during the first two years of life. During this time important biomechanical changes are observed. For instance, step width decreases, while step length and walking speed increases [1,2]. Kinematics and kinetics converge towards more adult like characteristics. Two of the most notable lower limb muscles for adequate gait function are the lateral gastrocnemius (LG) and medial gastrocnemius (MG) [3]. Little is known about form function relationships in infants less than 2 years of age. This is paramount because by 2 years of age mature features of gait and muscle function have already formed. In this study we evaluate infant muscle growth in the first 2 years. Understanding typical form function developments have important implications for clinical recommendations in pathologic gait.

### Methods

Four OptiTrack cameras were integrated with a custom 3D ultrasound setup. Forty-four infants (3 to 24 months) were scanned using a single-sweep method for the MG and LG. Muscles were segmented from the femoral condyle to the distal musculotendinous junction [4] in the Stradwin/Stradview software suite. We used the musculoskeletal analysis software GIAS2 (Geometry Image-Analysis Statistics) to perform principal component analysis.

### Results and Discussion

The gastrocnemius size increases across age and the LG and MG differentiate and become less symmetric (Figure A). Specifically, the LG appears more elongated and thinner while the MG shows a wider muscle belly with more volume. A secondary assessment (Figure B) involving a Procrustes analysis where muscle size is normalized revealed the primary shape change was in the muscle belly with the MG being wider than the LG as we get older. This is consistent with what we observe in children, and adolescents through to adulthood [5], where the MG is larger. Interestingly, we measured an increasing inversion ankle torque across the first year of walking and the MG muscle contributes to foot inversion [6].

**Figure:** Muscle shape changes across age (A) and with muscle volume removed (B). Mean and  $\pm 2$ SD are shown with RED increase and BLUE decrease and GREEN the mean.

### Conclusions

The medial gastrocnemius increases in size relative to the lateral gastrocnemius from the time independent walking occurs. This is in part explained by the developing inversion torque during the first year of walking.

## Summary

Muscle morphological parameters, such as fascicle length (FL) can significantly influence the muscle function. In this study, FL in medial gastrocnemius (MG) of two healthy adults was quantified using 3D freehand ultrasound (3DfUS) and Diffusion Tensor Imaging (DTI), respectively. The preliminary data analysis showed that 3DfUS over-estimated the FL in MG compared to DTI-based measurement. Further investigation is necessary to yield a more precise comparison.

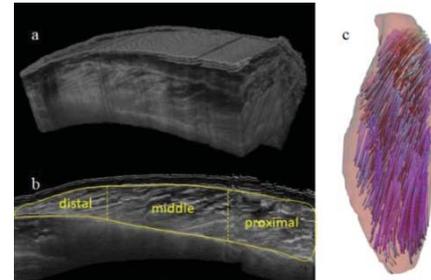

## Introduction

2D ultrasound (US) and magnetic resonance imaging (MRI) are often used to quantify *in vivo* FL. However, 2D US only provides 2D images with limited field of view. DTI measures the diffusion of water molecules in the tissue and can be applied to reconstruct 3D muscle fascicles, serving as a reference standard of *in vivo* FL quantification. But DTI-based measurement has poor portability and limited accessibility. 3DfUS combines 2D US and a 3D motion capture system, which has been shown to have good accuracy in measuring muscle length and volume [1]. The purpose of this study was to compare the quantitative measurement of FL in lower limb muscles using 3DfUS and DTI, respectively.

## Methods

Two healthy male subjects (age:  $58.5 \pm 3.5$  yrs, weight:  $77.0 \pm 0.1$  kg, height:  $183.0 \pm 5.7$  cm) voluntarily participated in the study approved by the local ethics committee. B-mode US images of lower limbs were recorded using a 38-mm wide linear transducer (Mindray M9). A probe holder with four reflective markers is fixed rigidly to the transducer. A 10-camera optical motion capture system (Vicon Motion Systems) was used to simultaneously track the position and orientation of the transducer during the US image acquisition. The 3D reconstruction of 2D US images was performed based on a previously published pipeline [2]. Bilateral legs of the two subjects were previously scanned using a 3.0 Tesla MRI scanner (Siemens Trio). During both data acquisition sessions, subjects were lying in a supination position with identical joint alignment. T1-weighted MR and DT images were acquired. The FL was determined using DTI-based [3] and 3DfUS-based [2] method, respectively. Mean FL of the whole muscle volume was calculated. Furthermore, the

muscle was evenly divided into proximal, middle and distal parts to quantify variance in the FL in 3DfUS-based measurement (Figure 1).

**Figure 1:** (a-b) 3DfUS based reconstruction of MG (c) 3D reconstruction of fascicles based on DTI measurement

## Results and Discussion

Only FL in medial gastrocnemius (MG) were reported here. The FL was found the longest in the proximal part of the MG and shortest in the distal part (Table 1). Compared to the DTI-based method, the FL was longer using 3DfUS-based measurement. The observed differences may be due to the probe compression and manually defined plane for FL calculation in the 3DfUS-based measurement.

## Conclusions

Based on this preliminary study, 3DfUS measurement overestimated FL in MG compared to the DTI measurement. Further investigation is needed to improve our measurement protocol in the 3DfUS in order to perform a precise comparison.

## Summary

Chronic obstructive pulmonary disease (COPD) is linked with increased falls risk, but the mechanisms of this are not understood. Using treadmill-based perturbations during walking, we found that COPD does not appear to result in significant deficits in stability following sudden perturbations and patients do demonstrate some adaptability to repeated perturbations. The approach was also found to be feasible, meaning that perturbation-based balance training could be further explored in COPD.

## Introduction

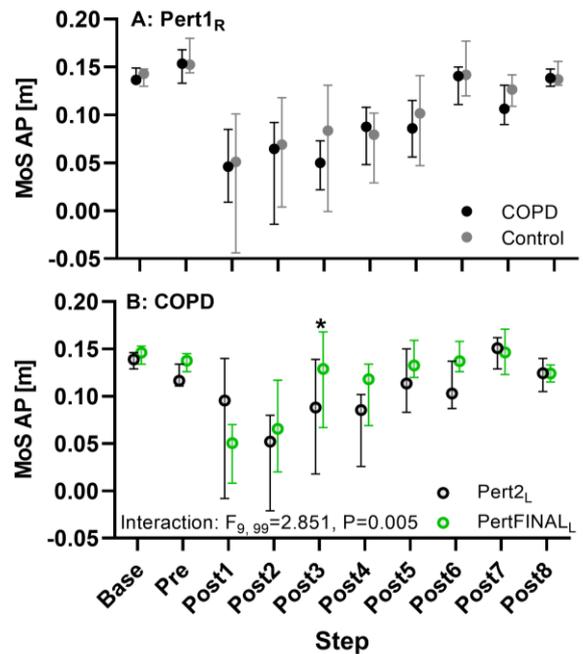

Falls risk is elevated in chronic obstructive pulmonary disease (COPD) but little is known about the contributing factors. We examined the feasibility of, and initial responses to, large walking perturbations in COPD, as well as the adaptation potential to repeated walking perturbations that might indicate potential for perturbation-based balance training in COPD.

## Methods

12 participants with COPD undergoing inpatient pulmonary rehabilitation and 12 age-gender-matched healthy control participants walked on an instrumented treadmill at a stability-normalised walking speed [1] and experienced repeated treadmill-belt acceleration perturbations (first perturbation to the right leg, then up to eight times to the left leg as conducted in [2]). Three-dimensional motion capture was used to quantify the margin of stability [3] during perturbed walking. Feasibility, stability following the initial perturbations and adaptation to repeated perturbations were assessed.

## Results and Discussion

Perturbations in this manner were feasible in COPD (no harness assists and 11 of 12 participants completed the minimum number of perturbations (5), with an average of 8). No significant deficit in reactive walking stability in COPD was found versus controls (Figure 1A). There were mixed results for the adaptability outcomes (no significant perturbation number effect but a significant interaction) which overall indicated some adaptability to repeated perturbations (Figure 1B), but not to the same extent as the healthy controls.

**Figure 1:** Medians and 95% confidence intervals of the AP MoS during unperturbed walking prior to each perturbation (Base), the final step prior to each perturbation (Pre) and the first eight recovery steps following the perturbations (Post1–8) for **A**, the first perturbation to the right leg in COPD and matched control participants, and **B**, during the first and final (for each individual) perturbation to the left leg within the COPD participants. \*: Sidak's multiple comparisons test:  $P=0.046$ .

## Conclusions

Treadmill-based perturbations during walking are feasible in COPD. COPD does not appear to result in significant deficits in stability following sudden perturbations and patients do demonstrate some adaptability to repeated perturbations. Perturbation-based balance training may be considered for fall prevention in research and practice in people with COPD.

### Summary

Understanding spatiotemporal gait strategies could help develop individualized transfemoral prostheses and provide better rehabilitation regimes. This study aimed to classify the spatiotemporal gait patterns across a range of walking speeds in unilateral transfemoral amputees (UTFAs). Hierarchical cluster analysis (HCA) was conducted on the step lengths and cadences at eight different speeds in 24 UTFAs. This HCA revealed three clusters based on a higher cadence, a longer step length, and a hybrid pattern. Current results suggest that there is more than one gait strategy in UTFAs.

### Introduction

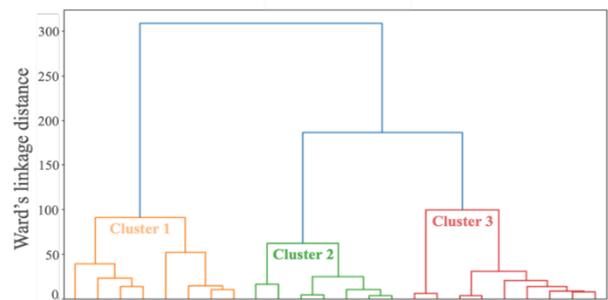

Walking is one of the most fundamental activities of daily life. In healthy subjects, spatiotemporal gait parameters, such as cadence and step length, have been shown to be automatically controlled by common mechanisms during steady gait [1]. In contrast, a previous study reported that below-knee prosthesis users have shown a greater variability of the parameters than healthy subjects across a range of walking speeds [2], indicating that prosthesis users are likely to have several different gait patterns. The aim of this study was to classify gait patterns using step length and cadence across a range of walking speeds in unilateral transfemoral amputees (UTFAs). We hypothesized that there would be two clusters of gait patterns based on a longer step length or a higher cadence.

### Methods

Twenty-five UTFAs (18 M, 7 F; age  $30.3 \pm 9.0$  years; mass  $65.3 \pm 14.3$  kg; height  $1.66 \pm 0.75$  m) participated in this study. Spatial and temporal footfall data were collected while each subject walked on a split-belt instrumented treadmill (FTMH-1244WA, Tec Gihan, Kyoto, Japan) at eight different speeds (2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, and 5.5 km/h). The collected footfall data were processed to derive the cadence (step/s) and step length (m). The Mahalanobis distance criterion [3] was used to eliminate any outliers. Hierarchical cluster analysis (HCA) was then conducted to identify subgroups with homogeneous gait patterns, based on the relationships between cadence and step length in both the prosthetic limb and intact limb of each subject. Squared Euclidean distance was chosen as the metric for this analysis, and Ward's linkage method was adopted. After forming the clusters, a univariate analysis of variance (ANOVA) or a Kruskal–Wallis test was performed on cadence and step length. When a significant main effect was observed, post-hoc comparisons (*T*-test or Mann–Whitney *U* test) were performed on the variables between the clusters. Statistical significance was set to  $p < 0.05$ .

### Results and Discussion

After an outlier was eliminated (Mahalanobis distance criterion  $> 4.0$ ), a final sample of 24 participants was left for further analysis. HCA identified three clusters based on step lengths and cadences (Figure 1). Cluster 3 ( $n = 9$ ) had a significantly longer step length than Cluster 2 in their intact limb over a wide range of walking speed and longer step length in their prosthetic limb at 2.5 and 3.5 km/h. Cluster 2 ( $n = 7$ ) had a significantly higher cadence than Cluster 3 in their intact limb over a wide range of walking speeds, and in their prosthetic limb at 2.5 and 3.5 km/h. The step lengths and cadences in Cluster 1 ( $n = 8$ ) exhibited nearly intermediate values between Cluster 2 and 3. These results indicate that the spatiotemporal gait parameters of UTFAs have different modes [4], suggesting the existence of different gait control mechanisms that adjust at least either their cadences or step lengths.

**Figure 1:** Dendrogram of hierarchical cluster analysis (HCA). Linkage distance is shown on the y-axis and UTFAs are shown on the x-axis. Three clusters were identified.

### Conclusions

We showed that gait characteristics of UTFAs can be classified into three clusters based on their spatiotemporal parameters (cadence and step length) across a range of walking speeds, suggesting the existence of different gait control mechanisms in UTFAs. These results would help to develop individualized transfemoral prostheses, and to provide better rehabilitation regimes.

### Summary

We collected simultaneous measurements of Achilles tendon, patellar tendon, and knee contact loading during walking in a patient with an instrumented total knee replacement. Tendon load was tracked using non-invasive shear wave tensiometers. This novel dataset will enable objective evaluations of predictions of internal tissue loading using either musculoskeletal modeling or machine learning approaches.

### Introduction

The ability to characterize internal joint loads during walking from external measurements is hindered by muscle redundancy. Tensiometers are a novel wearable technology to assess *in vivo* loading by measuring shear wave propagation along superficial tendons [1]. Tensiometer data could potentially be used to resolve muscle redundancy when estimating internal tissue loads. This study aimed to collect coupled tensiometer and knee joint load data to assess the utility of tensiometer data to assess joint contact loads.

### Methods

We performed simultaneous tensiometer, motion capture, ground reaction force, electromyography, and knee contact force measurements on a subject (K5R, Male, 93kg, 1.7m, 72 years) with an instrumented knee replacement [2] during overground level walking at the CAMS-Knee OpenSim 2020 Workshop (<https://cams-knee.orthoload.com/>). EMG was collected on the rectus femoris, tibialis anterior and medial and lateral hamstrings, quadriceps, and gastrocnemii. The inverse kinematics and dynamics tools in OpenSim were used

to calculate joint angles and moments. The measured and calculated metrics were analyzed against the gait cycle.

### Results and Discussion

There was strong correspondence between the phasing of tendon wave speeds and knee contact forces. Specifically, the peak in the patellar tendon wave speed coincided with the first peak in the knee contact force, while the peak in Achilles tendon wave speed coincided with the second peak in knee contact force.

### Conclusions

These unique measurements provide additional insight into the contributions of the patellar tendon and Achilles tendon loading patterns to *in vivo* knee contact forces during walking. These results suggest that with advanced analysis techniques, tensiometers show potential to be applied as a wearable technology to indirectly assess knee contact forces.

# Musculoskeletal Simulation of a Gait for a Person with Unilateral Transfemoral Amputation: The Cause of Muscle Atrophy

Isna Riski Safira, Motomu Nakashima

Department of Systems and Control Engineering, Tokyo Institute of Technology, Tokyo, Japan

Email: [isna.r.aa@m.titech.ac.jp](mailto:isna.r.aa@m.titech.ac.jp)

## Summary

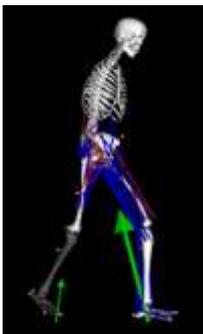

Muscle atrophy information in transfemoral amputation is one essential factor to design better prosthesis and rehabilitation process. The previous study has explained the atrophy distribution, but the mechanism behind atrophy formation is yet to be known due to the difficulties in accessing deep muscles. The current study proposes the answer through musculoskeletal simulation using kinematic and kinetic gait dataset to calculate and compare the maximum muscle forces between amputated and intact limb. The result showed that the reduction in muscles' moment arms after surgery might cause lower muscle forces resulting in atrophy. On the contrary, muscles with higher force become hypertrophied. The largest difference in muscle force between amputated limb and intact limb was observed in the adductor longus muscle and indicated high contribution of this muscle to compensate for lack of force from the other muscles in amputated limb.

## Introduction

Muscle atrophy in persons with transfemoral amputation (TFA) is one of the musculoskeletal comorbidities following surgery that occur in muscles at amputated limb (AL). However, a recent study shows that some muscles in AL become hypertrophied compared to the ones in intact limb (IL) [1], although the cause has yet to be confirmed. The cause can be elucidated by understanding the distribution of individual muscle forces, which has not been sufficiently studied before. For this purpose, a musculoskeletal simulation of a gait for a TFA was carried out in the present study.

## Methods

Kinematic information and ground reaction force were obtained from open-source data of TFA [2] during gait. A subject with unilateral transfemoral amputation (male; age= 38 years, mass= 104.3 kg, height= 1.91m; gait speed= 1.4m/s) was modeled as shown in Figure 1. A musculoskeletal model was constructed using modified Gait 2392 of OpenSim [3], which has 12 body segments and 23 degrees-of-freedom. AL was modeled by removing muscles that have no origin or insertion point in the above knee. The distal ends of the transected muscles in AL were re-attached to the new insertion points near the medial ridges of linea aspera. The final model had 22 muscles on AL and 34 muscles on IL with the same muscle properties as a healthy person to simulate the condition before the atrophy.

**Figure 1:** Musculoskeletal model of TFA

## Results and Discussion

Table 1 shows the result of simulation with respect to the maximum muscle forces. Almost all muscles in AL have lower forces compared to IL due to the reduction in muscles' moment arms as the result of amputation. Muscles in AL with higher forces, including adductor longus (ADDL), were obtained due to having the same insertion point.

**Table 1:** Muscle force in AL compared to IL.

Muscle	AL Fmax (N)	Force Ratio	CSA Ratio (% in [1])
Iliopsoas	984.5	Higher	64.2
Gluteus maximus	254.5	Higher	63.6
Tensor fascialatae	0.0	Lower	46.1
Rectus femoris	203.3	Lower	56.5
Vastus medialis	0.09	Lower	54.5
Vastus intermedialis	0.0	Lower	75.1
Vastus lateralis	0.0	Lower	54.5
Sartorius	81.6	Lower	70.1
Biceps femoris	0.0	Lower	127.4
Semitendinosus	12.9	Lower	128.1
Pectineus	65.0	Higher	48.0
Gracilis	2.6	Lower	108.6
<b>Adductor longus</b>	<b>246.0</b>	<b>Higher</b>	<b>143.8</b>
Adductor brevis	53.1	Higher	75.0
Adductor magnus	18.3	Lower	85.9

The largest difference was observed in ADDL muscle force between AL (246 N) and IL (27 N). It indicates high contribution of this muscle to compensate for the lack of power in AL. ADDL in AL becomes more activated and generate higher cross-sectional area (CSA) with 143.8% ratio [1]. Our study suggests to take benefit of this muscle in prosthesis design and rehabilitation process.

## Conclusions

The result showed that the reduction in muscles' moment arms might cause lower muscle forces resulting in atrophy. To compensate, AL muscles with the same musculature as before surgery will generate higher muscle forces. The largest difference in muscle force between AL and IL was observed in ADDL. It indicates the major contribution of ADDL to compensate the lack of force from the other muscles in AL.

### Summary

The ability for humans to stay upright in the face of unpredictable changes in their environment is remarkable, yet we understand little about this is achieved. Here, we determined how neuromuscular control and plantarflexor muscle-tendon dynamics are modulated to maintain stability during unexpected changes in ground height during hopping. We show that an unexpected drop in ground height introduces an automatic phase shift in the timing of plantarflexor muscle activity relative to ground contact and an increase in co-activation of the plantar and dorsi-flexor muscles. This leads to shorter fascicle lengths at ground contact and increased fascicle lengthening and forces during the perturbed step—enabling the plantarflexors to safely and effectively dissipate the energy injected by the drop.

### Introduction

Animals display a remarkable ability to stay upright during movement in the face of uneven or unpredictable terrain. Yet much of our knowledge regarding locomotion has come from studies conducted under steady-state conditions on level surfaces. Our previous work has shown that humans use the most distal lower-limb joints to absorb energy and recover from perturbations [1]. However, the muscle-tendon dynamics and neural control strategies that accompany these responses are not yet understood. Previous unexpected drop landings in birds highlight that muscle-tendon unit (MTU) series elasticity acts as a buffer to rapidly absorb energy and protect muscle fascicles from potentially injurious strains [2]. Our aim is to provide fundamental insights into the mechanisms for stability during unexpected perturbations.

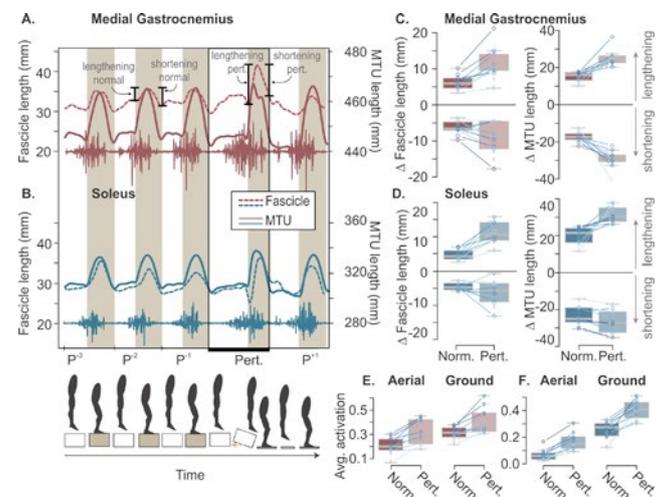

### Methods

Participants performed steady-state hopping at their preferred frequency on a 20cm platform. We elicited an unexpected perturbation via rapid removal of the platform. Motion capture (Vicon, UK) was used to quantify the 3D positions of the lower limbs. MTU lengths were computed from a scaled musculoskeletal model and motion capture data. Ground reaction forces were measured during hopping using a static instrumented split belt treadmill (Bertec, USA). Surface electromyography (EMG) was used to record muscle activations in the medial (MG) and lateral gastrocnemius (LG), soleus (SOL), and tibialis anterior (TA) (Biometrics, UK). MG and SOL fascicle lengths were determined from B-mode ultrasound images (Telemed, Lithuania). Linear mixed effects models were used to examine variation in muscle activation and muscle-tendon dynamics between conditions.

### Results and Discussion

The unexpected change in the height of the ground introduced an automatic phase shift that extended the aerial

phase of the perturbed hop. This altered the timing of muscle activation; MG and SOL activation shifted  $\sim 0.076$ s earlier during the perturbation relative to ground contact and average muscle activation increased during the aerial and ground contact phases of perturbation compared to normal hopping ( $P < 0.001$ , Fig. 1). These alterations resulted in (1) more fascicle shortening prior to the perturbation, (2) shorter fascicles upon initial ground contact, and (3) increased fascicle lengthening during ground contact of the perturbed hop ( $P < 0.001$ ). Similarly for the MTU, the perturbation leads to (1) increased MTU lengthening and shortening during the ground contact phase, and (2) shorter MTU lengths upon ground contact ( $P < 0.001$ ) (Fig. 1A-D). These alterations in fascicle and MTU length changes together with increases in muscle force, led to increases in energy dissipation (negative power) during the perturbation. Finally, we find that the perturbation leads to co-activation of the plantarflexors and antagonist TA, which during normal hopping activate out of phase. This co-activation improves the capacity of the plantarflexors to rapidly absorb energy upon ground contact, and may also aid in avoiding potentially damaging strains.

**Figure 1:** Muscle activation, MTU, and fascicle length during normal (Norm.) hopping ( $P^{-3}$ ,  $P^{-2}$ ,  $P^{-1}$ ) and the perturbation (Pert.).

### Conclusions

Our study provides novel insight into how humans alter their neural control to modulate *in vivo* muscle-tendon dynamics in response to unexpected perturbations. These data provide insight to guide design of lower-limb assistive devices that can perform within varied and unpredictable environments.

Email: a.malki@umcg.nl

## Summary

Rocker shoes are used to offload high-risk areas of the foot to prevent foot ulcers in diabetic patients with loss of protective sensation. Forefoot rocker shoes can reduce the peak plantar pressure of the hallux and MTH regions, however pressure in the heel region is often elevated by this type of footwear. Therefore, the effect of different heel rocker designs (12) on the heel plantar pressure (at 7 masks) is analyzed in this study. Results have shown a significant main effect of the rocker radius on the relative peak plantar pressure for the different heel masks. Patients with high risk areas in the proximal heel region benefit more from a rocker shoe with larger heel radii whereas smaller heel radii are beneficial for patients with high risk areas in the distal heel region.

## Introduction

Rocker shoes are used to offload high-risk areas of the foot to prevent foot ulcers in diabetic patients with loss of protective sensation. These high-risk areas are the hallux, metatarsal heads (MTH) and heel region [1]. Forefoot rocker shoes can reduce the peak plantar pressure of the hallux and MTH regions, however pressure in the heel region is often elevated by this type of footwear, indicating great importance to focus on this region [2,3,4]. No studies have analyzed the effect of different heel rocker designs on the heel plantar pressure yet.

## Methods

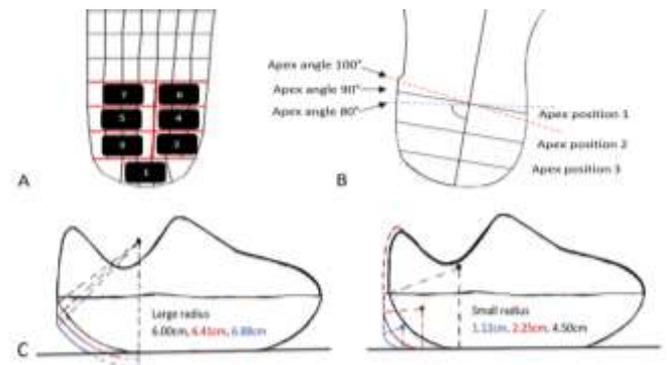

Shoes with 12 different heel rocker configurations were designed having different heel rocker radii, apex positions and apex angles (Figure 1). The relative peak plantar pressure (RPP) of each configuration at 7 heel locations (masks, Figure 1) was studied in 10 healthy participants.

## Results and Discussion

There is a significant main effect of the rocker radius on the RPP for the different heel masks. Compared to a smaller radius (SR), a larger radius (LR) causes a significantly lower RPP in mask 1, 2 and 3 whereas the same radius causes a significant increase in RPP in mask 5 and 7. Moreover, a significant interaction effect between the rocker radius and the apex position for mask 1 and 3 was found. A LR, compared to a smaller, with a proximal apex position causes a significantly lower RPP in mask 1 and 3. The same result is seen in mask 1 with the mid-apex position.

The shape of the heel rocker affects heel pressure during the loading response of the first rocker. The radius of the

curvature influences how the pressure is redistributed. A steep curve (=SR) resulted in an increased RPP in the proximal heel region compared to a LR, probably due to a shortened rear curve rolling time. Lin et al. showed that the efficacy of rocker shoes is reduced when the curve rolling time is decreased, which could explain this finding [5].

**Figure 1:** (A) The numbers represent the 7 masks (B) Red, black and blue lines respectively represent: apex angle of 100°, 90° and 80°. The distal, mid and proximal apex position are also shown in the same image. (C) Left image illustrates heel rockers with large radii (range: 6.00 - 6.88cm) and right image shows heel rockers with small radii (range: 1.12 - 4.50cm).

## Conclusions

Patients with high risk areas in the proximal heel region benefit more from a rocker shoe with larger heel radii whereas smaller heel radii are beneficial for patients with high risk areas in the distal heel region.

## Acknowledgments

The authors gratefully acknowledge EIT Health for funding the project.

### Summary

Femoroacetabular impingement syndrome is commonly treated via arthroscopic surgery or conservative management. This randomised controlled trial compared the effects of these treatment approaches on external biomechanics during self-paced walking at baseline and 12-month follow-up. We observed no differences in trunk, pelvis, and lower-limb biomechanics between treatment groups, though both groups exhibited altered biomechanics at follow-up compared to baseline. The clinical implications of these relatively small changes require further investigation.

### Introduction

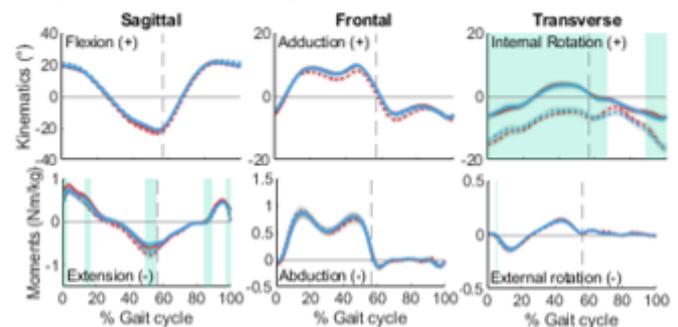

Femoroacetabular impingement syndrome (FAIS) is a motion-related hip disorder, whereby an abnormally shaped femoral head/neck and/or acetabulum leads to mechanical impingement and hip pain [1]. FAIS may predispose an individual to hip osteoarthritis. Hip arthroscopy and physiotherapist-led conservative management are common treatments, though patient reported improvements in symptoms and function are modest. Although hip arthroscopy rates increased 460% from 2005 to 2013 [2], arthroscopic hip surgery does not restore normal walking patterns in those with FAIS [3]. The effects of conservative treatment on walking biomechanics in FAIS have not been explored, nor have treatment approaches been compared. We compared changes in trunk, pelvis, hip, knee, and ankle angles, and hip, knee, and ankle moments during self-paced walking following arthroscopy or conservative management of FAIS.

### Methods

The Australian FASHIoN Trial recruited patients from waiting lists for arthroscopic treatment of FAIS (n=140), and a subset underwent biomechanical analysis (n=45). Patients were randomly assigned to arthroscopy (ARTH; n=21) or 12 weeks of conservative care (Personalised Hip Therapy, PHT; n=24) [4]. Three-dimensional body motion and ground reaction forces were measured prior to treatment (baseline) and at 12-months (follow-up) during four self-paced walking trials. Inverse kinematics and dynamics were performed in OpenSim [5]. Trunk, pelvis, and lower-limb angles (°), and lower-limb external moments (Nm/kg), were compared between baseline and follow-up and treatment groups using a two-way repeated measures analysis of variance via statistical parametric mapping ( $p < 0.05$ ).

### Results and Discussion

We observed no differences in treatment effects for any angles or moments during walking. Compared to baseline values, both ARTH and PHT patients walked with mean increased hip external rotation (mean difference (MD) 7.5° 95% confidence interval (CI) 3.2 to 11.8,  $p < 0.001$ ) angles, reduced hip flexion (MD 0.12 Nm/kg 95%CI 0.02 to 0.23,  $p = 0.03$ ), increased hip extension (MD 0.16 Nm/kg 95%CI 0.04 to 0.29,  $p = 0.01$ ), hip external rotation (MD 0.02 Nm/kg 95%CI 0.004 to 0.04,  $p = 0.04$ ), knee flexion (MD 0.09 Nm/kg 95%CI 0.04 to 0.14,  $p = 0.01$ ), and plantarflexion (MD 0.07 Nm/kg 95%CI 0.04 to 0.11  $p = 0.02$ ) moments (Figure 1).

**Figure 1.** Ensemble average ( $\pm 1$  standard deviation) hip angles (°) and moments (Nm/kg) for PHT (blue) and ARTH (red) at baseline (solid) and follow-up (dashed). Green shading indicates significant differences between baseline and follow-up for both treatment groups ( $p < 0.05$ ). Grey dashed line - toe off (mean for all participants).

### Conclusions

The effects of ARTH and PHT on walking biomechanics in patients with FAIS did not differ. Regardless of treatment, several lower-limb biomechanical parameters were altered at 12-month follow-up. The clinical and structural implications of these relatively small changes require further investigation over both the short- and long-term.

# The effect of a foot strengthening exercise intervention on restoring foot strength in people with diabetic peripheral neuropathy

Karen J. Mickle<sup>1</sup>

<sup>1</sup>School of Allied Health, Human Services and Sport, College of Science, Health and Engineering, La Trobe University, Melbourne, Australia

## Summary

This study evaluates the effect of a specific foot strengthening exercise program on foot strength in people with diabetes and peripheral neuropathy. After 12 weeks, 20 participants returned to the laboratory for retesting (77%). We found a significant interaction between groups and time, whereby participants in the intervention group increased their toe strength compared to baseline. This study has provided good pilot data to show that a foot strengthening exercise program may be suitable for people with diabetic neuropathy.

## Introduction

Diabetic polyneuropathy (DPN) is one of the most common complications associated with diabetes, present in 50-70% of older people with diabetes [1]. In later stage DPN, sensory and motor dysfunction occurs and muscle weakness develops, with muscle weakness progressing with the level of neuropathy [1]. Foot strength is particularly diminished in people with diabetes and peripheral neuropathy. Little is known as to whether strength can be altered through targeted exercise in people with diabetes and peripheral neuropathy. This study evaluates the effect of a specific foot strengthening exercise program on foot strength in people with diabetes and peripheral neuropathy.

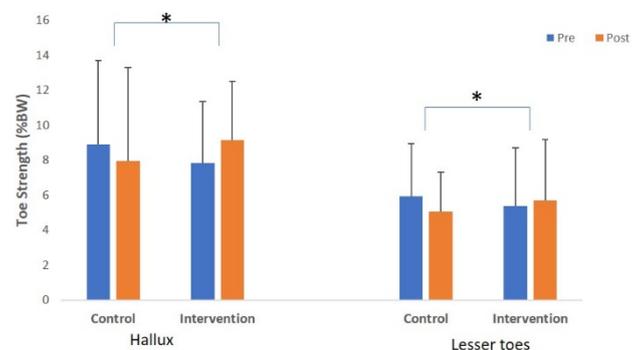

## Methods

A randomized control trial design was conducted to assess change in outcome measures following a 12-week foot strengthening exercise program. 26 participants presented with peripheral neuropathy and were eligible to be randomized to the foot strengthening exercise program (n = 15) or control groups (n = 11). Toe and ankle strength at baseline and after the intervention were measured [2]. A two-way repeated measures analysis of variance design, with one between factor (group: Toe-Training class and control) and one within factor (test session: pre and post), was then conducted to test whether the foot strengthening exercises affected foot strength over time.

## Results and Discussion

20 participants returned to the laboratory for retesting (77%; control = 9, intervention = 11). Significant time x group interaction effects were found for both hallux and lesser toe

strength (Figure 1). For hallux strength, there was a decrease in the Control group ( $M_{diff} = -0.99$  %BW), but there was a significant increase in hallux strength from pre- to post-intervention testing for the intervention group ( $M_{diff} = 1.31$  %BW). Similarly, for lesser toe strength, there was a decrease in strength across time for the Control group ( $M_{diff} = -0.87$  %BW), but there was a increase in lesser toe strength from pre- to post-intervention testing for the intervention group ( $M_{diff} = 0.32$  %BW). There were no significant interactions for ankle strength (plantarflexion, dorsiflexion, inversion, eversion).

**Figure 1:** Change in toe strength for the control and intervention groups over the 12 week intervention period (\* indicates significant group\*time interaction  $p \leq 0.05$ )

## Conclusions

This study has provided good pilot data to show that a foot strengthening exercise program may be suitable for people with diabetic neuropathy. The progressive, supervised 12-week exercise program class was able to increase both hallux and lesser toe flexor strength and minimize loss of foot and ankle strength associated with diabetic neuropathy.

## Accuracy Estimation of a MIMU-based Functional Calibration for Ankle Kinematics Assessment

Paolo Brasiliano<sup>1</sup>, Guido Mascia<sup>1</sup>, Paolo Di Feo<sup>1</sup>, Andrea Cereatti<sup>2</sup>, Camomilla Valentina<sup>1</sup>

<sup>1</sup>Bioengineering and Neuromechanics of Movement, University of Rome Foro Italico, Rome, Italy

<sup>2</sup>Department of Electronics and Telecommunications, Polytechnic of Turin, Turin, Italy

### Summary

Ankle kinematics was estimated from magneto-inertial measurement units (MIMU) data, devising an *ad hoc* functional calibration procedure. Intra/inter operator repeatability was tested to be in the range of 1 and 2 deg, respectively. The accuracy of the method, obtained as comparison with stereophotogrammetric data, showed high waveforms' shape similarity, even though with variable and ample posture angles disagreement, calling for further studies.

### Introduction

In-field assessment of ankle joint kinematics is relevant in several different applicative settings. It can be obtained by positioning two MIMUs on shank and foot segments, estimating MIMU orientation in a common global coordinate system and then orienting them according to the anatomy of the relevant segment. To this aim, typically for the knee joint, functional calibration approaches are used that reconstruct selected anatomical axes starting from the direction of the average angular velocity vector measured during *ad-hoc* passive or active movements of a segment about two of its anatomical axes. However, this approach has not been applied to the ankle joint, possibly due to its complex functional anatomy and smaller range of motion. The aim of this study is to develop a MIMU-based functional calibration approach for the ankle joint which combines a functional and a reference pose imposition approach. The procedure inter and intra-operator repeatability and its accuracy, as a comparison to stereophotogrammetric gold standard measures, were also assessed during walking.

### Methods

The functional calibration entails determining foot and tibia anatomical frames (AFs) using as key axes (Fig. 1): *i.* the plantar-dorsiflexion (PD) axis obtained through a passive functional movement ( $a_f$ ); *ii.* the gravity direction when the subject is in orthostatic posture (shank vertical axis,  $a_v$ ); *iii.* by aligning the foot to a wooden plate equipped with a MIMU (foot long axis,  $a_l$ ). Determining  $a_v$  and  $a_l$  required the subject to be in orthostatic posture for a few seconds. The sequence to achieve foot and shank AFs is depicted in Figure 1.

Four healthy subjects (1F, 3M; age =  $26.8 \pm 3.2$  years; mass =  $69 \pm 13$  kg; height =  $1.8 \pm 0.1$  m) were recruited. Candidates wore 2 MIMUs (Trident, Vicon, UK, @1200 samples/s), each attached to a plate equipped with retro-reflective markers captured by a 7-camera optoelectronic system (Vero/Bonita, Vicon, UK, @100 sample/s). A total of 3 operators performed 3 times the calibration procedure

performing 10 passive PDs, to estimate the PD functional axis ( $a_f$ ) as the mean positive angular velocity vector. Three orthostatic posture measurements were performed. Each subject performed 3 linear gaits at chosen velocity. Ankle kinematics was computed according to ISB-recommendations [1]. Intra and inter-operator repeatability was quantified in terms of root mean squared distance between curves ( $RMSD_{rep}$ );  $RMSD_{acc}$  and  $r$  correlation coefficient between MIMU- and optoelectronic-based kinematics were used to assess accuracy. Accuracy was computed for the posture angles and, after aligning the AFs to the same posture, for the task.

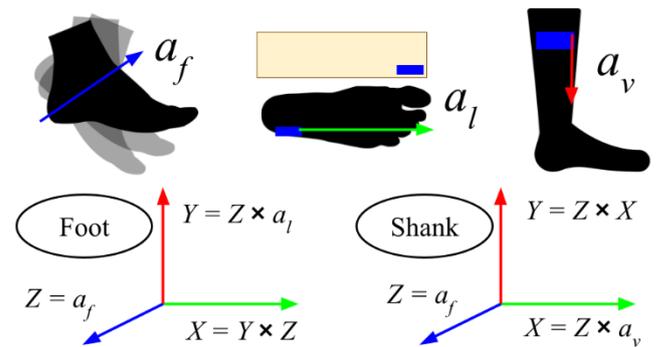

Figure 1: AFs definition for foot and shank.

### Results and Discussion

Results relative to level walking PD angles revealed a good intra and inter-operators  $RMSD_{rep}$  ( $0.8 \pm 0.4$  and  $1.7 \pm 1.0$  deg, respectively).  $RMSD_{acc}$  was of  $8.5 \pm 5.9$  deg for upright posture and  $4.3 \pm 1.4$  deg for walking, with  $r$  correlation coefficient of  $0.94 \pm 0.05$ . Although  $RMSD_{acc}$  values indicate the presence of an offset between the curves that may be related to different procedures to obtain  $a_v$  when using MIMUs or stereophotogrammetry, high  $r$  correlation coefficient suggests good waveforms' shape similarity.

### Conclusions

The proposed functional methodology led to a repeatable estimation of lower limb kinematics. Inter/intra-operator repeatability were in line with those obtained with former anatomical calibration procedures [2] and denote it as promising approach for applied research. Discrepancies relative to the accuracy estimated here and elsewhere [2] may be attributed both to differences in calibration procedures and to different procedures to calculate the RMSD.

# The energetic function of the human foot and its muscles during rapid accelerations and decelerations

Ross Smith<sup>1</sup>, Glen Lichtwark<sup>1</sup>, Luke Kelly<sup>1</sup>

<sup>1</sup>School of Human Movement and Nutrition Sciences, University of Queensland, Queensland, Australia

## Summary

While growing literature has detailed the foot's energetic capacity during steady-state locomotion, its energetic capacity during accelerations and decelerations is unknown. Here we examined the foot and its intrinsic muscles' energetic contributions to non-steady state tasks with increasing work demands.

## Introduction

When accelerating or decelerating, energetic demands at the centre of mass are met by generation (positive work) or dissipation (negative work) of energy of lower body joints like the hip, knee, and ankle. A recent study showed the foot and its intrinsic muscles also make energetic contributions to the centre of mass during stepping tasks [1]. However, the work magnitudes used in this study were small, and the force capacity of the small intrinsic foot muscles is likely limited. Therefore, we investigated the capacity for the foot to generate energy across a range of jumping heights, and dissipate energy over a range of landing heights. We hypothesized that the foot's net-work magnitudes would increase for both tasks (e.g. more negative foot work when landing from higher height) as work demands increased. We also compared normal task performance to a condition where recruitment of the intrinsic foot muscles was blocked, and further hypothesized that less net foot work would be performed at each height for each task in the blocked condition.

## Methods

11 participants performed unilateral, submaximal jump trials onto three box heights and drop landings from three box heights (see Fig. 1). Then, a tibial nerve block was administered to participants' dominant leg to block recruitment of the intrinsic foot muscles. The task protocol was repeated. All tasks for both conditions were performed in a randomized manner. For all trials, motion capture (Oqus, Sweden) and force plate (AMTI, USA) data were collected at 250 and 2500 Hz, respectively. From motion data, inverse kinematics were calculated using a hip, knee, ankle, and foot chain. Kinematic data were combined with force data to calculate inverse dynamics (Visual 3D, USA). A unified-deformable foot model [2] was used to quantify the whole foot's (including soft tissue) energetic contributions from all structures distal to the calcaneus.

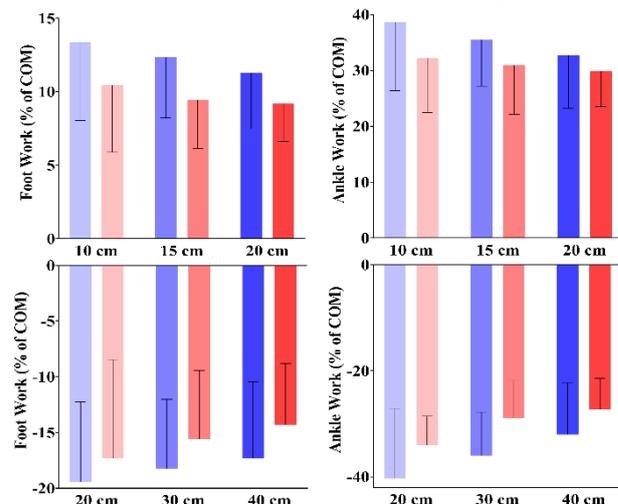

A 2 x 2 (Height x Condition) repeated-measures ANOVA was performed in order to assess the effects of the nerve block on task performance as work demands increased.

## Results and Discussion

Negative foot work increased as landing height increased ( $p=0.001$ ) but remained constant in relation to COM work ( $p=0.288$ ). The nerve block resulted in a decrease in negative work performed by the foot during landing ( $p=0.015$ ) and ~3% reduction relative to COM work ( $p=0.02$ ). Positive foot work increased with increasing jump height ( $p=0.004$ )

without any changes in foot contributions to COM work ( $p=0.102$ ). Also, the nerve block resulted in decreased positive foot work during jumping ( $p=0.001$ ) and ~3% reduction in relation to COM work ( $p=0.001$ ). The foot still played a large energetic role in both jumping (10% net positive COM work) and landing (12% net negative COM work) without the intrinsic foot muscles, which indicate the extrinsic foot muscles, which our nerve block did not affect, play a large role in the foot's energetic function. Also, our study highlights the importance of soft tissues like the plantar fat pads in energy dissipation when decelerating.

For jumping and landing in the blocked condition, relative ankle contributions to COM work decreased compared to normal conditions ( $p=0.010$ ,  $p=0.002$ ). This finding is consistent with previous literature employing a similar nerve block during running [3]. Previous authors have suggested the intrinsic foot muscles may act to control the centre of pressure, influencing to the ankle plantar flexors' external moment arm [4]. Through this mechanism, the reductions in ankle contributions observed in our data may stem from the intrinsic foot muscle block, but this remains speculative.

**Figure 1.** Group mean foot and ankle work values in relation to the COM work for jumps (top row) and landings (bottom row) at all heights. Blue bars are normal conditions, red bars are blocked.

## Conclusions

While blocking recruitment of intrinsic foot muscles had small effects on net work contributions, their role in affecting proximal ankle work contributions may warrant further investigation.

## Summary

Elastic wave propagation in skeletal muscles is essential in supersonic shear imaging and noninvasive therapies. This study examines the viability of using a Hill-type muscle model with distributed mass to simulate the shear wave propagation. A skeletal muscle with fixed ends is discretized by the proposed muscle element, and its wave propagation is initialized by the impact of a rigid ball. Numerical results of the shear wave velocity are validated by comparison with theoretical derivations, highlighting its use in the biodynamic analysis of musculoskeletal systems under large and impulsive loadings.

## Introduction

Elastic wave propagation within human muscles is crucial for dealing with musculoskeletal disorders. For example, it is the basis of sonoelastography and extracorporeal shock wave therapy. Unfortunately, assessing *in vivo* wave propagation in muscles during active contractions remains challenging. Musculoskeletal models provide a systematic pathway to deal with the muscle contractile force, whereas conventional Hill-type muscle models do not account for the muscular mass. Günther et al. [1] have proposed contractile muscle models with inertial mass distribution. However, these models remain difficult to be utilized in large-scale models. Recently, we developed a novel muscle-tendon model based on a flexible multibody dynamics approach [2,3], which simultaneously takes the muscular mass and the Hill-type contractile element into account. The purpose of the current study was to investigate its potential for simulating elastic wave propagation based on a computational benchmark.

## Methods

The skeletal muscle is discretized by the previously proposed flexible cable element [2,3]. Each end of this muscle is fixed to the ground by a spherical joint. The muscle geometry is idealized as a cylinder with a height of 1m, and other modeling parameters are taken from the rectus femoris within the OpenSim gait2392 model.

At the beginning of shock, a rigid ball of 0.1kg impacts the center node with a speed of 20m/s. After that, the muscle simultaneously produces the longitudinal wave and the shear horizontal (SH) wave at the middle node, and then these two waves spread to both ends. Numerical results of the SH wave velocity are compared with the analytical solution based on continuum mechanic theory.

## Results and Discussion

As shown in Figure 1, the longitudinal wave travels back and forth until the muscle stress stabilizes. The more refined the mesh, the more longitudinal waves interact with each other at the same time. The first SH wave is reflected by the ground to form a higher stress peak. Simulation accuracy of the SH wave velocity is negatively correlated with muscle activation level  $a^{\text{mus}}$  because the contact duration cannot be ignored at low-level muscle contractions. Consequently, the root-mean-square error is decreased from 6.65% at minimal activation ( $a^{\text{mus}} = 0.015$ ) to 3.96% at maximal activation.

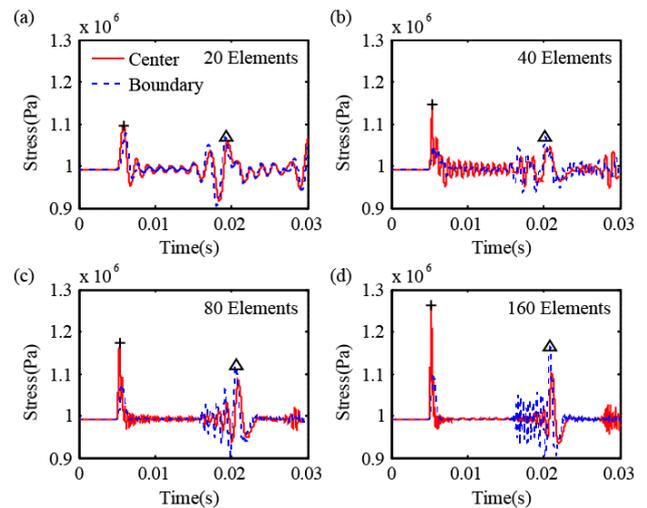

Figure 1: Muscle stress at maximal activation.

## Conclusions

The present study demonstrates that the Hill-type flexible cable with distributed mass successfully captures the elastic wave propagation behavior, suggesting its potential use in large-scale musculoskeletal models under impulse loadings.

## Accounting for vessel holes in finite element models of the femur affects strain prediction

Joeri Kok<sup>1</sup>, Karin Odin<sup>1</sup>, Sofia Rokkones<sup>1</sup>, Lorenzo Grassi<sup>1</sup>, Hanna Isaksson<sup>1,2</sup>

<sup>1</sup>Biomedical Engineering, Lund University, Sweden; <sup>2</sup>Orthopedics, Clinical Sciences, Lund University, Sweden  
Email: Joeri.kok@bme.lth.se

### Summary

Micro-CT ( $\mu$ CT) images of cadaveric femora, previously used for mechanical testing [1], were used to create finite element models. The models include vessel holes in the cortex of the lateral neck. Strains were compared to the experimental data (fracture line and surface strains [1]). The detailed models reveal strain concentrations surrounding vessel holes that affect the femur's fracture behavior.

### Introduction

Finite element (FE) models for prediction of the mechanical behavior of femora under sideways fall loading are becoming more and more accurate. Recently, bilateral digital image correlation (DIC) has been used to show strain concentrations surrounding vessel holes [1,2]. These strain concentrations could lead to fracture of the femur but are currently not captured by organ level FE models of the femur. The aim of this study was to more accurately predict surface strains and fracture locations in the femoral neck by including vessel holes in finite element models of the femur.

### Methods

In a previous study, 12 female cadaveric femora (age 22-88) were mechanically loaded under simulated sideways fall until macroscopic fracture occurred [1]. Strains were measured in the medial and lateral femoral neck using DIC.  $\mu$ CT images including hydroxyapatite calibration phantoms were taken before (isotropic voxel size of 52-60  $\mu$ m, 100 kVp, 0.2 mA) and after the mechanical testing experiment (isotropic voxel size of 60  $\mu$ m, 65 kVp, 0.13 mA). The images of the fractured bones were used to accurately determine the fracture line.

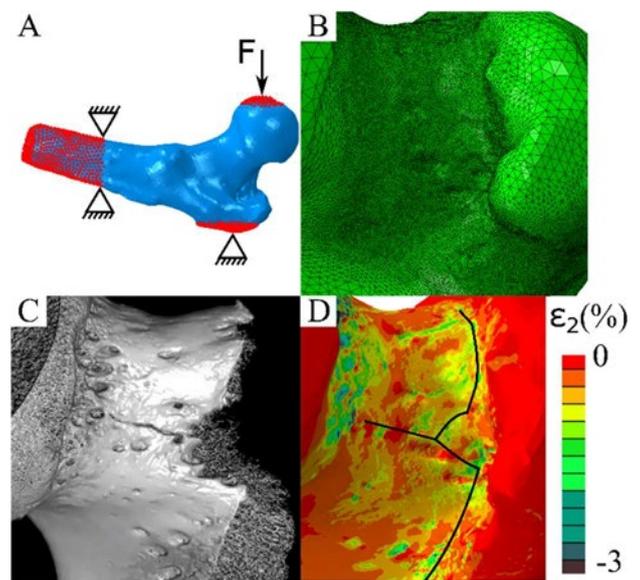

Linear elastic FE models of the proximal femur replicating the experiment were created (Figure 1A). The complete proximal femur was segmented from 8x downsampled  $\mu$ CT images of the intact femur. The lateral neck was segmented from the full resolution  $\mu$ CT images. From the segmentations a mesh was created with high detail in the lateral neck (element size  $\sim$ 0.25 mm) and lower detail in the rest of the femur (element size  $\sim$ 3 mm) (Figure 1B). The elements in the lateral neck were assigned a Young's modulus based on the mineral density obtained from the calibrated  $\mu$ CT images. For the remaining elements, clinical calibrated CT images were used to assign Young's moduli. The applied load was set to 90% of the experimental peak force. Strains predicted by the high-resolution FE models were compared to the strains measured by DIC and the resulting fracture line.

### Results and Discussion

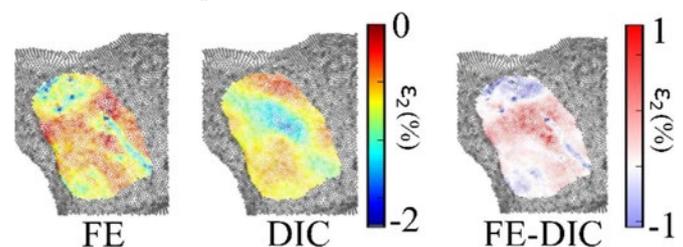

Preliminary results from one subject show that the resulting fracture line goes through some of the larger vessel holes in the lateral neck (Figure 1C). From the high-resolution FE

model we can also see strain concentrations surrounding these vessel holes (Figure 1D). A comparison between the strains predicted by the FE model and the strains measured with DIC reveals similarities in strains surrounding a large vessel hole (Figure 2). Due to the higher spatial resolution of the FE model the high strains are limited to a smaller area and some smaller regions with high strains are revealed that are not captured by the DIC measurements.

Models of the remaining 11 femora are being created to confirm these preliminary findings.

**Figure 1:** A) FE model with boundary conditions. B) Mesh in the lateral neck. C)  $\mu$ CT of the fractured femur. D) Strain in the lateral neck with experimental fracture line indicated in black.

**Figure 2:** A comparison between strains predicted by the high-resolution FE model and strains measured with DIC.

# A model of muscle mechanics elicits the important role of increased baseline tone in joint hyper-resistance in cerebral palsy

## Summary

We propose a neuromechanical model based on a detailed model of muscle mechanics to identify neural and non-neural contributions to joint hyper-resistance as observed during the pendulum test in children with spastic cerebral palsy (CP).

## Introduction

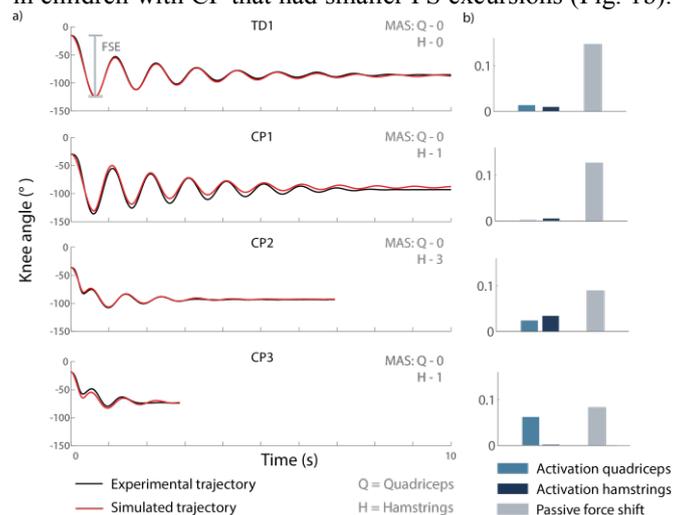

The pendulum test is a clinical test for measuring joint hyper-resistance. To perform this test, the examiner drops the lower leg of a seated and relaxed patient from the horizontal position [1]. The knee angle trajectory is recorded while the lower leg swings freely under the influence of gravity. With increasing levels of spasticity, as measured with the Modified Ashworth Scale (MAS), first swing excursion (FSE) decreases [1]. Yet there is large variability in FSE between children with the same MAS scores [1] (Fig. 1a), which might be caused by different neural contributions, i.e. hyperreflexia and muscle tone, and non-neural contributions, i.e. altered mechanical tissue properties, to joint hyper-resistance [2]. However, distinguishing these contributions based on clinical tests alone is challenging. Here, we propose a neuromechanical model to identify these different contributions. We previously demonstrated that modeling the interaction between short-range stiffness (SRS), a movement history-dependent increase in force upon stretch, and muscle tone was essential to capture the reduced FSE [3]. Yet our torque-driven model failed to explain fine details of experimental kinematics. We therefore modeled muscles by an extended Hill-type model that accounted for SRS. To test whether a muscle-driven model can explain the large variability in pendulum kinematics across typically developing (TD) children and children with spastic CP, we assessed (1) the quality of the fit between measured and simulated kinematics and (2) the differences in parameters between children with CP and TD children.

## Methods

We modeled the lower leg as a pendulum actuated by two antagonistic Hill-type muscles extended with SRS. SRS acted in parallel with the contractile element during the first stretch only since SRS disappears with prior movement, and was proportional to muscle tone and muscle stretch up to a critical stretch [4]. We allowed the onset of passive force development to shift to smaller ( $< 0.1$ , increased stiffness) or longer fiber lengths ( $> 0.1$ , decreased stiffness). We estimated baseline tone of both muscles as well as this shift by optimizing the fit between simulated and measured knee angle trajectories for two to four trials from four children.

## Results and Discussion

We could fit a wide range of pendulum test kinematics (Fig. 1a) by allowing only three parameters to vary (Fig. 1b). We found higher baseline muscle activations and passive forces in children with CP that had smaller FS excursions (Fig. 1b).

**Figure 1:** (a) Experimental and simulated pendulum kinematics. (b) Identified model parameters.

Through muscle mechanics, an increase in baseline tone was coupled to an increase in SRS force, muscle stiffness and damping, which captured changes in pendulum kinematics. Accurate models of muscle mechanics might therefore be important to identify contributions of abnormal muscle tone to joint hyper-resistance. We plan to extend our model with reflexes and to validate it by testing whether the identified model parameters capture the effect of pre-movement on pendulum test kinematics. We recently demonstrated that moving the leg prior to releasing it during the pendulum test, which reduced contributions from SRS, increased the FSE and that this increase was larger in children with CP [5].

## Conclusions

A detailed model of muscle mechanics elicited the important role of increased muscle tone in joint hyper-resistance.

### Summary

Estimation of contact forces is crucial for the assessment of a human joint. In this study, we present a contact model designed to work with automatic differentiation tools, recently shown to have sped up the computation of biomechanical simulations. The implemented contact model was applied in a knee pose estimation analysis, leading to both lower computational time and higher accuracy.

### Introduction

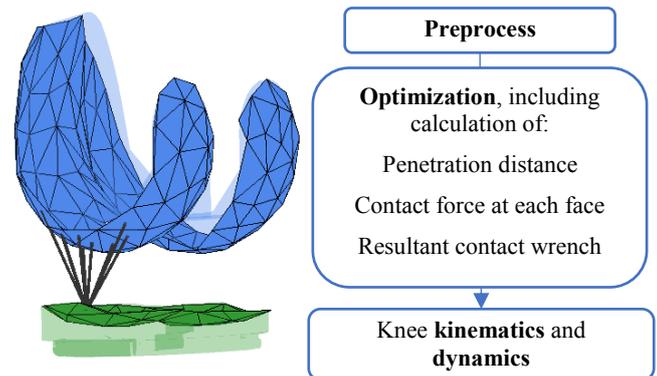

Biomechanical simulations aimed at estimating or predicting joint contact forces need an efficient contact model to obtain feasible solutions in a short period of time. In musculoskeletal simulations, automatic differentiation (AD) tools have been shown to be computationally efficient [1]. Using AD, simulations with complex musculoskeletal models can be up to 20 times faster than using traditional finite differences (FD). These tools exploit the expression graph of the mathematical expressions to obtain derivatives efficiently. However, contact models based on mesh contacts are not suitable for AD tools, since many *if statements* are required during the computation of contact pairs. In this study, we formulated an elastic foundation contact model to be used with mesh contacts and AD tools. The model was applied to a knee-prosthesis pose estimation analysis.

### Methods

The goal of the simulation is to obtain the poses of a tibial tray with respect to a femoral component. Experimental data of knee contact forces and moments and knee kinematics during a gait cycle were obtained from [2]. Before the optimization, the preprocess consisted of choosing the most appropriate mesh refinement and finding the potential pairs of faces to be in contact. The method to automatically calculate the penetration among faces of the mesh during the optimization iterations consists of the following steps: 1) Calculation of distances among potential contact faces (Figure 1); 2) Estimation of the potential penetration distances, similar to [3]; and 3) Identification of the maximum penetration based on a continuous function. After that, contact forces are estimated using the elastic foundation contact model from [4]. Finally, the resultant contact wrench is calculated at the center of the body.

An optimal control problem was formulated to pose the tibial tray as close to the experimental data as possible (cost function) so that the modelled contact forces and moments matched the experimental ones (constraints). The state variables were the six degrees of freedom of the tibial tray and their velocities. Accelerations of the tibial tray and residual

forces and moments were formulated as controls, and minimized in the cost function. The optimal control problem was formulated in CasADi and solved with AD and FD methods.

**Figure 1.** Meshes of the knee prosthesis with an example of potential contacting pairs (left). The process to compute the contact forces within the optimization (right).

### Results and Discussion

The optimization found optimal solutions with both AD and FD methods. The results were faster and slightly more accurate using AD tools (Table 1).

**Table 1.** Results of the optimization for AD and FD.

	iterations	Time (s)	RMSE forces (N)	RMSE moments (Nm)
AD	794	330	14.1 ± 21.3	0.83 ± 0.21
FD	891	563	14.8 ± 18.5	1.15 ± 0.23

### Conclusions

The results suggest that this model can be used in musculoskeletal simulations in combination with automatic differentiation tools. The model could be used to estimate joint contact parameters or to predict human movement.

<sup>2</sup>Mechanical Engineering and Mechanics, Drexel University, United States of America

Email: [bryce.killen@kuleuven.be](mailto:bryce.killen@kuleuven.be)

### Summary

Using a database of 20 subjects, a statistical shape model (SSM) of the hind- and mid-foot was generated using open-source software. The SSM contained distal tibia-fibula, talus, calcaneus, tarsal, and metatarsal bones. SSM-based reconstructions of these bones, for the mean, and first principal component (PC) variations were subsequently used to generate a musculoskeletal model of the hind- and mid-foot. PC variations, variations in geometry and mechanical function of the models were then established.

### Introduction

The ankle-foot is a highly complex structure containing > 20 bones. The complex structure is essential for the function of these joints during dynamic tasks such as walking providing an essential combination of flexibility, stability, and strength. Variations in the shape of any bone and subsequently joints, likely has an impact on the functionality of the ankle-foot. Previous research has applied statistical shape modelling (SSM) methods to assess variations in individual bones [1], and in isolated cases joint geometries [2]. Although providing valuable information, the potential functional impact of these structural variations is rarely considered. Such information could provide valuable information regarding functional interactions between the bones/joints of the hind- and mid-foot. Therefore, the aim of this study was to generate a SSM of the hind- and mid-foot to investigate (1) structural variability in a healthy cohort, and (2) the associated changes in function during simulated stance tasks.

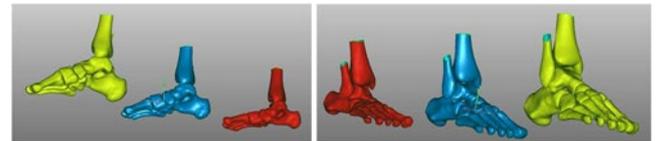

### Methods

Segmentations of the distal tibia-fibula, talus, calcaneus, tarsals, and metatarsals were performed from computed tomography (CT) scans of 20 healthy subjects. Due to irregular scan dimensions, tibia-fibula truncations were inconsistent between subjects. A previously validated SSM workflow [3] was used to (1) reconstruct full tibia-fibula bones for each subject, and (2) perform truncation to consistent anatomical regions. All segmentations were smoothed and re-meshed to the same number of vertices and faces (per bone) based on *a-priori* based on the lowest number of faces/vertices where reconstruction error was <1mm. Individual bones, for each subject, were then merged into a single mesh file. An established SSM workflow [4] was used to generate a SSM of the hind- and mid-foot in a three-step process. The first subject was used as a reference mesh, all remaining subject meshes were then morphed, using radial basis functions, to ensure node correspondence between subjects. Second, a rigid body transformation was performed to remove rotational and translational offsets. Finally, principal component (PC) analysis was used to extract the mean shape and statistical variations in geometry from the population. The mean shape model, and PCs were used to

generate bone models at the extremes of PC1 (i.e.,  $\pm 2$  standard deviation). Mean model, and PC1+2, and PC1-2 bone models were implemented in a dynamic musculoskeletal model [4]. Each model was subjected to cyclic moments between +3.5Nm and -3.5Nm in inversion/eversion. Geometrical properties and load-displacement characteristics were then compared between models.

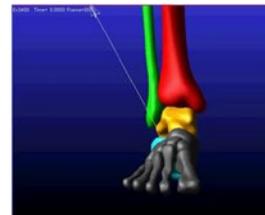

### Results

Comparing morphological differences demonstrate the main differences to be size (PC1-2 < Mean (PC1) < PC1+2) as well as differences in foot type where PC1-2 corresponds to a flat foot, PC1 a normal arched foot and PC1+2 to a high arch foot.

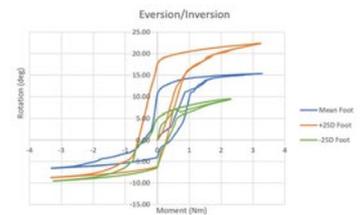

**Figure 1:** Comparison of bone model morphology of the three models: yellow (PC1+2), blue (Mean), and red (PC1-2).

Load-displacement characteristics in inversion/eversion obtained for each of the dynamic models (Figure 2) produced for mean, PC1+2 and PC1-2 were compared (Figure 3). The results clearly show a significant difference in the mechanical properties where PC1-2 (flatfoot) was the stiffest, followed by PC1 (normal arch), followed by PC1+2 (high arch).

**Figure 2:** Dynamic model of the foot (shown PC1+2).

**Figure 3:** Comparison of the ad-displacement properties of the three models.

### Discussion and Conclusions

Variation in the first PC of the SSM model of the foot are associated with variation both in size and foot type i.e., arch height (from flat arch to normal to high arch), these variations also produce significant changes in the mechanical characteristics. These differences may also manifest in other simulated tasks including gait like tasks.

### Summary

We investigated the mechanical and morphological properties of Achilles tendon rupture (ATR) in 24 patients as part of a prospective cohort study – NoARC. Ultrasonography and dynamometry were used to assess the muscle-tendon unit properties of non-surgically treated patients 1-year post rupture. Results showed that injured tendons were 13.5% longer and 93.2% thicker. MG-fascicles were 23.8% shorter and 21.7% more pennated in the injured limb. We found no difference in stiffness between the limbs. Inter-limb difference in MVC was moderately correlated with difference in stiffness ( $r_s=0.45$ ,  $p=0.026$ ) and MG-fascicles length ( $r_s=0.55$ ,  $p=0.005$ ). Poor self-evaluated functional outcome was associated with longer AT resting length ( $r_s=0.64$ ,  $p=0.004$ ). Even when stiffness of non-surgically treated tendons was similar to the un-injured, plantar flexion strength deficit was still present likely due to shorter muscle fascicle length.

### Introduction

Achilles tendon (AT) rupture appears to impair stiffness and elongation of the AT [1,2]. These deficits may alter the overall function of AT in force transmission and affect the triceps surae muscles. Optimal tendon stiffness is essential for efficient economy and performance of locomotion [3]. Understanding how the mechanical properties of the muscle tendon unit change post-rupture is an important pre-cursor to understanding the recovery process.

### Methods

Twenty-four participants (means: 43.2 y, 176.1 cm, 80.9 kg) were treated non-surgically in combination with early mobilization. The Ethics Committee of Central Finland Health Care District approved the study (2U/2018).

MG tendon resting length and AT thickness were measured using a 3.6-cm linear probe (UST-5411; 7.5 MHz, Aloka Alpha, Japan). MG fascicles length and pennation angle were assessed using a 6-cm linear probe (UST-5712; 7.5 MHz). Images were acquired with subjects in prone position with feet relaxed at the end of the table. Patients filled out Achilles tendon rupture score (ATRS) surveys (0-100= no-high impairments) during the 1-year follow up.

Force data were collected at 1 KHz via a transducer in the foot pedal of the ankle dynamometer. During maximal isometric contractions (MVC), displacement of MG muscle-tendon junction was imaged with 6-cm linear probe (UST-

5712; 7.5 MHz) in B mode while calcaneal movement was monitored using potentiometer. Tendon elongation and force were synchronised and fitted to a second order polynomial forced through zero. Tendon stiffness was defined as the slope of the fitted polynomial at 50% of the injured limb MVC. Bilateral differences were tested with t-test and associations with Pearson's correlation.

### Results and Discussion

Injured tendons were longer with a mean difference of 2.5 cm (1.5-3.5 cm;  $p<0.001$ ), and thicker 4.4 mm (3.5-5.1 mm;  $p<0.001$ ). MG-fascicles were shorter in the injured limb with a mean difference of 1.1 cm (0.9 -1.4 cm;  $p<0.001$ ) and more pennated  $4.5^\circ$  (2.6-6.4  $^\circ$ ;  $p<0.001$ ). We did not find statistically significant difference in stiffness 1-year post rupture between injured  $413.4 \pm 186.6$  N/m Vs un-injured  $486.5 \pm 210.2$  N/m. The injured tendon showed lower AT elongation during MVC with a mean difference of 3.5 mm (1.9-5.1 mm,  $p<0.001$ ). MVC difference between n limbs was correlated with difference in stiffness ( $r_s=0.45$ ,  $p=0.026$ ) and MG-fascicle length ( $r_s=0.55$ ,  $p=0.005$ ). ATRS was correlated with difference in AT resting length between limbs ( $r_s=0.64$ ,  $p=0.004$ ).

The persistence of plantar flexor torque deficits, even after stiffness of the tendon was similar to the un-injured, suggest that deficits in force production 1-year post-rupture may be largely due to the shorter length of MG fascicles.

### Conclusions

Non-surgically treated tendons seem to heal at an elongated length, accompanied by MG remodeling at a shorter and more pennate fascicle. Tendon elongation seems to be the associated and likely factor leading to the observed objectively measured and self-reported functional disabilities.

### Summary

The long-term effects of repeated mild joint injuries are an understudied area of research. This mouse model of double mild knee injury events separated by different lengths of time demonstrates cumulative joint pathology and early signs of osteoarthritic change. The greater change observed in injured joints with longer separation times between injuries may have implications for the timing of return to play.

### Introduction

Mild knee injuries characterised by contusions and low-grade sprains are common occurrences in sports players [1]. Prior injuries are associated with a higher risk of recurrent injuries [2] but little is known about the cumulative effects of repeated mild injuries over time or the longer-term impacts on joint health and function. A mouse model was used to investigate the effect of single and repeated mild knee injuries on the risk of major injury (anterior cruciate ligament, ACL, rupture) and joint pathology associated with the onset of osteoarthritis.

### Methods

Ten-week-old male C57BL/6J mice were randomly assigned to 1 of 4 mild knee injury groups: 1) naïve, no-injury (NI) control; 2) single injury (SI); 3) double injury separated by 2 weeks (DI-2w); 4) double injury separated by 4 weeks (DI-4w). Injury was induced by a single tibial compression load on the right hindlimb of anaesthetised mice. The injured knee was evaluated for changes in ACL biomechanics (tensile test: maximum load and stiffness; n=10/group at 14, 16 or 18 weeks of age) or osteochondral gene regulation in the patella and medial/lateral tibial epiphysis (RT-qPCR: *Acan*, *Coll1A1*, *Col2*, *Mmp-2,-3,-9*, *Timp-1,-3*; n=6/group at 14, 16, 18 or 26 weeks of age). A small subset of animals were assessed at 26 weeks for signs of structural histopathology (n=3/group). Data analysis was performed using mixed model regression for the biomechanical data and Kruskal-Wallis for gene expression.

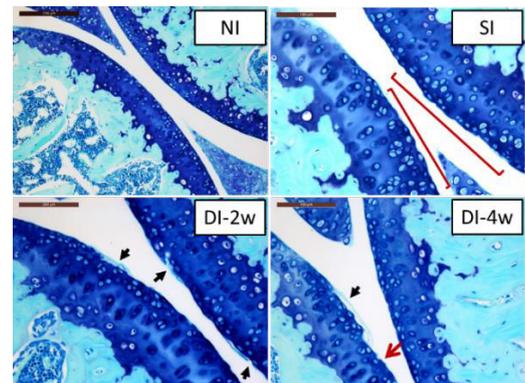

### Results and Discussion

ACL failure load and stiffness were not significantly different between groups, suggesting minimal direct damage to the ACL in this model. ACL stiffness at 18 weeks was significantly lower than earlier time points in all groups ( $P \leq 0.008$ ) except DI-2w ( $P \geq 0.759$ ). It is unclear if the absence of change in DI-2w is related to the timing of the second injury relative to the first injury.

Significant changes in gene expression occurred predominantly in the medial tibial epiphysis and the patella.

In the medial tibial epiphysis, the fold change of *Col2* increased significantly over time in both the SI and DI-2w groups ( $P \leq 0.05$ ). In contrast, *Mmp-3*, *-9* and *Timp1* were significantly upregulated in DI-4w at 26 weeks compared with earlier time points ( $P \leq 0.05$ ). In the patella, *Coll1A1*, *Mmp-2* and *Mmp-3* were significantly downregulated over time in both DI groups ( $P \leq 0.05$ ). At 26 weeks of age, *Mmp-3*, *-9* and *Timp-1* were significantly higher in DI-4w compared with DI-2w ( $P \leq 0.05$ ). These are genes which have been associated with the progression of osteoarthritis.

At 26 weeks all injury groups demonstrated signs of cartilage pathology compared with the smooth surface of NI joints (Figure 1). SI cartilage was roughened; DI-2w cartilage was fibrillated and the lamellar surface lost; DI-4w joints were marked by regions of partial thickness, non-calcified articular cartilage loss and more pronounced focal lesions. These findings suggest that repeated injuries, even when separated by 4 weeks, have cumulative effects on joint tissue integrity.

**Figure 1:** Sagittal toluidine-blue O sections of the knee. NI: smooth joint surface. SI: roughened joint surface (red bars). DI-2w: fibrillated articular cartilage (black arrows). DI-4w: fibrillated (black arrows) and loss of articular cartilage (red arrow).

### Conclusions

In this model there was no increased risk of ligament injury following repeated mild knee injuries however, cumulative damage to other joint tissues was evident even when injuries were separated by longer recovery times (4 vs 2 weeks). Gene expression and structural pathology findings resemble indicators of early osteoarthritis which may have implications for treating patients with idiopathic or accelerated disease.

# Analysis of post-operative osteoblastic activity patterns in unicondylar knee arthroplasties slated for revision

F. Dandois<sup>1</sup>, L. Beckers<sup>1</sup>, H. Vendenneucker<sup>1</sup>, L. Scheys<sup>1</sup>

<sup>1</sup>Institute for Orthopaedic Research and Training, KU Leuven/University Hospitals Leuven, Belgium

Email: felix.dandois@kuleuven.be

## Summary

Clinical evidence is often inconclusive to decide whether or not to revise unicondylar knee arthroplasty. Analysis of post-operative osteoblastic activity has potential to provide additional information to clinically corroborate this decision.

## Introduction

Although revision rates of unicondylar knee arthroplasty (UKA) are higher compared to total knee arthroplasty, two-thirds of UKA revisions are performed without clinical evidence other than patient reported pain [1]. Furthermore, the main UKA failure modes leading to revision can be linked to osteoblastic activity which can be quantified with SPECT-CT imaging. Such imaging thus has clear potential to further our understanding of such failures towards reduced revision rates. Therefore, this study aimed to compare post-operative osteoblastic activity patterns in the tibia between successful UKA's and UKA's slated for revision surgery.

## Methods

SPECT-CT scans were acquired in 23 patients (Age=61±8 years; BMI=29.23±4.71 kg/m<sup>2</sup>) with well-functioning medial UKA's at two years post-operatively. Additionally, SPECT-CT scans were also acquired in 10 patients slated for medial UKA revision surgery (Age=42±25 years; BMI=27.90±4.53 kg/m<sup>2</sup>). For these 10 patients, the interval time between initial UKA and scanning was on average 4.91 years (SD: 4.77, range: 0.96-13.96).

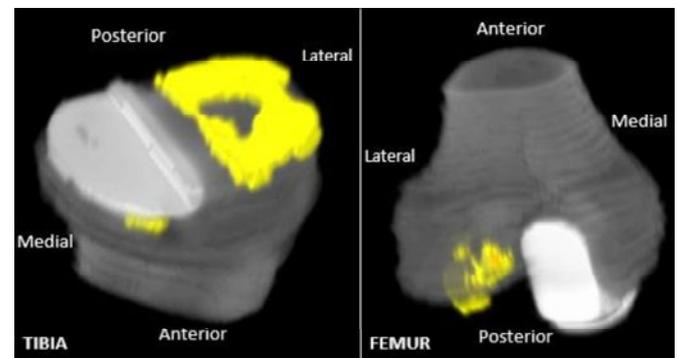

Using validated SCReg platform [2], spatial voxel-to-voxel correspondences were obtained between all SPECT-CT scans through a registration scheme. Osteoblastic activity was normalized according to activity in distal femur. Then, a statistical map was created by performing a Mann-Whitney U test on each voxel to compare successful UKA's and UKA's slated for revision. Finally, for each group, an aggregate map was created by averaging, for each voxel, normalized osteoblastic activity values over all specimens of the group.

## Results and Discussion

Main areas with significantly different normalized osteoblastic activity (p<0.05) were located on (1) the lateral

tibial plateau, (2) the antero-medial cortex at implant level and (3) the lateral femoral epicondyle (Figure 1). For all these regions, increased activity was observed in the UKA's slated for revision (Table 1).

Significantly higher normalized activity on the antero-medial cortex of the tibia was expected as that region is known to be directly involved in two primary modes of UKA failures, i.e. tibial loosening and anterior tibial pain. Concerning the observed differences in the lateral femoral and tibial compartment, we hypothesize this to be related to lateral osteoarthritis progression as another common mode of UKA failure. Finally, the fact that this study cohort included different UKA designs should be noted as a limitation.

**Figure 1:** Location of voxels significantly different between successful UKA's and UKA's slated for revision in terms of post-operative normalized osteoblastic activity

## Conclusions

Analysis of post-operative normalized osteoblastic activity using SPECT-CT imaging has diagnostic potential to confirm or infirm UKA revision surgery by elucidating failure mechanisms.

## Influence of Implant Alignment on Joint Laxity following Medially-Stabilized Total Knee Arthroplasty

Email: orcun.taylan@kuleuven.be

### Summary

Patient satisfaction following total knee arthroplasty relies heavily on postoperative joint laxity, which is known to be influenced by intraoperative implant alignment. This cadaveric study aimed to quantify the influence of such implant alignment parameters on the postoperative knee laxity by performing abduction-adduction stress tests on cadaveric knees. A stepwise multivariate regression analysis indicated that while valgus laxity was influenced by all considered component alignment parameters, varus laxity was influenced only by component alignment in the frontal plane. The impact of individual alignment parameters on postoperative joint laxity revealed by this study could inform intraoperative decisions and related biomechanical outcomes.

### Introduction

Postoperative patient satisfaction and biomechanical outcomes following total knee arthroplasty (TKA) are heavily dependent on intraoperative implant positioning [1]. Although novel techniques (e.g. kinematic alignment) and surgical tools (e.g. robotic-assisted surgery) specifically target improved component alignment [2], the influence of alignment parameters on biomechanical outcomes has not been studied to satisfactory depths. Therefore, this experimental study aimed at quantifying the biomechanical impact of several implant alignment parameters on postoperative joint laxity.

### Methods

Computed tomography (CT) was performed on 14 fresh-frozen cadaveric legs (KU Leuven, Belgium, NH019 2018-11-01) in their native condition, and after performing medially-stabilised TKA (GMK Sphere, Medacta International, Castel San Pietro, Switzerland). Specimens were then mounted on a custom jig whereby the hip was rigidly fixed while the knee was subjected to abduction-adduction stress tests at fixed knee flexion angles (0°, 30°, 60°, 90°). Varus-valgus moments of 10 Nm were generated at the knee by applying controlled tensile loads at the ankle using a handheld digital dynamometer (Mark-10, Copiague, USA). A six-camera optical motion capture system (Vicon Motion Systems, Oxford, UK) was used to track the trajectories of retroreflective marker clusters attached rigidly to the femur and tibia, and compute corresponding tibiofemoral kinematics based on pre-defined anatomical landmarks [3].

3-Matic (Materialise, Leuven, Belgium) was used to measure specimen-specific implant alignment parameters from the available CT-data in terms of hip-knee-ankle angle (HKA), femoral valgus (FV) and tibial varus (TV) in the frontal plane, and tibial slope (TS) in the sagittal plane. Subsequently, a

stepwise multivariate regression model with backward elimination was performed with alignment parameters as independent variables (input) and joint angles as the dependent variables (output), to quantify the influence of component alignment on tibiofemoral kinematics during the varus-valgus stress tests. The Akaike information criterion (AIC) was used for statistical evaluation of parameter weighting.

### Results and Discussion

Post-operative valgus joint laxity was influenced by all considered implant alignment parameters ( $p < 0.001$ ), with TS having the largest impact based on AIC. In contrast, varus joint laxity was influenced only by FV and TV ( $p = 0.002$ ), with the latter having a bigger impact.

Despite standardised intraoperative guidelines for implant sizing and alignment, often based on patient-specific instrumentation, surgeons also rely on experience-based intraoperative evaluation of the joint for subjective deviations from surgical plans. The impact of resulting individual alignment parameters on postoperative joint laxity revealed by this study could further inform such subjective intraoperative decisions, which would directly impact biomechanical outcomes following TKA.

	HKA	FV	TV	TS
<b>Valgus laxity</b>	0.93	-1.16	0.25	0.45
<b>Varus laxity</b>	-	-0.2	0.15	-

**Table 1:** Regression coefficients of various implant alignment parameters (inputs) for joint angles during varus-valgus laxity tests (outputs) calculated using stepwise multivariate regression analysis with backward elimination .

### Conclusions

The positioning of implant components influences postoperative joint laxity following TKA, with certain alignment parameters more vital than others in terms of biomechanical impact. This should be especially considered for intraoperative alterations to patient-specific surgical plans.

### Summary

The role of ACL on the pressure distribution at the knee cartilage during walking is still unclear. The current study showed that loss of ACL changes knee kinetics, resulting in higher pressure than normal at the medial side. Such findings shed light on post-traumatic knee loading conditions.

### Introduction

Understanding how the anterior cruciate ligament (ACL) influences the pressure distribution of the knee during daily activities is crucial for addressing the problem of osteoarthritis onset and progression. Maximum pressure suffered by the knee cartilage during dynamic activities is thought to be the key determinant of local matrix failure [1]. This study aims to explore inherent dynamics and pressure distributions in the ACL deficient (ACLd) knee during walking and compare with the healthy side using knee-specific motion.

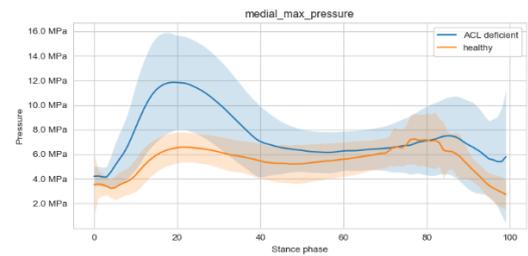

### Methods

Patient cohort included nine participants who sustained an ACL rupture. Knee kinematics and kinetics were calculated during overground walking at self-selected speed for both healthy and ACLd knees, by means of motion capture and musculoskeletal modeling [2]. Medial knee contact pressures were calculated during stance phase for both sides. Muscle activations and knee kinematics were computed using the concurrent optimization of muscle activations and kinematics algorithm [2]. Mean maximum knee contact pressures (max KCP) were calculated and interpolated to 100 points across subjects and gait cycles for both healthy and ACLd knee. Wilcoxon signed rank tests were used to identify significant differences between the two knees across subjects for peak maximum KCP, medial vertical force and tibiofemoral contact area, along with anterior displacement, during the first and second half of the stance phase.

### Results and Discussion

Average curves of medial max KCPs show a double peak profile for both healthy and ACLd knee (Figure 1). Higher variability seen in the ACLd knee compared to the healthy contralateral might indicate a rather highly variable post-

traumatic adaptive strategy for the inflicted side. Max KCPs in the ACLd knee were statistically higher (Table 1) than contralateral only during first peak of stance phase. This effect seems to be the result of higher medial vertical forces and smaller contact area estimated during the first half of the stance for the ACLd knee compared to the healthy side. The latter may be attributed in the excessive anterior translation of the tibia in respect to femur, leading to less available area for contact in the medial cartilage cup.

**Figure 1:** Knee medial max pressure in the healthy and ACL deficient knee along the stance phase of walking.

### Conclusions

Loss of ACL can trigger gait alterations and lead to overloading of knee structures, possibly at the expense of local homeostasis. Larger max KCPs in the ACLd knee found in this study can be associated to high prevalence of knee osteoarthritis seen in this patient group. Current findings provide clinically relevant information regarding the effects of ACL deficiency on gait parameters.

### Summary

In a walking stress test that may be suitable for assessing the acute mechanoreponse to interventions in patients with knee OA we observed that specific blood markers for articular cartilage (i.e. COMP, MMP-3, MMP-9 and resistin) consistently responded to an ambulatory load stimulus while other blood markers did not (i.e. MMP-1, C2C, CII, C2C/CPII, PRG-4, ADAMTS-4). The observed mechanoreponse was exaggerated after load modifying surgery for COMP but remained unaltered for all other markers.

### Introduction

Ambulatory load plays an important role in the initiation and progression of knee osteoarthritis (OA) [1]. High tibial osteotomy (HTO) is a joint preserving surgery aimed at modifying the load distribution at the knee with the goal of slowing the rate of knee OA progression. The response of articular cartilage to ambulatory load can be measured as acute changes in blood biomarkers of articular cartilage [2]. The aim of this study was to determine if load-induced changes in blood markers of articular cartilage change after load modifying surgery in patients with medial compartment knee OA.

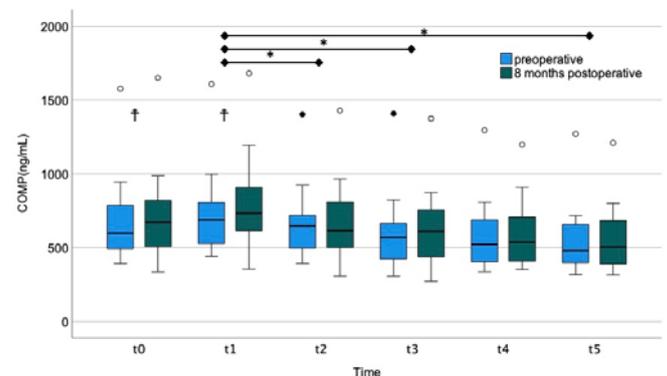

### Methods

Seventeen patients with medial compartment knee OA (12 male; median [interquartile range], age: 44 [36–51] years; body mass: 85.0 [74.0–97.2] kg; height: 1.75 [1.63–1.80] m; body mass index: 29.4 [24.1–31.1] kg/m<sup>2</sup>) completed a walking stress test with blood sampling (30 minutes walking, 5.5 hours sitting) before and 8-months after HTO. Blood samples were taken after 30 minutes of rest immediately before (t<sub>0</sub>) and 0h (t<sub>1</sub>), 0.5h (t<sub>2</sub>), 1.5h (t<sub>3</sub>), 3.5h (t<sub>4</sub>) and 5.5h (t<sub>5</sub>) after the walking stress and analyzed using enzyme-linked immunosorbent assays for cartilage oligomeric matrix protein (COMP), matrix metalloproteinases (MMP)-1, -3, and -9, epitope resulting from cleavage of type II collagen by collagenases (C2C), type II procollagen (CPII), interleukin (IL)-6, proteoglycan (PRG)-4, A disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS)-4 and resistin. We used a non-parametric test (Wilcoxon signed rank test) that does not rely on assumptions of absence of outliers and normality of the data (P<0.05).

### Results and Discussion

COMP at t<sub>0</sub> and t<sub>1</sub> (Fig 1) and IL-6 levels at t<sub>0</sub>, t<sub>1</sub> and t<sub>3</sub> were higher postoperatively than preoperatively. For all other

markers and time points, levels did not differ between baseline and 8-month follow-up. Compared to t<sub>0</sub> levels, COMP and MMP-3 levels were significantly different at t<sub>1</sub>, t<sub>3</sub>, t<sub>4</sub> and t<sub>5</sub>, and MMP-9 and resistin levels were significantly lower at t<sub>3</sub> and t<sub>5</sub>. Inconsistent mechanoreponses were observed for all other blood markers. The decreases in COMP from t<sub>1</sub> to t<sub>2</sub>, t<sub>3</sub>, and t<sub>5</sub> were significantly greater postoperatively than preoperatively (P=0.017; P=0.019; P=0.009, respectively; Fig 1). The load-induced changes in all other markers did not differ between the pre- and postoperative test.

**Fig 1:** Box plots of COMP concentrations during the walking stress test. °outlier; †significant pre- to postoperative difference; \*significant pre- to postoperative differences in decrease from t<sub>1</sub>.

### Conclusions

COMP was the only blood marker to respond to both the ambulatory load stimulus and to load modifying surgery further supporting the relevance of this marker in the context of knee OA and its treatment. Greater IL-6 levels 8 months postoperatively (when the osteotomy has completely healed) are surprising and should be closely monitored as they may counteract potential benefits of altering the load distribution at the knee regarding knee OA progression. In a next step, the relevance of the exaggerated delayed load-induced decrease in COMP levels but not MMP-3 after HTO regarding future progression of the disease and its relationship to the magnitude of ambulatory load must be determined.

## Summary

*In vivo* knee joint kinematics of healthy subjects during level walking were compared to three different total knee arthroplasty geometries using dynamic videofluoroscopy. While individual tibio-femoral rotations and condylar translations could be guided by the implant geometry, variability among the healthy subjects indicates the necessity for different implant geometries, to address individual needs while aiming to restore physiological knee joint function.

## Introduction

Despite the overall high success rates of total knee arthroplasty (TKA) surgery, 16-30% of all patients remain unsatisfied with the outcome, especially during dynamic functional activities [1]. To better identify the mechanisms leading to unsatisfactory results, and thus support correct implant selection in subjects with different limb alignments towards restoration of natural knee function, it is critical to understand the underlying kinematic deficits in TKA knees. Therefore, the aim of this study was to compare *in vivo* kinematics of healthy versus TKA subjects throughout complete cycles of level walking.

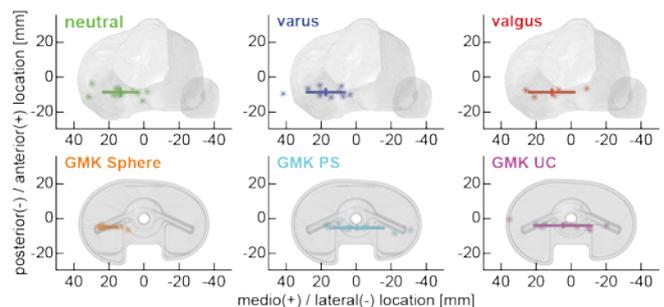

## Methods

27 healthy subjects with different limb alignment (neutral: n=12, Hip-Knee-Ankle angle  $0.5 \pm 1.6^\circ$ ; varus: n=10, HKA  $5.7 \pm 1.8^\circ$ ; valgus: n=5, HKA  $-5.6 \pm 1.5^\circ$ ) and 30 mechanically aligned ( $-3^\circ \leq \text{HKA} \leq 3^\circ$ ) good outcome subjects with a TKA (GMK Sphere: n=10; GMK PS: n=10; GMK UC: n=10) [2] were assessed during 5-6 complete cycles of level walking using dynamic videofluoroscopy [3]. 2D/3D registration of the videofluoroscopic images was performed using 3D models of the bones (CT) or the implant components [4,5]. Tibio-femoral rotations, condylar A-P translations as well as the location of the centre of rotation (CoR) were determined.

## Results and Discussion

While only the GMK UC showed a reduced range of flexion, all three implants exhibited smaller ranges of abduction/adduction as well as tibial rotation compared to the healthy subjects (Table 1). The additional constraints of the implant geometry, especially for the GMK Sphere and GMK UC, can therefore be assumed to restrict axial rotation. While the neutral, varus and GMK Sphere subjects,

exhibited less medial than lateral condylar A-P translation and an overall medial CoR, the valgus, GMK PS and GMK UC subjects demonstrated equal condylar translation and a more central CoR (Table 1, Figure 1). However, in all three alignment groups as well as in the GMK PS and GMK UC group, inter-subject variability was high, resulting in a contrary translational behaviour for certain subjects. Despite these differences, it seems that individual kinematic patterns can be guided by implant geometry but the necessity for different implant geometries to address individual functional needs is also evident.

**Figure 1:** Location of the CoR over the complete gait cycle. Mean  $\pm$  STD over all subjects as well as individual subject means.

## Conclusions

These results can provide a first basis to support clinical decision-making and help to further improve orthopaedic interventions aiming to restore physiological knee joint function. However, intra-operative component alignment remains controversially discussed and further evidence on component alignment and the desirable level of limb alignment correction is needed.

### Summary

This study investigated the effect of carrying handheld weights on knee joint loading, in terms of tibiofemoral contact forces during forward lunge as well as the effect of different positions to carry the weights. Resultant tibiofemoral contact forces increased as handheld load increased. No major effect of position was observed on total knee loading as well as the medial-lateral load distribution.

### Introduction

After musculoskeletal injuries, it is crucial in rehabilitation to progressively reload the injured structures, avoiding to overload the damaged tissue yet providing sufficient stimuli to trigger mechanobiological adaptation processes underlying restoration of homeostasis. To date, exercises are selected primarily based on clinical experience rather than scientific evidence, assuming that when the level of difficulty is increased, higher loads are imposed on the structures [1]. Therefore, this study investigated the effect of adding additional handheld weights and different weight carrying positions during a forward lunge on knee joint loading, in terms of tibiofemoral contact forces.

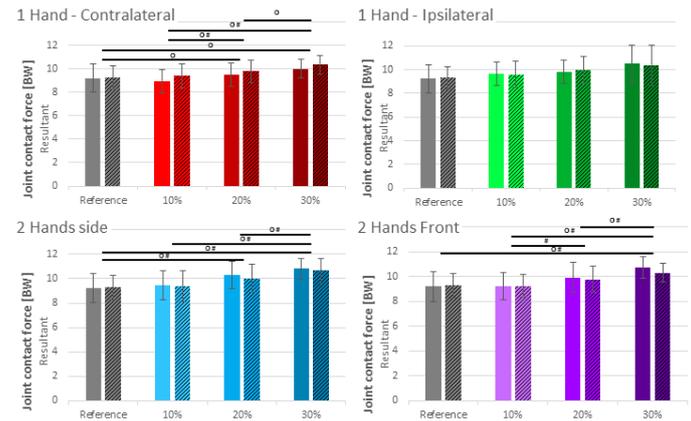

### Methods

10 healthy subjects performed a forward lunge while carrying handheld weights (0%, 10%, 20%, 30% of body weight) in 4 different positions (two hands either side of the body, two hands in front, one hand ipsilateral or contralateral side of the leading limb). Markers were attached to the body according to an extended plug-in-gait markerset and 3D motion capture data was recorded using a 10 camera vicon system (100Hz). Simultaneously, ground reaction forces were recorded under the leading limb (1000Hz). The data were processed using the Catelli model for deep knee flexion and a standard musculoskeletal modelling workflow in OpenSim 3.3 to estimate the peak resultant tibiofemoral contact forces of the leading limb during the weight-acceptance and push-off phase of the forward lunge [2,3]. The distribution of the vertical contact force over the medial and lateral compartment was calculated based on the method proposed by Winby et al., (2009) [4]. A two-way analysis of variance (ANOVA) was used to evaluate the effects of added weights and weight position on the peak knee contact forces as well as the joint kinematics and kinetics (external moments) and medial and lateral contact forces at instance of peak loading.

### Results and Discussion

With increasing weight, external joint moments significantly increased. In addition, with increasing weight lumbar flexion increased significantly, whereas knee flexion angle was not

affected by adding weights. Resultant tibiofemoral contact forces significantly increased with increasing weight (Figure 1). During the different lunge variations, the medial compartment was loaded more compared to the lateral compartment.

**Figure 1:** Effect of adding weights on peak knee contact forces during weight-acceptance (solid bars, # indicates significance) and push-off phase (hatched bars, O indicates significance).

Frontal plane knee moments were affected by weight position, where a significantly increased knee adduction moment was observed for the contralateral weight position and a significantly increased knee abduction moment for the ipsilateral weight position. However, no significant effect of weight-carrying position on resultant knee contact force was observed, nor did it affect the medial-lateral loading distribution, lateral contact forces were only increased when carrying the load at the ipsilateral side compared to the contralateral side in the 10%BW condition ( $2.97 \pm 0.58$  BW vs  $2.69 \pm 0.45$  BW, respectively).

### Conclusions

Resultant tibiofemoral contact forces increased as external load increased. No major effect of weights position was observed on total knee loading. However, carrying added weights had limited effect on load distribution (despite altered frontal plane joint moments) justifying further investigation in support of evidence-informed clinical care.

## High tibial osteotomy effectively redistributes compressive knee loads during walking

Enrico De Pieri<sup>1,2</sup>, Corina Nüesch<sup>2,3,4,5</sup>, Elke Viehweger<sup>1,2,6</sup>, Christian Egloff<sup>2,3,5</sup>, Annegret Mündermann<sup>2,3,4,5</sup>

### Summary

This study analyzed ambulatory knee loads in patients who underwent high tibial osteotomy (HTO) by means of musculoskeletal modeling. HTO effectively unloads the medial knee compartment while increasing the compressive load on the lateral one.

### Introduction

The development of degenerative joint diseases such as knee osteoarthritis (OA) is often determined by altered joint mechanics that lead to increased or abnormal intra-articular forces [1]. Individual variations in ambulatory knee mechanics can influence the rate of progression of cartilage degeneration [2]. High tibial osteotomy (HTO) is a well-accepted surgical procedure for patients with knee OA and varus alignment aimed at re-establishing a more even distribution of ambulatory load between the affected medial and the lateral knee compartment. We hypothesized that HTO would reduce the knee adduction moment and the medial compartment compressive force while increasing the compressive load in the lateral compartment in a cohort of patients with medial knee OA.

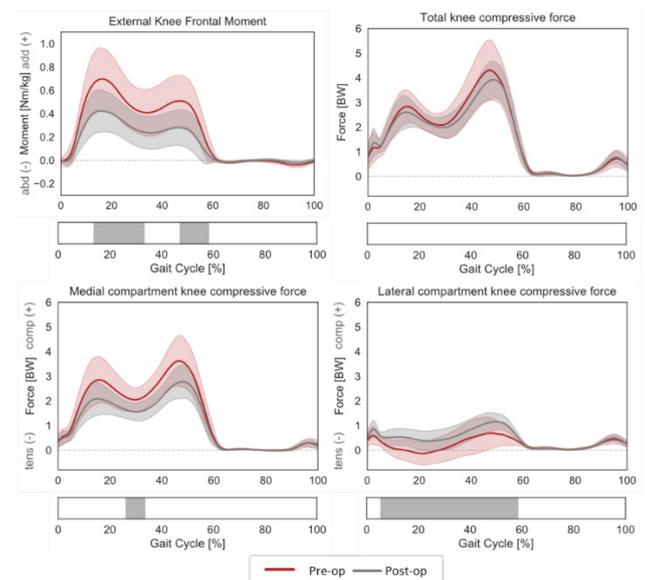

### Methods

Twelve patients (mean  $\pm 1$ SD, age:  $45 \pm 9$  years) diagnosed with isolated symptomatic medial compartment knee OA underwent opening wedge HTO. Kinematic and kinetic data were recorded using the Plug-In Gait model in 3D gait analysis sessions before (pre-) surgery as well as  $9 \pm 3$  months postoperatively. The collected motion capture data was used as input for an inverse dynamics analysis (AnyBody Technology, Denmark) to evaluate external knee moments and knee contact forces. Personalized models were created from a generic lower-limb model [2], scaled according to marker data from a static trial. Knee varus/valgus alignment was estimated from the static trial and implemented as a fixed change in orientation of the knee joint axis. The distribution of the compressive knee force across the medial and lateral compartments was evaluated [4]. Differences between pre- and postoperative knee adduction moment, as well as total, medial, and lateral knee compressive forces were evaluated over the whole gait cycle through statistical parametric mapping (SPM), with one-tailed paired t-tests ( $\alpha = 0.05$ ).

### Results and Discussion

Modelled mean varus knee alignment in the cohort was  $7.2 \pm 3.7^\circ$  preoperatively and reduced to  $1.3 \pm 3.2^\circ$  after HTO. A statistically significant reduction in the postoperative external

knee adduction moment was observed during mid and terminal stance leading to a reduction in the medial compartment compressive force during mid stance and an increase in lateral compartment compressive force during most of the stance phase. The total compressive load through the knee did not present any statistically significant difference.

**Figure 1:** Predicted internal knee adduction moment, and total, medial, and lateral knee compressive forces in patients before (red) and after (grey) HTO. Significantly different phases of the gait cycle are indicated as grey bars below each force component.

### Conclusions

HTO effectively unloads the medial knee compartment by redistributing part of the overall compressive force to the lateral compartment during gait. The timing of reductions in compressive force may not always coincide with the timing of reductions in knee adduction moments suggesting that the knee frontal moment may not adequately describe ambulatory load or changes induced by interventions at the compartment level.

## Assessment of variations in scapular morphology and bone quality in patients with B glenoids

### Summary

A systematic description of variability in the scapular shape and bone mineral density (BMD) distributions in shoulder osteoarthritis (OA) can be valuable input for implant design and surgical intervention, especially in surgically challenging glenoids with asymmetric posterior erosion. Statistical shape (SSM) and intensity modeling (SIM) of these patients identified changes in the posterior and inferior shape of the glenoid cavity as main shape variations, whereas BMD variations were identified in all regions of the glenoid cavity, except for the posterior part of the bone consistently demonstrating the highest bone density.

### Introduction

Shoulder osteoarthritis (OA) occurs in up to 20% of the population. In Bercik et al.'s classification, B glenoids comprise 32% of this population. It is characterized by asymmetric posterior wear of the glenoid and associated with regional bone density variations, which pose a known challenge for glenoid component fixation and survival in total shoulder arthroplasty surgery (TSA). Literature reports that at a minimum follow-up of 24 months after TSA surgery around 50% of the B glenoids demonstrated evidence of radiological glenoid component loosening [1]. Therefore, a systematic description of variations in BMD and morphology within this specific patient group can serve as valuable information for categorizing patients in terms of the risk of glenoid component loosening. The main objective of this study was therefore to develop a statistical shape and intensity model of the scapula for patients with B glenoids and describe their principal modes of variations.

### Methods

The training dataset for the pathological SSM and SIM consisted of 31 CT images from subjects with B glenoids, as judged by an experienced shoulder surgeon. 3D surface full scapular models were constructed from the segmented images in Mimics (Materialise®, Belgium) after which an open-source non-rigid registration algorithm was used to obtain point-to-point correspondences between subjects and a generic surface template mesh [2]. For developing the SIM, volumetric registration was performed by elastically deforming the corresponding generic volumetric template mesh to each training subject driven by the known displacements between the surface nodes on the template and the corresponding surface nodes of each subject, using Abaqus software (Dassault Systemes Simulia Corp., Providence, RI, USA) [3]. Each scapular mesh was then transformed back into its original CT coordinates and Hounsfield units (HU) were assigned to each volumetric mesh' nodes. Corresponding BMD for each nodes was

defined using existing mathematical relationships between HU and BMD [3]. Finally, the SSM and SIM was established through principal component analysis after which the main modes of variations in both models were interpreted by perturbing the mean by  $\pm 2$  standard deviations.

### Results and Discussion

The first five modes of the SSM and SIM represent 79.2% and 51.1% of their corresponding variability, respectively. Except mode 1 of the SSM, primarily describing a uniform scaling of the scapula, changes in the posterior and inferior shape of the glenoid cavity were observed in the subsequent four modes. Based on the SIM of this study, the posterior part of the glenoid was observed to have the highest average bone density in B glenoids. This contrasts with the glenoid bone of healthy subjects where the center of the glenoid typically has the best bone quality [3]; but is in agreement with previous studies investigating BMD in large sub-regions of asymmetric glenoids with OA [4]. Furthermore, the first principal mode of the SIM (15.6% of variability), described variations in glenoid BMD in the anterior-inferior region, while the second mode (13% of variability) primarily described differences in BMD affecting the other regions (Figure 1).

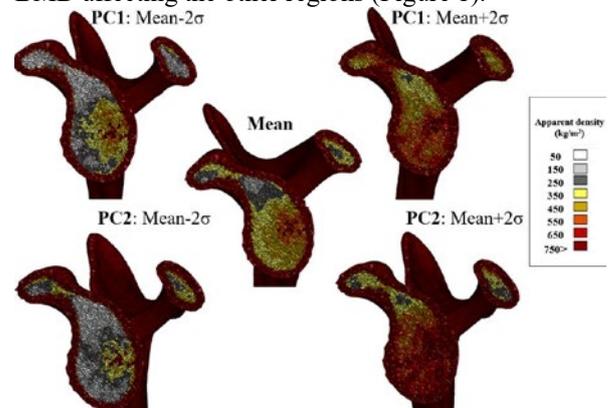

Figure 1: Variation in the bone mineral density of the B glenoids.

### Conclusions

In B glenoids, higher bone density was found in posterior region of the glenoid. Nevertheless, important variations in the other regions should be taken into consideration before surgical intervention. These findings highlight the potential of SSM and SIM for assessing variations in shape and bone quality among pathological subjects.

# Impact of personalized geometry and motor control on musculoskeletal simulation results – How much detail is needed?

Hans Kainz<sup>1</sup>, Mariska Wesseling<sup>2</sup>, Ilse Jonkers<sup>2</sup>

<sup>1</sup>Neuromechanics Research Group, Centre for Sport Science and University Sports, University of Vienna, Vienna, Austria

## Summary

We compared musculoskeletal simulation results from highly subject-specific models with less sophisticated models. The impact on gait deviation was evaluated based on root-mean-square-differences (RMSD) in simulation results between children with cerebral palsy (CP) and a typically developing (TD) child. The modelling choice had a minor impact on joint kinematics and kinetics. Muscle and joint contact forces were more sensitive to the modelling choice. The impact of including subject-specific musculoskeletal geometry was higher than the impact of including electromyography (EMG) data. Gait deviation was similar between modelling frameworks.

## Introduction

Musculoskeletal simulations can improve clinical-decision making in children with CP [1]. Typically, linear scaling methods based on surface markers are used to personalize generic models to each participant's anthropometry [2]. Subject-specific musculoskeletal geometry and motor control is mostly neglected in the models and simulations due to the tedious process which is required to create highly personalized models. To assess the impact of these simplifications, we compared the simulations results from highly subject-specific models with linearly scaled generic models.

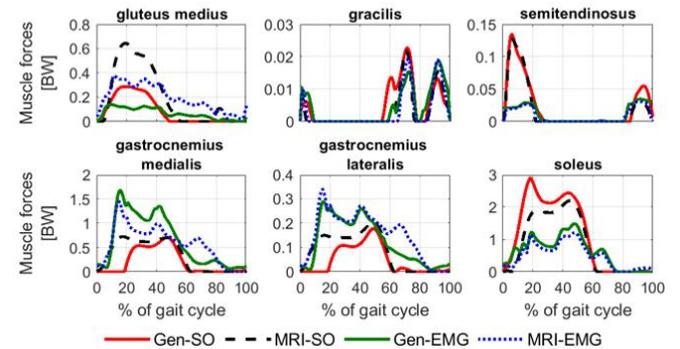

## Methods

Magnetic resonance images (MRI) and gait data of one TD child and three children with CP were analyzed. For each participant a generic-linear scaled and MRI-based model were created based on a previously developed workflow [3]. Musculoskeletal simulations were performed using four modelling frameworks: 1) Generic-scaled model with static optimization, 2) Generic-scaled model with an EMG-informed approach [4], 3) MRI-based model with static optimization, and 4) MRI-based model with an EMG-informed approach. Joint kinematics, joint kinetics, muscle forces and joint contact forces were calculated with OpenSim [2] and compared between modelling frameworks. The impact on gait deviation was evaluated based on RMSD in simulation results between children with CP and a TD child.

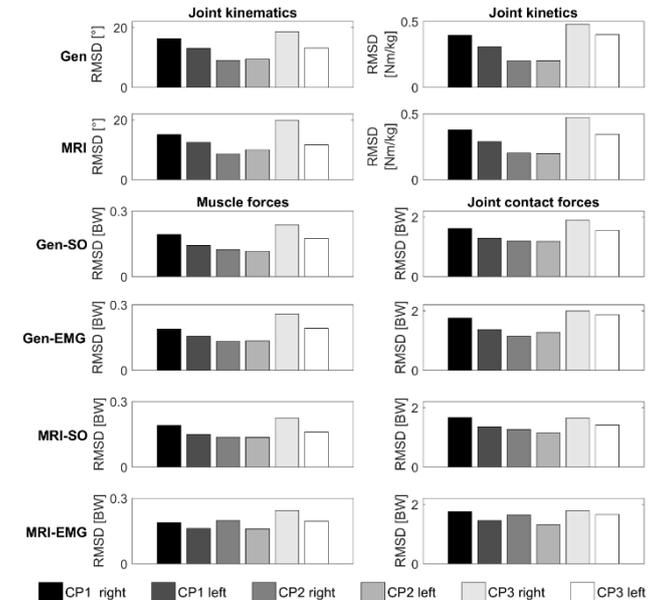

## Results and Discussion

RMSD in joint kinematics and kinetics between generic-scaled and MRI-based models were below 5° and 0.15 Nm/kg, respectively. RMSD over all muscles was below 0.2 body weight for every participant. Nevertheless, differences of ~200% in maximal individual muscles forces were observed in some participants (Figure 1). RMSD in joint contact forces between the different modelling frameworks were up to 2.2 body weight. Comparing the musculoskeletal simulation

results from the TD child with the results from the children with CP showed similar RMSD for all modelling frameworks (Figure 2).

**Figure 1:** Example of muscle forces from one participant with CP calculated with the four different modelling frameworks.

**Figure 2:** RMSD in simulation results between our participants with CP and the TD child. The overall trend was similar across modelling frameworks.

## Conclusions

Overall group effects based on RMSD between CP and TD children are unlikely affected by the modelling choice, whereas caution is warranted if simulations are used to evaluate specific musculoskeletal parameters of an individual.

## Altered triceps surae muscle dynamics and force demand at different stride frequencies.

Wannes Swinnen<sup>1</sup>, Wouter Hoogkamer<sup>2</sup>, Friedl De Groot<sup>1</sup>, Benedicte Vanwanseele<sup>1</sup>

### Summary

While it is well recognized that the preferred stride frequency (PSF) in running closely corresponds with minimal energy consumption, the underlying mechanism is still unclear. Changes in ankle and knee joint mechanics when altering stride frequency are likely to affect triceps surae dynamics. Here, we investigated triceps surae muscle dynamics and force production in 10 runners while running at five different stride frequencies using ultrasound imaging (for Soleus, SOL and Gastrocnemius medialis, GM) and dynamic optimization. When deviating from PSF both SOL and GM muscles operated at shorter lengths during ground contact, implying a reduced force capacity, while average muscle force demand was increased. Differences were most pronounced at lower than preferred stride frequencies especially for SOL. Our results shed new light on the mechanisms that may be at least partly responsible for the increased energy consumption observed when deviating from PSF.

### Introduction

Self-optimization, i.e. intrinsically adopting kinematics and kinetics associated with minimal energy consumption, is a well-known phenomenon in running with stride frequency often used as a textbook example. While the concept is well recognized, it is still unclear why a certain stride frequency corresponds with minimal energy consumption. Yet, previous research demonstrated that altering stride frequency affects lower limb kinetics and kinematics [1] presumably affecting muscle-tendon dynamics and thus possibly altering energy consumption. One important muscle-tendon unit is the triceps surae, spanning both the ankle and knee joint, and consuming 25% of the total metabolic energy rate [2]. Here, we investigated how the triceps surae muscle dynamics and force production are affected when changing stride frequency.

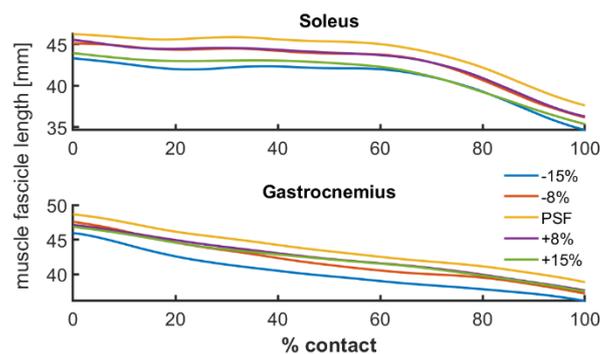

### Methods

10 experienced runners ran on a force measuring treadmill at 12 km/h while adopting five different stride frequencies (PSF; PSF  $\pm$  8%; PSF  $\pm$  12%). During each trial, we measured lower limb kinematics and kinetics, metabolic energy expenditure and SOL (N = 9) and GM (N = 10) muscle fascicle behavior through dynamic ultrasound. Next, we used a dynamic optimization algorithm to individualize triceps surae muscle-tendon parameters of a musculoskeletal model (including 43 lower limb muscles), using the SOL and GM ultrasound images [3]. To estimate triceps surae muscle forces, we solved a new muscle redundancy problem, now including the individualized muscle-tendon parameters, by minimizing the muscle activation squared of all 43 lower limb muscles.

### Results and Discussion

Runners consumed the least metabolic energy while running at PSF. During ground contact, we found significant shorter fascicle length and greater pennation angle when deviating from PSF for both muscles (**Figure 1**). In contrast, fascicle velocity was not different during mid-stance when muscle forces were highest. Average muscle force during ground contact was lower when running at PSF. Post-hoc analyses revealed significantly lower average force production at PSF compared to -15% for SOL and +15% for GM.

During running, the triceps surae muscles are operating on the ascending limb of the force-length relationship [4] and hence shorter lengths imply reduced force capacity. As our results also demonstrated increased triceps surae force demand when deviating from the PSF, muscle activation and subsequently muscle energy consumption is likely to be increased. Especially at frequencies lower than PSF, shorter operating lengths and increased force demand (only for SOL) are most prominent.

**Figure 1:** SOL and GM fascicles lengths throughout ground contact phase at different stride frequencies.

### Conclusions

Our results indicate that increased energy consumption when deviating from PSF is at least partly the result of both reduced triceps surae force capacity and increased force demand.

### Acknowledgments

WS obtained a PhD fellowship from the Research Foundation Flanders (11E3919N).

# Predictive simulations of hemiparetic gait to explore the effects of muscle weakness on walking asymmetry and energetics

Tom J.W. Buurke<sup>1</sup>, Geert Verheyden<sup>2</sup>, Friedl De Groot<sup>1</sup>

<sup>1</sup>Department of Movement Sciences, KU Leuven, Leuven, Belgium

<sup>2</sup>Department of Rehabilitation Sciences, KU Leuven, Leuven, Belgium

## Summary

We used predictive simulations to explore the effect of unilateral muscle weakness on step length asymmetry and metabolic cost of transport. 90% unilateral plantar flexor, dorsiflexor, and knee flexor weakness, but not knee extensor or hip flexor/extensor weakness, led to step length asymmetry. Imposing step length symmetry increased the cost of transport for all simulations. These results suggest that walking with asymmetric step lengths after stroke may be more economical than imposing symmetric step lengths.

## Introduction

Post-stroke hemiparetic walking is often characterized by step length asymmetry, which is associated with an increased metabolic cost of transport compared to able-bodied walkers. Research suggests that reducing step length asymmetry may reduce the cost of transport [1], but the different underlying impairments in muscle function, motor control, and sensory function and their interactions complicate investigation of the relationship between improving step length symmetry and cost of transport post-stroke [2]. With predictive simulations based on neuromusculoskeletal models [3], we can study the isolated effects of different impairments on walking symmetry and energetics. Here we study the isolated effects of muscle weakness of the hip, knee, and ankle flexor and extensor muscle groups on step length asymmetry and cost of transport. In addition, we impose step length symmetry on the simulations, to investigate the effect of reducing asymmetry on the cost of transport in hemiparetic walking.

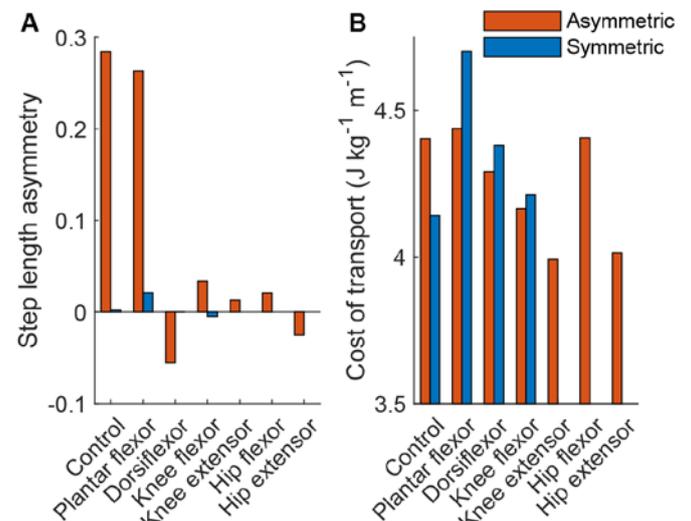

## Methods

We used an existing neuromusculoskeletal model with 31 degrees of freedom and 92 muscles. Gait mechanics and energetics were predicted by minimizing a multi-objective cost function containing muscle effort, metabolic cost, and joint accelerations while imposing gait speed ( $1.33 \text{ m s}^{-1}$ ) and periodicity as described in [3]. First, we performed a control simulation without weakness. Then, we simulated 90% unilaterally (left side) reduced maximal isometric force on six muscle groups (Fig. 1). Second, we added step length symmetry constraints to the simulations where a substantial asymmetry ( $>0.03$ ) occurred in the initial simulation. Third, we imposed a step length asymmetry constraint on the control simulation, which matched the largest asymmetry from the weakness simulations. We compared step length asymmetry ( $SL_{\text{left}} - SL_{\text{right}} / SL_{\text{Left}} + SL_{\text{Right}}$ ) and cost of transport ( $\text{J kg}^{-1} \text{ m}^{-1}$ ) between simulations.

## Results and Discussion

The results (Fig. 1) show a substantial step length asymmetry with a longer paretic step in the simulations of unilateral

plantar flexor (0.26) and knee flexor (0.03) weakness and shorter paretic step in dorsiflexor weakness (-0.06). Furthermore, we found an increase in the cost of transport in simulations of unilateral plantar flexor (7.2%), dorsiflexor (3.6%), and hip flexor weakness (6.4%). When we imposed step length symmetry upon the plantar flexor, dorsiflexor, and knee flexor weakness simulations, this led to a further increase in the cost of transport in all three simulations (resp. 5.9%, 2.1%, 1.1%). Finally, imposed step length asymmetry (0.28) in the control simulation led to a 6.4% increase in the cost of the transport.

**Figure 1:** A) Step length asymmetry and B) cost of transport outcomes of predictive simulations of symmetric and asymmetric walking with weakness of different muscle groups.

## Conclusions

Unilateral weakness of the more distal, but not proximal, muscle groups leads to step length asymmetry. Walking with asymmetric step lengths after hemiparesis may be more economical than walking with imposed symmetric step lengths. Further research is necessary to understand the effect of muscle weakness on walking stability and the interaction of muscle weakness with other impairments after stroke.

## Biomechanical Analysis of Industrial Exoskeletons

Ulrich Glitsch, Jasper Q. Johns, Kai Heinrich

Institute for occupational safety and health (IFA), Sankt Augustin, Germany

Email: ulrich.glitsch@dguv.de

### Summary

In an interventional study with 12 participants, the biomechanical effects of a passive trunk supporting exoskeleton during symmetric lifting tasks were investigated. Based on biomechanical motion analysis in combination with inverse dynamics modelling, the exoskeleton supportive function and the musculoskeletal loadings were determined. The presented approach aimed to provide comprehensive insights into the biomechanical effects of an industrial exoskeleton on the musculo-skeletal system, which could be applied in a similar manner to other exoskeleton types and working tasks.

### Introduction

In recent years, more and more exoskeletons were introduced to the commercial market specifically for use in industrial workplaces. Although discrete benefits of exoskeletons were already described in numerous laboratory studies [1], the actual overall benefit in industrial practice is still largely unknown. Many studies provided only a very restricted set of parameters, which limits the biomechanical understanding of the exoskeleton's supporting function related to a designated working task.

The goal of the present study was to establish a fundamental biomechanical approach for analyzing the supporting effect of an industrial exoskeleton on the musculo-skeletal loading of the relevant body region.

### Methods

Twelve healthy subjects (8 males, 4 females) volunteered in the interventional study, in which a passive commercially available trunk supporting exoskeleton consisting of a rigid segmented structure (mass = 3.3 kg) was used. Repeated symmetric lifting tasks (from below knee level to pelvis level) with weights of 10 and 20 kg were analyzed using a combined motion capture setup (12 cams Vicon, 2 Kistler force plates, bilateral lumbar and thoracic erector spinae EMGs). The support torque characteristic of the exoskeleton was experimentally determined using a digital force gauge and a digital inclinometer.

The lumbar moments and the compression forces (L4-L5) were determined by applying an inverse dynamics model [2, 3]. Repeated measures ANOVAs were conducted for each output variable of the lifting trials (SPSS V23).

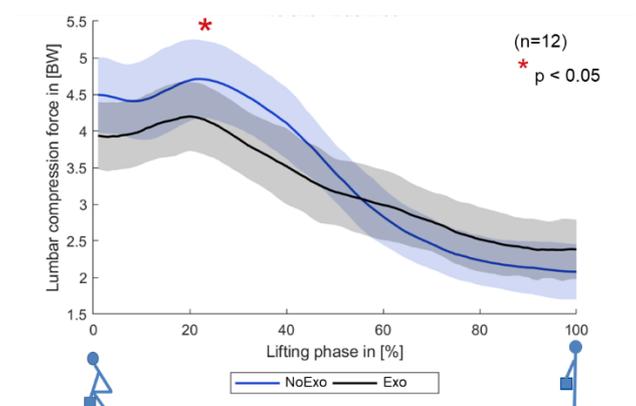

### Results and Discussion

During flexion, the supportive torque of the exoskeleton achieved a maximum of 45 Nm at about 84°. During

extension, the hysteresis effect reduced the supportive torque on average of about 50%.

Use of the exoskeleton significantly reduced the maximum lumbar joint moments by an average of 19% to 20% (10/20 kg). Averaged over the entire lifting phase, significant stress alleviation effects of 6% to 8% were observed. Similarly, the maximum lumbar compression forces were significantly reduced by an average of 17% to 18% (10 / 20 kg) (Figure 1). Averaged over the entire lifting phase, the forces were significantly reduced by an average of 5% to 7%.

The EMG of the back extensors revealed significant reductions of peak values by an average of 18% to 27%. In contrast, mean EMG-values did not change significantly.

**Figure 1:** Mean and SD time histories of lumbar compression forces ( $\times$  bodyweight) during lifting of a 20 kg weight.

When using a (passive) exoskeleton, the effective reduction of the lumbar loads might be less than proposed by the manufacturer or even compared to other studies [1].

### Conclusions

For the biomechanical assessment, a comprehensive approach is necessary to enlighten the functional interaction of an exoskeleton with the musculo-skeletal system and sufficient intermediate parameters have to be provided, making the assessment transparent. The presented approach may be a proposal for establishing a standardization in the biomechanical assessment of industrial exoskeletons.

# A multiscale constitutive description for load bearing soft biological tissue that incorporates the interfibrillar sliding of constituent collagen.

C. Miller<sup>1</sup>, T.C. Gasser<sup>1,2</sup>

<sup>1</sup>Solid Mechanics unit, Dept. Engineering Mechanics, KTH Royal Institute of Technology, Stockholm, Sweden

<sup>1</sup> Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark

## Summary

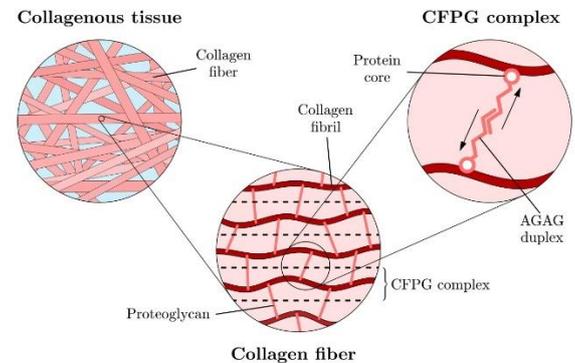

A generalized multiscale constitutive framework is outlined that specifically accounts for several key features of the collagenous microstructure. Specifically, the continuous recruitment of undulated collagen fibrils and their time-dependent relative sliding are included. Macroscopic tissue properties are captured for numerous types of loading [1].

## Introduction

Soft biological tissues are composed of numerous extracellular matrix (ECM) proteins. Their complex structural arrangement and interaction define their macroscopic material properties. Fibrous collagen is known to be the principal load bearing ECM constituent. Its hierarchical architecture and deformation mechanisms that act over multiple length scales, greatly determine observed physical phenomena. Furthermore, current evidence for various tissue types suggests that the interlinking of collagen fibrils by proteoglycans (PG's) promotes the relative sliding of fibrils and influences features such as stress relaxation, strain-rate sensitivity, and the transitioning point of the mechanical response [2,3].

## Methods

A 1D model for a collagen fibril proteoglycan (CFPG) complex is employed, where overloaded fibrils are considered to reduce their loading through a time-dependent PG facilitated sliding. It is assumed that this sliding enables fibrils to reach a homeostatic target stress that can be inferred from physiological loading conditions. The sequential straightening of fibrils is described by a probability distribution, and the overall response of a collagen fiber is obtained through a novel integration strategy over all CFPG-complexes. The fiber model is subsequently numerically integrated over the unit sphere using spherical t-designs. This well established framework determines the macroscopic stress contribution of collagen at the Gauss point level and has been applied to the description of collagen fiber reinforced soft tissue previously [4]. Collagen fiber orientation varies greatly between different tissue types, a feature that greatly determines their overall mechanical response and function. This methodology readily accounts for this as it permits the inclusion of appropriate orientation density functions to characterise the tissue of interest. Furthermore, the contribution of non collagenous matrix material is described by a classical isotropic Neo-Hookean model.

**Figure 1:** Hierarchical structural diagram of collagenous soft tissue microstructure. Collagen fibers are assembled by numerous CFPG-complexes, which consist of a collagen fibril and interconnecting PG's. PG's themselves are composed of a protein core and a GAG duplex that allows for a time dependent sliding deformation.

## Results and Discussion

The outlined framework was applied to the uniaxial deformation of the human Calcaneal tendon. A transversely isotropic collagen fiber distribution was assumed as they are arranged predominantly along the axis of loading. The model was able to qualitatively capture nonlinear strain dependent stress relaxation in tendons, with increased strain leading to increased rates of relaxation. It was also able to characterize nonlinear creep phenomena, with significant applied stress leading to propagating creep failure. Finally, strain rate stiffening behavior was observed as increased strain rates inhibit the development of interfibrillar sliding, leading to a stiffer response.

## Conclusions

The discussed constitutive model is informed by soft tissue histology and the microstructural deformation mechanisms that characterize the tissues overall mechanical response. Through accounting for interfibrillar sliding in particular, the model was able to successfully describe the non linear viscoelastic behavior of tendons, correlating well with experimental findings in the literature. The outlined framework is generally applicable to numerous soft tissue types and is well suited towards further expansion and the investigation of collagens role in both tissue failure and remodeling.

## Complementary Functions of the Joint Morphology and Ligaments in Providing Stability to First the Carpometacarpal Joint

### Summary

A morphology-function model was created to assess the influence of variability in bony anatomy of the first carpometacarpal (CMC) joint and the translation of the joint when there is disruption to the ligaments. Variation in first metacarpal torsion and articular tilt angles contributed the most to the variability in first CMC joint translation.

### Introduction

The first CMC joint depends on its ligaments to provide stability. However, it is not clear how the morphology of the first metacarpal and trapezium works with the ligaments in maintaining joint stability. Hence, the objective was to use a morphology-function model to determine the interplay between the ligaments of the first CMC joint and its bony morphology in preventing joint subluxation.

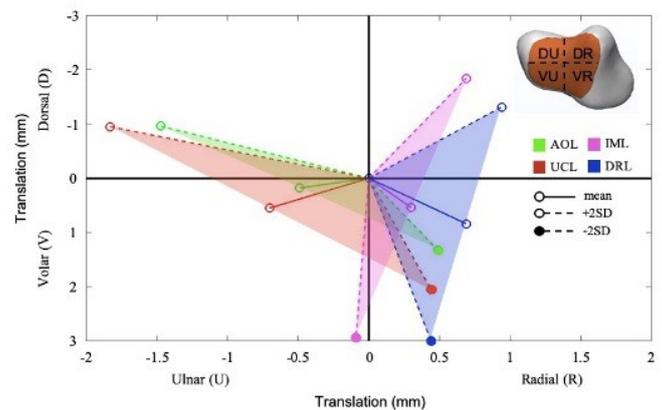

### Methods

Sixteen specimens (8 males; 52.4±11.7 years, 7 left hands) were used in this study. Semi-automatic segmentation was done to computed tomography images of the specimens using MIMICS (v.17, Materialise, Belgium) to obtain 3D models of the first metacarpal and trapezium. ***In-vitro experiment:*** The first and second metacarpals, trapezium and trapezoid were removed from each specimen, taking care not to violate the first CMC joint capsule. The distal end of the first metacarpal was fixed in a specimen holder. The trapezium, trapezoid and proximal end of the second metacarpal were similarly fixed. An Instron testing machine equipped with a customised jig was used to apply external loads to the specimen in its neutral orientation. Each specimen was tested during intact and ligament sectioned conditions. Four ligaments were sequentially sectioned – anterior oblique ligament (AOL), ulnar collateral ligament (UCL), intermetacarpal ligament (IML) and dorsal radial ligament (DRL). The position of the joint in its intact state was taken as the baseline. ***Anatomical features:*** The first metacarpal articular tilt and torsion angles and length and width of the first metacarpal facet on the trapezium were measured on the 3D model of each of the specimens (ver. 9, Materialise, Belgium). ***Principal component analysis (PCA):*** The anatomical features and the translation data of the first CMC joint were used to develop a morphology-function model. PCA was implemented to reduce the dimension of the morphology-function model and highlight the relationship between the ligaments and the anatomical features in the translations of the first CMC joint.

### Results and Discussion

The first principal component indicated that, in all four directions, the first metacarpal torsion angle (-2.60° (-2SD) to

21.67° (+2SD)) contributed to the magnitude of translation. As this angle twisted more ulnarly (+2SD), the translations of the first CMC joint in the direction of loading increased after the transection of the IML and DRL (Figure 1). The second principal component indicated that variation in the first metacarpal articular tilt angle (-4.58° (-2SD) to 9.92° (+2SD)) also contributed to the magnitude of joint translation, for all four load directions. An increased first metacarpal torsion angle could enable a better match between the concavity of the trapezium articulating surface with the convexity of the first metacarpal articulating surface during opposition. This would maximise bony stability, preventing subluxation of the first CMC joint. An increase in the first metacarpal articular tilt angle could reduce bony stability in the volar region of the articulating surface of the joint. With this, disruptions in the ligaments may be more likely to cause first CMC joint subluxation. Hence, the joint may rely on its convex-concave articulating surface at the dorsal region to help prevent subluxation of the joint.

**Figure 1:** The translation (mean and ± 2 standard deviation) of the first CMC joint when displaced by load in the VD directions with variation in the first metacarpal torsion angle obtained in the first principal component. The colored region shows the region of subluxation of the joint that resulted from variations in the first metacarpal torsion angle with the presence of ligament disruption.

### Conclusions

This study assessed the interactions between first CMC joint kinematics and its anatomical features. The morphology of the first metacarpal, particularly the torsion and articular tilt angles, was important in maintaining the stability of the first CMC joint.

# Scan-Driven Fully Automated Pipeline for a Personalized, 3D Printed Low-Cost Prosthetic Hand

## Summary

The loss of a hand can drastically reduce one's quality of life by decreasing the ability to perform activities of daily living. A prosthetic arm can help assist in such activities but cost of production and manual fitting processes limit the use and prescription of these devices. Moreover, prosthetic devices still have high rejection rates for various reasons, one of which is social acceptance. In this research we propose a novel, digital design process to create a personalized prosthetic hand. Our proposed fitting paradigm is entirely digital to minimize the design time and the high cost and dependency of trained professionals throughout the process, while potentially achieving a low-cost, tailor-made design that can be accessible from anywhere on the globe.

## Introduction

Although there are many solutions in the field of upper limb prosthetics, financial resources play a crucial role in prescription of these devices, especially in children due to constant growth [1]. The cost of a prosthetic hand ranges from \$3,000 for a body powered prosthesis and up to \$100,000 for a neuro-prosthetic arm [2]. The very high price tag makes these devices inaccessible to large portions of the population. In many cases, the price is greatly affected by the time spent on manually fitting the device. Even when financial barriers are surpassed, rejection rates of prosthetic devices are considerably high and are usually related to the following causes: age of first fitting, lack of social acceptance, weight, vulnerability of the device and lack of sensory feedback [3]. Not using a prosthesis could lead to degeneration of joints and muscles, inflammations, and other complications.

## Methods

The process, in general, is obtaining user data, then automatically generating a ready to print CAD model, a circuit

board and a bill of materials based on standard off-the-shelf parts and finally, assemble all parts together. The last step is the only manual one in the process but is shortened significantly by optimizing the previous steps. More specifically, we collect 2D images of the healthy hand for a parametrized model of the hand based on a functional *skeleton* and a *skin* to customize appearance thus increasing social acceptance and sense of ownership. In addition, we collect depth images of the residual limb for the hand's socket parametric design. The last type of user data collected is the user preferences which determines the user interface, such as simple body-powered or a motorized hand controlled by EMG, FMG or other interfaces, and haptic feedback. The entire process is illustrated in Figure 1.

## Results and Discussion

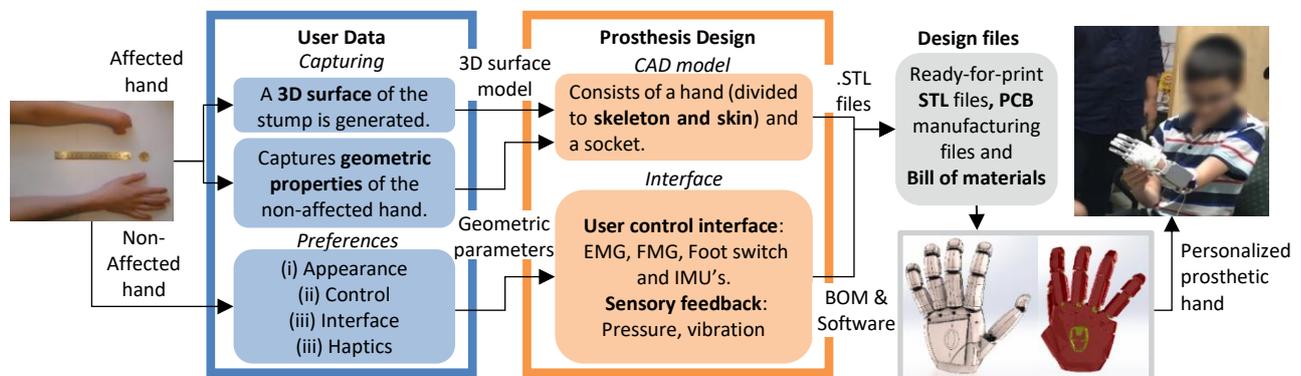

Feedback from prospective users and from healthy subjects was collected in addition to inputs from professionals in the field. Based on the inputs received, the pipeline was improved and future research on each of the blocks will be conducted. In addition, validation tests for the hands performance and production were also conducted.

## Conclusions

The proposed process and the outcome could potentially help overcome the above-mentioned difficulties and help push the prosthetic hands field into the digital design era. The entire research and final design are shared online for anyone in the world to use.

# UNIFORMITY OF PERFORMANCE DURING THE COLLECTION OF MAXIMUM VOLUNTARY CONTRACTION TASKS FOR THE MUSCLES OF THE WRIST

Mercedes Aramayo Gomes Rezende<sup>1</sup>, Oluwalogbon Akinnola<sup>1</sup>, Angela E. Kedgley<sup>1</sup>  
<sup>1</sup>Department of Bioengineering, Imperial College London, London, UK  
a.kedgley@imperial.ac.uk

## Summary

Maximum voluntary contraction (MVC) plays an important role in how we interpret electromyographical data. No protocol exists for finding MVC in forearm muscles though recommendations are available. This investigates the uniformity of MVC performance in recommended tasks and whether variance muscle activity is due to variance in force generated.

## Introduction

Electromyography (EMG) is commonly used to record muscle activity. To enable inter- or intra-subject comparisons, measurements of maximum voluntary contraction (MVC) are used to normalize EMG data. There is no standardised protocol for obtaining MVCs of muscles of the upper limb. To create the most efficient protocol, it is important to understand the relationship between the forces and moments applied by participants during tasks designed to elicit MVCs. Therefore, the objective of this study was to quantify EMG signals and kinetics during a series of isometric tasks to provide a basis for an efficient and effective protocol to obtain MVCs in muscles of the forearm.

## Methods

Fifteen right-handed participants (10 female, 5 male, 23.67 ± 4.5 years old) had nine surface EMG sensors (Delsys, Natick, MA) placed on their dominant forearm to capture muscle activity of the flexor carpi radialis (FCR), flexor digitorum superficialis (FDS), flexor carpi ulnaris (FCU), extensor digitorum communis (EDC), extensor carpi ulnaris (ECU), extensor carpi radialis (ECR), pronator teres (PT), biceps and triceps. Adapting the method from Ngo and Wells [1], participants performed tasks designed to elicit MVC of each muscle. These were: pull up, push down, radial pull, ulnar pull, pull, pronation, finger flexion, finger extension, grip, as well as two activities of daily living (ADL), which were turning a key in a lock and pouring a glass of water from a jar. The ADL tasks provided a baseline measure for expected muscle activations. A six degree of freedom load cell mounted to a handle measured the forces and moments applied.

## Results and Discussion

The activity that elicited MVC for each muscle varied between participants (Fig. 1). For example, the MVC for PT occurred for most participants during the pronation-supination task, but it occurred during the pull up task and pull down tasks for two participants. Data from the load cell confirmed that the directions of the external forces exerted by the hand were the same for all participants (Fig. 2), indicating that the participants performed the activities correctly.

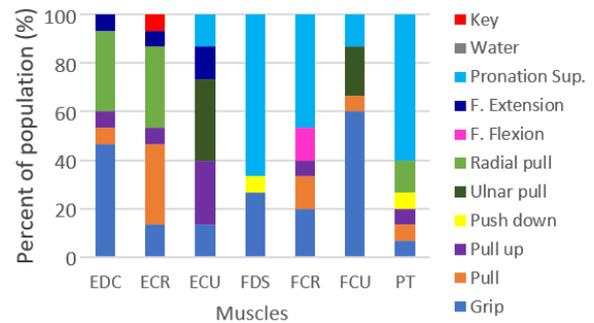

Figure 1: The percentage of people that generated maximum voluntary contraction for each muscle for all tasks.

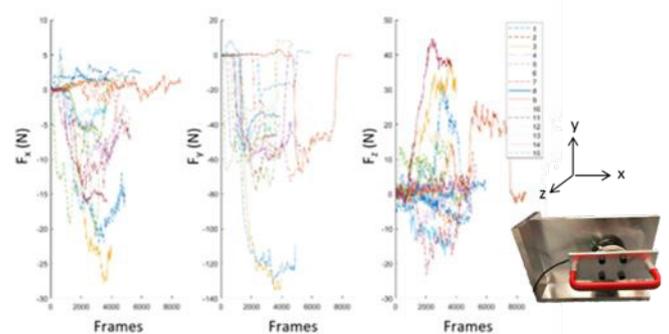

Figure 2: Load cell readings for all 15 participants for the push down task.

The forces and moments applied to the load suggest participants used different combinations of muscles to achieve the same external reaction force at the hand. Physiological differences may be the reason. This agrees with the findings of Maier et al., who investigated muscle synergies during precision grip and found that the interindividual variability was large enough to preclude the creation of a standard synergistic pattern [2]. They concluded that it was not the moments involved in the task but the central nervous system that chooses short-term, flexible synergies to achieve the task. This could result in participants using different muscles to achieve the same end task-oriented goal.

## Conclusions

These findings indicate that, rather than prescribing a single activity to obtain the MVC of each muscle, a range of activities should be used to quantify the MVCs of wrist and hand extrinsic muscles to account for variations in activation strategies across the population.

### Summary (150/ 150 word)

The purpose of this study is to clarify the characteristics of wrist flexion and extension torques in college baseball players. Bilateral wrists of 50 college baseball players were evaluated. Throwing and non-throwing side, and hitting and non-hitting side were defined by the self-report. The players were divided into pitchers (P) and fielders (F) groups. In each group, the torques were compared between throwing and non-throwing side, hitting and non-hitting side. In addition, the wrist torques were compared between P and F groups for each of throwing side, non-throwing side, hitting side and non-hitting side. In group F, wrist extension torque was significantly larger on the throwing side compared to the non-throwing side. The wrist torques in F group were significantly larger than the P group in all conditions. This suggests that hitting requires more wrist flexion/extension torques than pitching. There were no significant effects in the throwing and hitting side.

### Introduction

To prevent baseball pitching injury, it may be helpful to measure muscle strength related to the kinetic chain in the pitching motion. Although the wrist flexion is the end point of the kinetic chain, there is few knowledges of wrist flexion and extension torques in the baseball players. The purpose of this study is to clarify the characteristics of wrist flexion and extension torques in college baseball players. We hypothesized that the wrist flexion torque of the pitcher's is larger on the throwing side than on the non-throwing side, and is larger in the pitcher than in the fielder.

### Methods

Bilateral wrists of 50 college baseball players (age: 18-21, all male, 24 pitchers and 26 fielders) were evaluated. We measured the maximum torques of wrist flexion and extension in the forearm neutral position using a self-designed wrist torque measuring machine (Three-One Design, Inc., Tsukuba, Japan) [1]. The throwing and non-throwing side, and the hitting and non-hitting side were defined by the self-report. The players were divided into pitchers (P) group and fielders (F) group. The results were divided into the throwing side or non-throwing side, and the hitting side or non-hitting side for group P and F. The wrist torques were compared between the P and F groups for each of throwing side, non-throwing side, hitting side and non-hitting side. In each group, the torques were compared between the throwing and non-throwing side, and between the hitting and the non-hitting side.

### Results and Discussion

In the results of wrist flexion torques, there was no significant difference between throwing side and non-throwing side, and

hitting side and non-hitting side for both P and F groups. The measurements of F group were significantly larger than P group for all comparisons. (Fig.1).

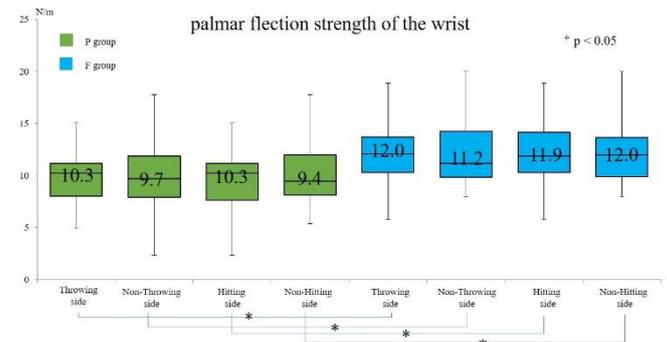

Figure 1: Results of wrist extension torques.

In the results of wrist extension torques, the throwing side torque was significantly larger than the non-throwing side in the F group. There were no significant differences in the other comparative items within the groups. The wrist extension torques in the F group were significantly larger than in the P group for all comparisons. (Fig.2).

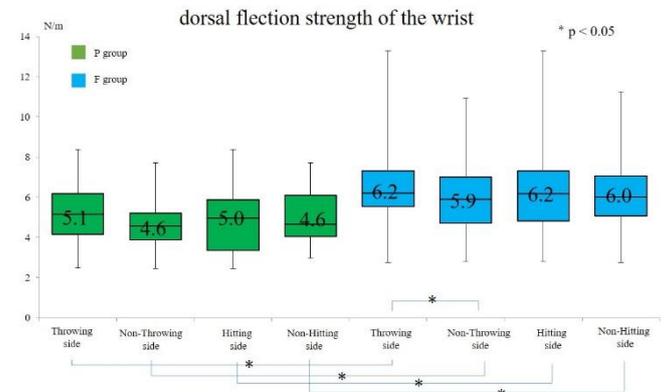

Figure 2: Results of wrist extension torques.

### Conclusions

The wrist flexion and extension torque were larger in the fielders than in the pitchers in college baseball players. Fielder have more opportunities to hit, and this suggests that the wrist strength is more important in the hitting than in the pitching.

## The effect of wrist posture on grip and muscle force capacities: comparison of a prehensile and a non-prehensile task.

Caumes. Mathieu<sup>1</sup>, Vigouroux Laurent<sup>1</sup>, Berton Éric<sup>1</sup>, Goislard de Monsabert. Benjamin<sup>1</sup>

<sup>1</sup>Aix-Marseille Univ, CNRS, ISM, Marseille

Email: mathieu.caumes@univ-amu.fr

### Summary

The wrist and finger are biomechanically coupled because of the hand extrinsic muscles, originating in the forearm. This coupling also influences the force-generating capabilities of the muscles crossing it. The goal of this study was to compare the effect of wrist posture on the grip and muscle force capabilities of 4 forearm muscles in a prehensile and a non-prehensile task. The non-prehensile task resulted in less co-contraction of extensors which modified the interaction between the force-length relationships of flexor and extensor muscles.

### Introduction

The hand musculoskeletal system is composed of many joints and more than thirty muscles. The specific configuration of the hand musculature, including extrinsic muscles originating in the forearm, results in mechanical couplings between finger forces and the wrist joint equilibrium [1]. More precisely, it has been shown that the position of the wrist has a direct influence on the maximal grip force [2]. This influence seems to be explained by the interaction of the different force-length properties of forearm muscles [3]. However, this interaction could be modified in non-prehensile tasks, like finger pressing, as the wrist equilibrium constraints results in less antagonist activation [4]. The objective of this study was to compare the effect of wrist posture on grip and muscle force capacities for two different tasks: a finger pressing and a pinch grip task.

### Methods

Nineteen volunteers (9 females, age: 21.7±2.5 years, hand length: 18.4±1.0cm) were instructed to exert a maximum force with their fingers in either a four-finger pressing or a thumb-index pinch grip configuration and in four different wrist postures. One posture was freely chosen by the participants, referred to as a “spontaneous” (S) position. The other three were imposed on the participants: a neutral (N) posture (0° of flexion and deviation), a maximal flexion (F) and a maximal extension (E). The force was recorded by a 6-axis force gauge (Nano25, ATI, Apex, NC). Simultaneously, the posture of the wrist and index finger was recorded using a 7-camera motion capture system (Qualysis, Göteborg, Sweden; 100Hz) tracking fourteen markers. Surface electromyographic (EMG) signals of six hand muscles were also simultaneously acquired (Trigno, Delsys, Natick, MA, 2000Hz).

For each trial, the maximal finger force was calculated as the mean on a window centered on the finger force peak. On this same window, joint angles were deduced from average marker positions and the activation from RMS of the EMG signal normalized by the maximal RMS. Muscle length and force of different forearm muscles were computed from joint angles

and activation using a biomechanical model [3, including a geometrical model of tendon excursion and muscle force-length-activation relationships [5].

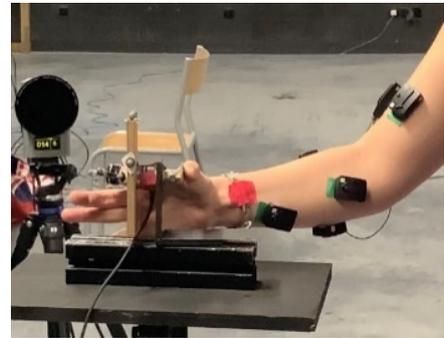

Figure 1: Photography of the experimental setup.

### Results and Discussion

Wrist posture influenced differently the maximal force exerted in pinch grip and finger pressing. The highest maximal finger force in pinch grip was observed for the spontaneous wrist posture, as it has been observed for power grip [2,3]. This confirms participants spontaneously chose the wrist posture resulting in optimal flexor and extensors capabilities [3]. The maximal finger force during pressing task was less influenced by wrist posture. These different influences were explained by a change of muscle coordination, identified by EMG activity. The pressing task indeed reduced the level of co-contraction of finger and wrist extensors compared to the pinch grip task. As a result, the spontaneous posture is more variable. As the activation of extensors is low, the grip force is primarily influenced by force-length relationships of flexors which seems to produce a near-optimal force for a wide range of wrist posture. In this case, wrist posture might be more related to the participant's daily hand use, such as sports or professional activities.

### Conclusions

This study showed that wrist posture influences differently the grip capabilities and the muscle mechanics in non-prehensile and prehensile tasks. These results could help surgeons in designing tendon transfers at the wrist or give insight to ergonomic engineers in optimizing hand-object interfaces.

# Development of Spontaneous Motor Activity with Age in Healthy Infants and Infants with Infantile Cerebral Palsy

C. Disselhorst-Klug<sup>1</sup>,

<sup>1</sup> Department of Rehabilitation & Prevention Engineering, Institute of Applied Medical Engineering, RWTH Aachen University, Germany

Email: disselhorst-klug@hia.rwth-aachen.de

## Summary

Abnormalities of age-appropriate motor development in infants may be a sign of a progressing motor impairment. This paper presents a method for objectively assessing the motor development of infants. It is demonstrated that and how the motor development of infants with ICP differs from that of healthy infants.

## Introduction

Coordination between perception and action is required to interact with the environment successfully. This training is already undertaken by very young infants who perform spontaneous movements to learn how their body interacts with the environment. The strategies used by the infants for this purpose change with age. Therefore, investigations of motor development during the first month of life will give insight into the very early progresses made to control action. This information becomes even more important when it is reasonably expected that a newborn infant might develop a movement disorder due to infantile cerebral palsy (ICP).

In developmental neurology visual observation of spontaneous motor activity has turned out to be the most important diagnostic criterion. However, objective methods, which allow the evaluation of spontaneous movement development, are not available so far. This paper aims to introduce an objective methodology which allows the quantitative evaluation of the development of spontaneous motor activity in newborns.

## Methods

The introduced methodology is based on the acquisition of spontaneous movements of the newborns by accelerometry. 4 lightweight accelerometers were attached to the infant's hands and feet (Figure 1). The unclothed babies lie prone and acceleration data are recorded over a 2-minute period.

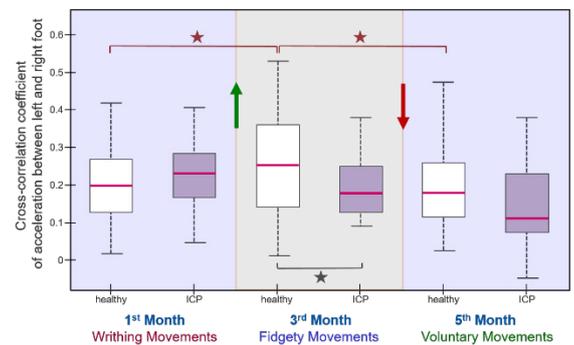

**Figure 1:** Acquisition of spontaneous movements of the hands and feet in newborns.

To evaluate the spontaneous movements, eight movement parameters, which have been shown to be sufficient to discriminate between normal and pathological movement patterns in infants [1], were extracted from the recorded accelerations.

The spontaneous movements of 24 infants, comprising 16 healthy full-term infants (mean gestational age 39.7 weeks, 11 female, 5 male) and eight pre-term infants (mean gestational age 28.6 weeks, 3 female, 5 male) with developing infantile cerebral palsy (ICP), were analyzed around the first, the third and the fifth months of life.

## Results and Discussion

In the healthy group, three of eight parameter values showed significant changes between the first and the third month of life; values of two additional parameters changed significantly between the third and the fifth month of life. Figure 2 demonstrates with the example of the parameter "Cross-correlation coefficient of acceleration between left and right foot" how spontaneous movements in healthy infants change with motor development. In babies suffering from ICP, most differences to the healthy group can be found between the first and the third month of life (Figure 2), a trend which was reflected in this study in four of eight parameter values.

**Figure 2:** Parameter Cross-correlation coefficient of acceleration between left and right foot. Comparison between healthy subjects and patients with ICP. (\* significant different  $p < 0.05$ )

## Conclusions

It was possible to provide an objective description of motor development in healthy newborns. Furthermore, it was shown that pathologies influence development of motor activity significantly. Since the introduced methodology is objective and quantitative, it is suitable to monitor the development of spontaneous motor activity with age.

Email: [peter.raffalt@nih.no](mailto:peter.raffalt@nih.no)

### Summary

The inter-limb coupling of individuals with transtibial amputation (TTA) was investigated. The difference in inter-limb coupling between individuals with TTA and unimpaired individuals was direction-dependent and weaker in the anterior-posterior direction for the individuals with TTA.

### Introduction

Balance control during upright standing requires the center of mass to be kept within the base of support whilst maintaining both the flexibility and stability to perform simultaneous actions and adjust to external perturbations. In individuals with permanent alterations to sensory input and to volitional control of movement due to unilateral foot or limb amputation, it is crucial to investigate the inter-limb coordination to fully understand how stable upright standing is controlled [1]. The aim of the present study was to determine how upright standing is controlled in individuals with unilateral TTA in terms of the inter-limb coupling of the center of pressure dynamics between the limb on the prosthetic side (COP<sub>P</sub>) and the intact limb (COP<sub>I</sub>).

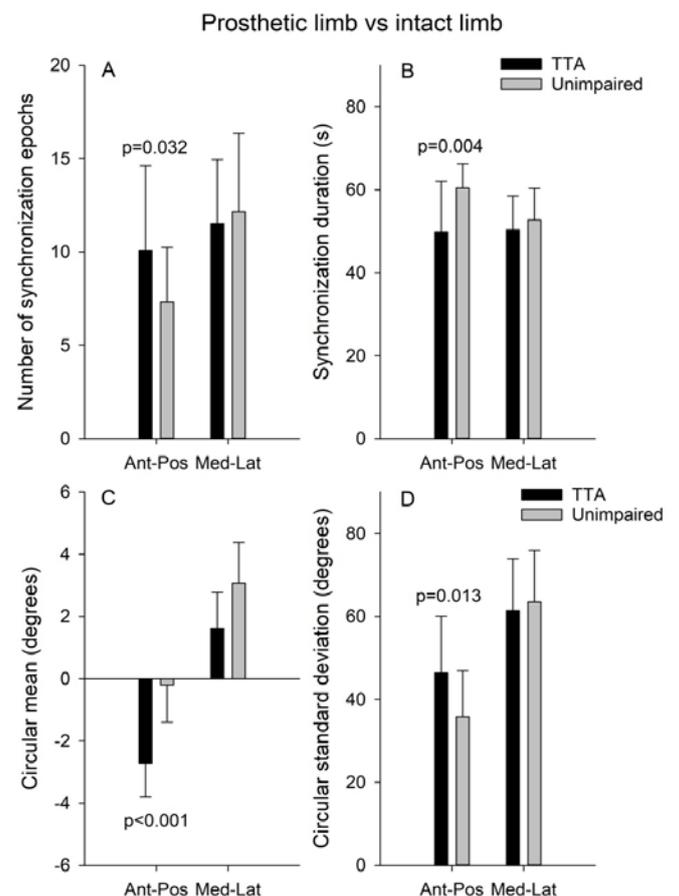

### Methods

Twenty-one individuals with TTA (male/female: 17/4; mean  $\pm$  SD age: 59.7  $\pm$  15.0 yrs; height: 1.79  $\pm$  0.07 m; mass: 100.3  $\pm$  15.6 kg) and 18 unimpaired individuals (male/female: 14/4; mean  $\pm$  SD age: 54.1  $\pm$  16.0 years; height: 1.73  $\pm$  0.10 m; mass: 85.2  $\pm$  18.4 kg) completed 90 seconds of upright standing with each foot on a separate force platform operating at 600Hz. The COP time series were filtered using a Daubechies wavelet, downsampled to 100Hz and the initial 15 seconds were removed. The inter-limb coupling was assessed from the COP<sub>P</sub> and COP<sub>I</sub> in terms of 1) the number of synchronization epochs between the signals (i.e. number of shifts between stable coordination states), 2) the total duration of the synchronization (i.e. stability of coordination), 3) the mean relative phase angle between the signals (i.e. coordination type) and 4) the deviation phase (i.e. coordination variability) [2]. A two-way mixed design ANOVA or Harrison-Kanjo test (for relative phase) with group and direction as independent factors was applied, Holm-Sidak post hoc test and level of significance at 5 %.

### Results and Discussion

In the anterior-posterior direction, the TTA group had a significantly higher number of synchronization epochs, lower total synchronization duration, less in-phase relative phase angle and a greater deviation phase (Figure 1). No group

differences were observed in the mediolateral direction. The altered control of bilateral standing in individuals with TTA was characterized by more shifts between stable coordination states, less overall stability, a different coordination pattern and greater coordination variability compared to unimpaired individuals. This indicated a weaker inter-limb coupling in the AP direction for the individuals with TTA.

**Figure 1:** Inter-limb coupling characteristics for individuals with TTA and unimpaired individuals.

### Conclusion

The difference in inter-limb coupling between individuals with TTA and unimpaired individuals was direction dependent and weaker in the AP direction for the individuals with TTA.

## Unrestricted age-related compensation in a daily life sit-to-walk task

van der Kruk, Eline<sup>1</sup> & Bull, Anthony M. J.<sup>2</sup>

<sup>1</sup>Biomechanical Engineering, Delft University of Technology, Delft, the Netherlands

<sup>2</sup>Department of Bioengineering, Imperial College London, London, UK

Email: [e.vanderkruk@tudelft.nl](mailto:e.vanderkruk@tudelft.nl)

### Summary

The prevention and treatment of age-related movement impairments, ideally, requires early diagnosis. As the human movement system has physiological and functional redundancy, movement limitations do not promptly arise at the onset of physical decline: humans will compensate. The aim of this study was to observe (early) compensation during the sit-to-walk task in relation to neuromuscular capacity and movement objectives in young and older adults. Participants' upper- and lower limb strength, nerve conduction, joint sense acuity, and balance were tested. Moreover, standardized questionnaires on fear of falling, pain, dizziness, lifestyle, and frailty were taken. Their kinematics and muscle activity during sit-to-walk tasks were recorded in an unrestricted experimental set-up. Key finding was that standing up from a chair by pushing off with the arms is not strictly a compensation strategy for a lack of muscular capacity.

### Introduction

An important daily life activity is standing up from a seated position. This movement has been widely studied in biomechanics, however most studies have imposed standardizations on protocol, so the possibility of compensation is restricted [1]. For example, most studies on sit-to-stand did not permit participants to compensate using their arms. However, from the onset of age-related physical decline (mid-twenties) until the point that movement impairments arise, compensation is part of human movement strategies. Compensation can therefore be a clinically relevant early indicator of physical decline. Scientifically compensation is interesting as it tips the hand on how humans within the functional redundancy of the neuromuscular systems select a movement strategy. The aim of this experimental study was to capture unrestricted compensation in the sit-to-walk task and relate this to neuromuscular capacity and movement objectives (psychological considerations) in young and older adults.

### Methods

This study (N=50) comprises 14 young women (YW) (age: 27.1±5 years), 13 young men (YM) (27.3±4.3), 12 relatively healthy older women (EW) (75±5.6), 11 relatively healthy older men (EM) (76.8±7.2). All participants gave their informed consent. Participants sat down on an instrumented chair with instrumented armrests with the seat at approximately knee height. Participants were asked to stand up and walk to a table 3m in front of them: 5x at self-selected speed, 5x at fast speed. Their kinematics (Vicon) and muscle activity (Delsys EMG) were recorded.

Additionally, to assess their neuromuscular capacity, we measured their maximum peak isokinetic joint moments for the knee, hip, ankle, and elbow on a dynamometer (Cybex), handgrip strength (Jamar), balance in a standing balance task, proprioceptive acuity with an ipsilateral matching task of knee flexion, joint range of motion of the hip and ankle (Cybex), and nerve conductivity and maximal muscle excitation with a nerve conduction test. To assess psychological considerations, a questionnaire reviewed their (former) profession, levels of activity, diet, general health, experienced injuries, level of frailty (Edmonton), fear of falling (FES-I short), hearing, level of Dizziness, hand dominance (Edinburgh), and pain (visual analogue scale).

For the purpose of this abstract we will focus on the results of the applied arm strategies.

### Results and Discussion

Four arm strategies were observed: standing up without arms, swinging the arms, pushing off on the knees, and pushing off on the armrests. Note that all participants could stand up without arms. There was a distinct result: EM used an arm push off in 91% of all trials (N=55) at self-selected speed, and in *all* trials at fast speed, whereas YM, YW and EW only pushed off in less than half of all trials. The hypothesis was that EM had less lower limb joint strength than the other groups. However, their peak isokinetic strength corrected by bodyweight did not differ significantly from YW and was mostly higher than EW for all measures. Also, no differences were found between the means of the arm strategy groups with proprioceptive acuity, balance scores, hand grip strength, muscle excitation, or nerve conduction. Nor with the anthropometric data (BMI, length, weight), FES-score (fear of falling), or frailty score. The only significant difference was that the participants with an arm push-off had a significant lower hip flexion range of motion on the dominant side ( $p<0.05$ ) and a lower ankle plantar-flexion range of motion on the non-dominant side ( $p<0.01$ ).

### Conclusions

Standing up from a chair by pushing off with the arms is not strictly a compensation strategy for a lack of muscular capacity in older men.

## Lumbar extensor muscle isometric torque steadiness and torque-HDsEMG coherence is altered in individuals with chronic low back pain

Michail Arvanitidis<sup>1</sup>, David Jiménez-Grande<sup>1</sup>, Nadège Haouidji-Javaux<sup>1</sup>, Deborah Falla<sup>1</sup>, Eduardo Martínez-Valdes<sup>1</sup>

<sup>1</sup>Centre of Precision Rehabilitation for Spinal Pain (CPR Spine), School of Sport, Exercise and Rehabilitation Sciences, College of Life and Environmental Sciences, University of Birmingham, Birmingham, UK

Email: [marvanitidis@outlook.com](mailto:marvanitidis@outlook.com)

### Summary

Lumbar extensor muscle isometric torque steadiness (TS) was evaluated in individuals with chronic low back pain (CLBP) and asymptomatic (AS) age- and gender-matched controls, during two submaximal torque-matching tasks at different torque levels. This study is the first to show that individuals with CLBP fail to increase common fluctuations in torque and electromyographic (EMG) activity when exerting higher forces. This finding shows that the CLBP group were still able to exert the requested amount of torque likely by utilising compensatory back-extension patterns.

### Introduction

The ability of humans to exert steady torque during a submaximal voluntary contraction is defined as TS. Generation of smooth torque is essential for physical function, and the impairment of TS can influence the precision of voluntary movements. People with CLBP present with impairments in lumbar extensor muscle force accuracy compared to AS controls [1]. However, it is unclear whether people with CLBP also present with higher deficits in TS compared to AS controls. We investigated 1) whether individuals with CLBP present with reduced lumbar extensor muscle TS compared to AS controls, and 2) the neuromuscular mechanisms underlying reductions in TS by applying high-density surface EMG (HDsEMG)-torque coherence with principal component analysis (PCA).

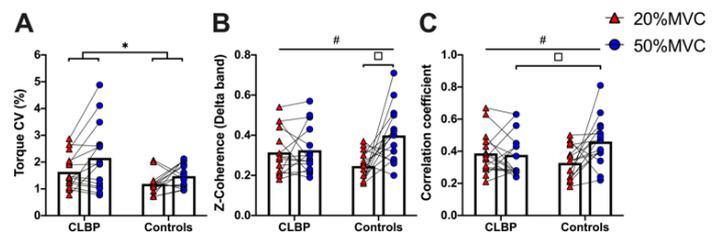

### Methods

15 individuals with CLBP and 15 AS controls were included. Submaximal isometric lumbar extensor TS was measured with an isokinetic dynamometer during two torque target-tracking tasks at 20% and 50% of their maximal voluntary contraction (MVC). HDsEMG signals were acquired from their lumbar erector spinae (ES) with a 64-electrode grid. Root mean square (RMS) was determined as an average for all electrode pairs (59 bipolar). TS was quantified as the coefficient of variation (CV) of torque. Coherence and cross-correlation analyses were conducted to quantify the degree of similarity between the filtered interference HDsEMG and torque signals for each submaximal contraction. PCA was used to reduce dimensionality of HDsEMG data, in order to improve HDsEMG-based torque estimation [2]. Coherence values were calculated for the  $\delta$  (0-5Hz),  $\alpha$  (5-15Hz) and  $\beta$  (15-30Hz) frequency bands and then they were transformed to z-scores to allow statistical comparisons.

### Results and Discussion

Overall, TS was lower in individuals with CLBP ( $p=0.029$ ; Figure 1A). Z-coherence in the  $\delta$  band and cross-correlation

increased with the increase in torque for the AS controls but not in the CLBP group ( $p=0.018$ ,  $p=0.030$ ; Figure 1B, C). Coherence in the  $\alpha$  and  $\beta$  bands did not differ between groups. Overall HDsEMG RMS amplitude, the center of ES muscle activity and co-activation levels did not differ between groups. As previously postulated, the neural drive to the muscles in the  $\delta$  band mirrors the common drive to the muscle in the same bandwidth and is the main determinant for the control of torque [3]. Additionally, an increase in torque is commonly accompanied with an increase in  $\delta$  band coherence, as seen in the AS group. Thus, the TS deficits observed in the CLBP group could be attributed to the lack of an increase in common synaptic input, with the increase in torque. This is also supported by the cross-correlation results, showing that in the CLBP group, the net increase in torque was not accompanied by an increase in the contribution of the ES muscle to the resultant torque fluctuations. Given that both groups exerted similar amount of torque during the task, the individuals with CLBP could be compensated by activating synergistic muscles. Interestingly, the RMS amplitude alone could not explain the differences in TS, but the proposed coherence analysis enabled us to explain the differences in TS, showing that HDsEMG can improve the estimation of the exerted torque, providing a more accurate assessment of lumbar ES activity than conventional RMS amplitude calculations.

**Figure 1:** Torque CV (A),  $\delta$ -band coherence (B) and cross-correlation (C) values (mean  $\pm$  SD) of the CLBP group and AS controls at 20% and 50%MVC respectively (\*main effect of group, #interaction effect: group\*torque, □: post hoc tests).

### Conclusions

This study uniquely demonstrates that individuals with CLBP have reduced TS and fail to increase the common fluctuations in torque and HDsEMG activity with increasing torque, likely due to the use of compensatory back extension patterns during this task.

## Summary

Fragile X Syndrome (FXS) is a genetic condition, mainly characterized by intellectual disability, musculoskeletal alterations and behavioral problems. This project aims to investigate association between abnormal motor control and altered spectral attributes of electromyography signals in FXS. Results showed increased instantaneous mean frequency during gait in Rectus Femoris (RF) and Biceps Femoris (BF) in FXS children. Furthermore differences in the percentage of energy allocated in various frequency bands between analyzed populations were detected.

## Introduction

FXS is the leading form of inherited intellectual disability and autism spectrum disorder, caused by a tri-nucleotide CGG repeat expansion in the promoter region of the FMR1 gene [1]. In these subjects, the most frequent musculoskeletal manifestations include severe flexible flat feet, excessive laxity of the joints, and possible scoliosis [1], that justifies a referral for gait analysis evaluation. The aim of the present study was to identify the relationship between observed musculoskeletal manifestation and altered motor control in FXS children. For this purpose surface electromyography (sEMG) was acquired within standard clinical ambulatory assessment conditions and its spectral attributes extracted.

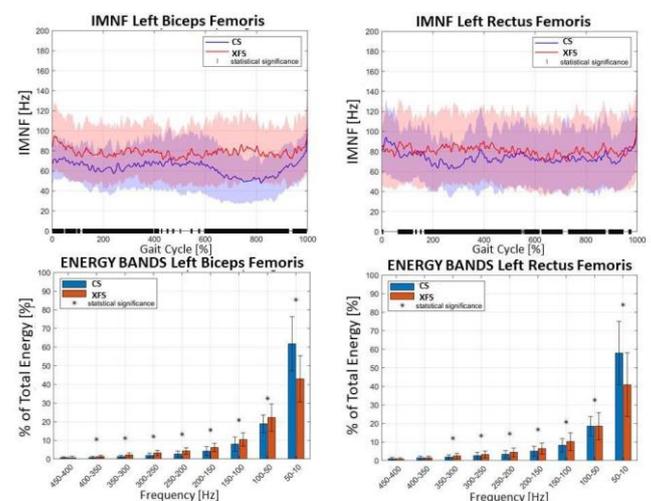

## Methods

After appropriate informed consent by the parents, 23 FXS children ((FXSC) mean ( $\pm$ SD) age and BMI respectively of 9,00 ( $\pm$ 3,92) years and 18,77 (3,07 $\pm$ ) Kg/m<sup>2</sup>) and 20 controls ((CS) mean ( $\pm$ SD) age of 9,68 ( $\pm$ 2,90) years and 21,52 ( $\pm$ 4,61) BMI of Kg/m<sup>2</sup>), were evaluated at the BiomovLab of the Department of Information Engineering, and at the Women and Children Health Department of the University of Padua. Kinematics and sEMG data were simultaneously acquired through four synchronized cameras (GoPro Hero3, 30fps) and an 8 channel sEMG system (FreeEmg, BTS, 1000Hz) that collected the activity of Tibialis Anterior (TA), Gastrocnemius Lateralis (GL), RF and BF. Each subject performed several gait trials and at least three trials per subject were processed. The following sEMG parameters were

extracted: instantaneous mean frequency (IMNF) and percentage distribution of signal energy in frequency bands.[2]

## Results and Discussion

Results consistently showed the presence of an altered muscle activity (Fig. 1): FXS displayed increased IMNF values in RF and BF, decreased percentage of energy in the band between 10-60 Hz and increased percentage in the bands between 50-400 Hz.

**Figure 1:** IMNF of left BF and RF (blue CS and orange FXSC; mean $\pm$ SD) during gait cycle and percentage distribution of energy in the frequency bands of left BF and RF (blue CS and orange FXSC; mean $\pm$ SD); (\* - significant difference)

## Conclusions

Results suggest that FXSC increases their muscle activity during the gait cycle and also the number of motor units in low frequencies. This information can help to determine the degree of improvement in FXSC walking ability.

# Injury and Surgery Are Associated with Shoulder External Rotation During Exam and Baseball Pitching

Hannah L. Stokes<sup>1</sup>, Nigel Zheng<sup>1</sup>, Koco Eaton<sup>2</sup>

<sup>1</sup>Department of Mechanical Engineering and Engineering Science, University of North Carolina at Charlotte, NC, USA

<sup>2</sup>Tampa Bay Rays and University of South Florida, FL, USA

Email: [nzheng@uncc.edu](mailto:nzheng@uncc.edu)

## Summary

The study included 109 college baseball pitchers and compared shoulder rotational properties, ball speed, and maximum external angle during baseball pitching with pitchers before and after injury and surgery and a healthy control group. One-way analysis of variance with Tukey post-hoc tests were performed using SPSS. The shoulder external rotation during exam and baseball pitching trended to being greater before surgery compared to those recovered from surgery, but there was not statistically significance.

## Introduction

Baseball pitching is demanding on the shoulder and it is common for injuries to occur. The relationship of shoulder range of motion and injury has been studied [1]. A study showed that increasing ball speed also increased the risk for injury [2]. Improving performance and reducing injuries are a focus for both coaches and pitchers.

The purpose of this study is to investigate how elbow and shoulder injuries and surgeries are related to shoulder external rotation during exam and baseball pitching. This connection could allow for correction of baseball mechanics and reduce the number of injuries. We hypothesize that injuries and surgeries are not related to shoulder external rotation during exam and baseball pitching.

## Methods

The study included 109 college baseball pitchers (height: 186±8 cm and weight: 85±9 kg). This study was approved by an institutional board and all pitchers gave informed consent. All pitchers were healthy during testing. The pitchers came into the lab for biomechanical testing and the self-reported injury questionnaire. The injury questionnaire reports if the pitcher has had a surgery or injury exclusively. Additionally, the pitchers were followed annually to complete the injury questionnaire. The shoulder rotational test measured the end-point angle (EPA), shoulder rotational flexibility (SRF), and resistant onset angle (ROA) using a custom-made wireless device [3] (Figure 1).

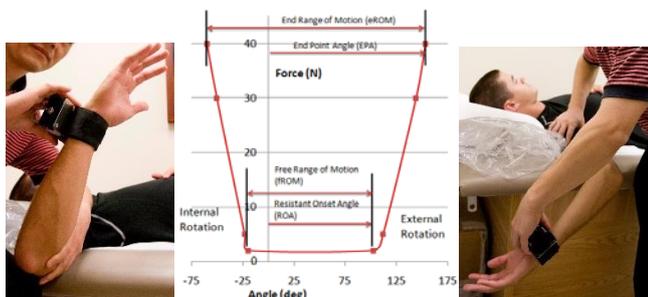

Figure 1: Shoulder rotational test performed during the exam.

Ten overhead fastball pitching motions were collected at 240 Hz using a motion capture system. Averages of top three strike pitches for ball speed and shoulder maximum external rotational (MER) angle were used for comparison. The surgery and injury groups had surgeries or injuries, respectively before or after testing. The healthy group had no reported surgeries or injuries before and after testing. One-way analysis of variance with Tukey post-hoc tests were performed using SPSS with an alpha set to 0.05.

## Results and Discussion

Ball speed (mph), EPA (deg), SRF (deg/Nm), and MER (deg) were all greater in those before surgery (post-test) when compared to those after injury and surgery (pre-test) (Table 1). Eight subjects were excluded due to both pre-test and post-test surgeries or injuries.

Table 1: Results Mean±SD for the ball speed (mph), EPA (deg), SRF (deg/Nm), ROA (deg), and MER (deg).

	After Surgery	After Injury	Healthy	Before Injury	Before Surgery	P
N	19	16	41	12	13	-
Ball Speed	76±5	78±3	76±4	79±4	79±5	0.14
EPA	134±8	138±13	137±10	140±12	139±9	0.68
SRF	4.0±2.1	3.8±1.6	4.5±1.6	3.7±1.0	5.4±1.7	0.06
ROA	105±12	110±12	107±10	111±13	102±12	0.26
MER	169±11	173±12	173±10	179±13	178±12	0.12

Findings emphasize that shoulder rotational properties should be monitored in order to improve performance and reduce injury during baseball pitching. Future work should study shoulder rotational properties and injury mechanisms at the professional level for an extended duration of time.

## Conclusions

The pitchers had trended to have greater ball speed, range of motion, flexibility and maximum external rotation during baseball pitching before surgery compared to after surgery; however, there was no significant difference.

## Acknowledgments

## Whole-body angular momentum and external torque during the block phase of the sprint start

Paul Sandamas<sup>1</sup>, Elena M. Gutierrez-Farewik<sup>2,3</sup> and Anton Arndt<sup>1,3</sup>,

<sup>1</sup>BMC Laboratory, The Swedish School of Sport and Health Sciences, Stockholm, Sweden

<sup>2</sup>KTH MoveAbility Lab, Dept. Engineering Mechanics, KTH Royal Institute of Technology, Stockholm, Sweden

<sup>3</sup>CLINTEC Institution, Karolinska Institute, Stockholm, Sweden

Email: [paul.sandamas@gih.se](mailto:paul.sandamas@gih.se)

### Summary

Whole-body angular momentum ( $\mathbf{H}$ ) and its time derivative, net external torque ( $\mathbf{T}$ ), in the three spatial directions during the block phase of the sprint start were investigated. Nine competitive sprinters performed maximum effort block starts. A whole-body model was created and  $\mathbf{H}$  and  $\mathbf{T}$  computed from each athlete's trial with the greatest normalised average horizontal block power. The greatest peak block phase components of  $\mathbf{H}$  and  $\mathbf{T}$  were found in the sagittal plane whilst the smallest were found in the transverse plane. Sprinters generate two angular impulses in each plane. One during the double push (DP) phase followed by an opposite directed impulse during the single push (SP) phase. Regulation of angular impulses could explain segment motion outside the sagittal plane.

### Introduction

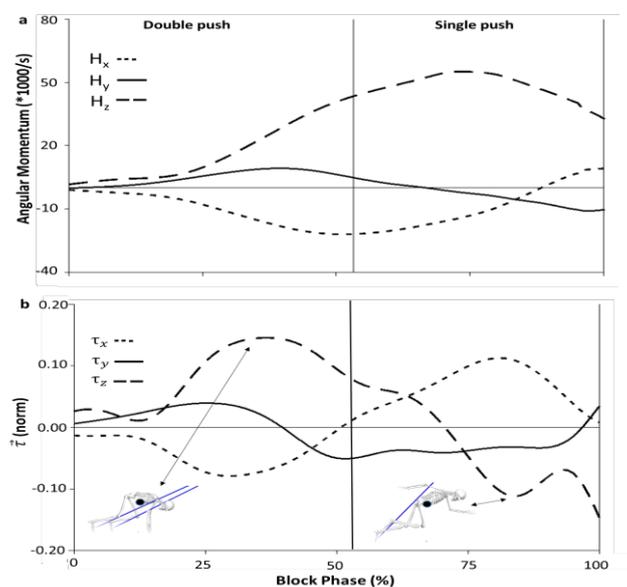

From a force application perspective, the block phase in sprinting is a unique part of the race for several reasons. These include: initial simultaneous impulses from both feet, greatest contact time and greatest net external anterior impulse (i.e. greatest change in velocity) [1,2]. These present a challenge to the athlete in how to direct these large and varying external reaction forces in order to maximise external power whilst generating rapid upper and lower body segment rotations and rising from a crouched to an extended position at block exit. However, neither  $\mathbf{H}$  nor  $\mathbf{T}$  during the sprint start have been described in the scientific literature. Investigating the sprint start using the basic principles governing whole-body rotation is a basis for understanding why segment motions take place in the frontal and transverse planes. Therefore, the aim of this study was to investigate wholebody angular momentum and its time derivative, net external torque, during the block phase of the sprint start.

### Methods

Nine competitive sprinters (8 male, 1 female) performed five maximum effort block starts. Block forces and three-dimensional kinematics were recorded throughout the block phase using a 12-camera (Oqus 4, Qualisys AB,) motion analysis system (250 Hz). A 15 segment full-body model was created using Visual3D, (C-Motion Inc.). The trial with the greatest normalised external block power was used to compute  $\mathbf{H}$  and  $\mathbf{T}$  with respect to the CoM. External torque was computed by taking the derivative of  $\mathbf{H}$  with respect to time. Each athlete started with their left foot on the front block. To allow comparison between athletes,  $\mathbf{H}$  and  $\mathbf{T}$  were normalised.

### Results and Discussion

The largest peak magnitudes of  $\mathbf{H}$  and  $\mathbf{T}$  were found in the sagittal plane and the smallest were seen in the transverse plane (Figure 1a). Two angular impulses were generated in each plane, one during the DP phase followed by an opposite directed impulse during the SP phase (Figure 1b). The angular impulses in the transverse and frontal planes during the DP phase were virtually equal and opposite to their corresponding angular impulses during the SP phase.

**Figure 1:** Ensemble average components of angular momentum ( $\mathbf{H}$ ) (a) and external torque ( $\mathbf{T}$ ) (b). Positive values indicate a counter clockwise rotation when viewed from the right side, front and above. The skeleton images give an illustration of the direction of the net external force vector(s) with respect to the CoM of the sprinter in the sagittal plane.

### Conclusions

A possible reason for segment motion outside the sagittal plane is to help regulate the non-sagittal plane angular impulses to prevent unwanted whole-body rotation.

## Summary

Iliotibial band syndrome (ITBS) is a leading knee overuse injury that is related to running biomechanics. A total of 192 male runners were recruited, and 179 of them finished the eight-week running program. Fifteen of them developed ITBS and comprised the ITBS group, and 15 matched healthy runners comprised the control group. One force platform and a motion capture system collected biomechanical data before and after the intervention. At week 9, the ITBS group exhibited greater anterior pelvic tilt angle and hip flexion angle than the control group. They showed increased trunk inclination angle, whereas the control group demonstrated lower hip flexion and adduction moments than those at week 0. Decreased hip flexion and adduction angles were gait adjustment strategies that could be used to avoid ITBS occurrence. Excessive trunk posture and pelvic activity during running are also ITBS risk factors.

## Introduction

The popularity of running leads to an increased number of running-related injuries. ITBS is the second most common running injury, accounts for 1.6%–12% of all running-related injuries. The exact etiology of ITBS is unclear, but biomechanics is considered one of the factors [1]. Most of the previous studies on ITBS were retrospective ones. It was difficult to elaborate on the pathogenesis. Therefore, we designed a prospective study to explore the effects of running biomechanics of male runners on the occurrence of ITBS.

## Methods

A total of 192 male runners were recruited, and 179 of them finished the eight-week running program. They run approximately 38 Km/week at approximately 3.7 m/s pace. Fifteen of them developed ITBS, comprised the ITBS group, and 15 matched healthy runners comprised the control group. Participants were asked to undergo two gait test trials, before and after the training. In each trial, all participants were asked to run on a 90 cm × 1500 cm platform at a velocity of  $3.7 \pm 0.2$  m/s. A Kistler force plate with sampling at 1000 Hz was embedded at the center of the platform to collect ground reaction force data. An eight-camera motion capture system (Vicon, Oxford Metrics Ltd., UK) with sampling at 100 Hz was used to collect kinematic data synchronously (Figure 1). Group and training effects were examined by two-way ANOVA with mixed design. The significance level was set at 0.05.

## Results and Discussion

At week 9, the ITBS group ( $19.2 \pm 5.4^\circ$ ) exhibited greater ( $p < 0.001$ ) anterior pelvic tilt angle than the control group ( $11.8 \pm 6.3^\circ$ ), whereas the control group demonstrated lower hip flexion angle (week 0:  $42.8 \pm 10.2^\circ$ , week 9:  $32.8 \pm 7.2^\circ$ ,  $p = 0.006$ ), and hip adduction moment (week 0:  $8.8 \pm 2.6$  Ng/kg, week 9:  $6.4 \pm 3.3$  Ng/kg) than those at week 0.

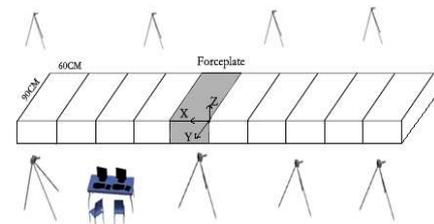

Figure 1: Laboratory settings

A greater anterior pelvic tilt angle in the ITBS group was observed than in the control group. This factor that may be linked to running injuries, such as ITBS. The increased anterior pelvic tilt may be due to weakness in the core muscles and the hip flexor musculature's tightness. Excessive pelvic activity during running is also an ITBS risk factor. The control group decreased the hip flexion after training to reduce strain and relieve tension in the Iliotibial band. It could be a gait adjustment strategy to avoid ITBS occurrence. The control group exhibited a significant reduction in hip adduction moment after training. This change may have been created to reduce the risk of developing ITBS because greater hip adduction is associated with tension and strain on the ITBS.

## Conclusions

Decreasing hip flexion, adduction angle, and abductor moment may be a reasonable strategy to avoid ITBS. Risk of ITBS could be reduced by timely gait adjustment. Excessive trunk inclination and anterior pelvic tilt angles may be risk factors in the development of ITBS during running.

### Summary

Individuals with anterior cruciate ligament reconstruction (ACLR) demonstrate aberrant movement patterns associated with risk of re-injury. Individuals with ACLR also report persistent pain and symptoms. It is unclear how symptoms potentially influence lower extremity loading mechanics after ACLR. Therefore, the purpose of this study was to evaluate the relationship between symmetry of drop-vertical jump (DVJ LSI) kinetics and patient reported symptoms 6-months after ACLR. Symptoms (KOOS-symptoms) and vertical ground reaction force (vGRF) LSI was related in individuals with ACLR ( $\Delta R^2 = 0.231$ ). A better understanding of how worse symptoms influence movement patterns post-ACLR is needed and may clarify an important link between symptom resolution and risk of re-injury.

### Introduction

Individuals with ACLR exhibit aberrant knee joint biomechanics and loading patterns that increase risk of secondary ACL injury [1]. Almost 40% of individuals with ACLR report unacceptable symptoms for several years following surgery [2]. However, it is unclear how symptoms potentially influence lower extremity loading mechanics after ACLR. Therefore, the purpose of this study was to evaluate the relationship between DVJ LSIs and patient-reported knee symptoms (KOOS-symptoms) 6-months following ACLR.

### Methods

Recreationally active individuals with primary unilateral ACLR participated in this study. All participants completed the Knee Osteoarthritis Outcomes Score symptoms (KOOS-symptoms) subscale at enrollment. Assessment of peak vGRF and knee extension moment (KEM) were conducted utilizing three-dimensional motion capture (120 Hz; Vicon Motion Systems, Ltd., Oxford, UK) and two integrated force platforms (1200 Hz; Advanced Medical Technology Inc., Watertown, USA). Participants were asked to drop off a 30-cm box and immediately jump upward to attain maximal height. The box was positioned at a distance  $\frac{1}{2}$  participant height away from the force platform. Peak vGRF and KEM were extracted, normalized to body weight (BW), and LSIs were calculated using the following equation:

$$LSI \% = \frac{\text{involved limb value}}{\text{uninvolved limb value}} \times 100\%$$

Separate linear regression models were developed to evaluate the association between KOOS-symptoms, and peak DVJ vGRF and KEM LSIs. Age and time since surgery were entered as the first step in all regression models. Alpha was set a priori at 0.025 (0.05/2) to account for multiple comparisons.

### Results and Discussion

Sixteen individuals (age: 18.4 $\pm$  3.0 years, 7 male/ 9 female, BMI: 27.2 $\pm$  6.4 kg/m<sup>2</sup>, time since surgery: 6.3 $\pm$  0.5 months, graft type: 11 HAS/ 4 BTB/ 1 ALL, pre-injury Tegner activity score: 9 [5,10]) participated in this study. KOOS-symptoms (60.48 $\pm$  8.60) and vGRF LSI% (73.83 $\pm$  18.59) were associated (Table 1). KOOS-symptoms was not significantly associated with KEM LSI% (88.07 $\pm$  26.42).

**Table 1.** Regression Models

Model	Predictor Variables	R <sup>2</sup>	$\Delta R^2$	P-Value
<b>Peak vGRF LSI %</b>				
1	Age, TSS	0.289	0.289	0.010
2	KOOS-Symptoms	0.519	0.231	0.034
<b>Peak KEM LSI %</b>				
1	Covariates Age, TSS	0.149	0.149	0.351
2	KOOS-Symptoms	0.205	0.056	0.414

Table 1. Linear regression models to evaluate the relationship between KOOS-symptoms and DVJ peak vGRF and KEM LSI%. TSS= Time since surgery.

### Conclusions

Patient symptoms are associated with ACLR limb underloading 6-months following ACLR. However, investigation of longitudinal changes in patient symptom burden and loading patterns in individuals with ACLR is needed in order to better understand the link between symptom resolution and risk of secondary injury.

## Elbow load variability in youth elite baseball pitchers

### Summary

Elbow injuries are a major problem in baseball pitching. The elbow internal varus torque is associated with elbow injuries in baseball pitching. It can be assumed that the within pitcher load variability is related to injuries, however, it is unknown what the pitcher within load variability is. Eleven youth elite Dutch baseball pitchers threw 25 fastballs. Peak internal varus torque was calculated and the variability was defined as the standard deviation of the 25 throws. The preliminary results show an indication of differences in within pitcher elbow varus torque variability between pitchers. Future research should investigate how this load variability is distributed over different elbow stabilizers.

### Introduction

Baseball pitching exposes the upper extremity to high loads and is strongly associated with medial elbow injuries [1]. The most common medial elbow injury in baseball is the Ulnar Collateral Ligament (UCL) rupture. Inverse dynamics shows a peak external valgus torque around the elbow during pitching. This torque forces the forearm to move away from the upper arm. The UCL is one of the elbow structures that resist this torque and provide elbow stability but it is only possible to estimate the UCL load during pitching. Studies show that UCL injuries and UCL thickness are associated with internal varus torque [1,2]. Therefore, the internal varus torque can be used as proxy for UCL load.

It is hypothesized that an increased within pitcher load variability increases injury risk. It is, however, never investigated whether there is a difference in load variability between pitchers. Therefore, the aim of this study is to investigate whether there is a difference in within pitcher elbow internal varus torque variability between youth elite baseball pitchers.

### Methods

Eleven youth elite baseball pitchers (age 15 to 23 year) threw twenty-five fastballs as fast and accurate as possible to the strike zone center at the regular distance of 18.4m. Body kinematics were measured in a motion laboratory with a VICON motion capture system sampled at 400 Hz. Ball speed was measured with a portable radar gun, positioned next to the strike zone. Peak internal varus torque was calculated by inverse dynamics for each throw with a custom-made model in Python. The standard deviation was used to quantify the within pitcher internal varus torque variability. Gaussian distribution was calculated to visualize within pitcher load variability.

### Results and Discussion

Preliminary results of the within pitcher peak internal elbow varus torque are shown in figure 1. The results show a difference in the width of the normal distribution between pitchers. For example, participant 2 (orange line) shows a very low elbow internal varus torque variability compared to participant 6 (brown line). Indicating a difference in within pitcher load variability. The dashed horizontal lines in figure 1 show the mean internal varus torque of each pitcher. Some pitchers show higher internal varus torques compared to others, which is in line with the literature [1,2]. Future studies should investigate how this torque is distributed over different elbow stabilizers and thus investigate if there is a relation between internal varus torque variability and UCL load variability.

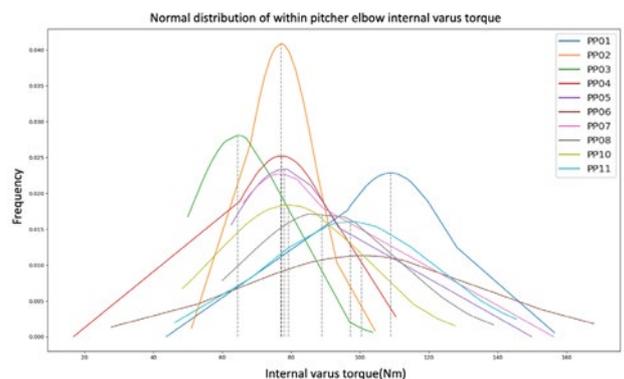

Figure 1: Normal distribution of the within pitcher elbow internal varus torque.

### Conclusions

It can be concluded, based on the preliminary results, that there is a difference in peak elbow internal varus torque magnitude and variability between youth elite baseball pitchers. However, as this torque can also be resisted by muscle forces, understanding why some pitchers sustain an injury and others do not, cannot simply be explained with the magnitude of the internal varus torque.

# Spinal palpation error and its impact on marker-based spinal curvature estimation in adult spinal deformity

Pieter Severijns<sup>1</sup>, Thomas Overbergh<sup>1</sup>, Lieven Moke<sup>1</sup>, Lennart Scheys<sup>1</sup>

<sup>1</sup>Institute for Orthopaedic Research and Training, KU Leuven/University Hospitals Leuven, Leuven, Belgium

Email: [pieter.severijns@kuleuven.be](mailto:pieter.severijns@kuleuven.be)

## Summary

Palpation error (PE) is increased in deformed adult spines and relates to the severity of the deformity. Radiograph-based PE correction results in more accurate marker-based spinal alignment measurement, primarily in the coronal plane.

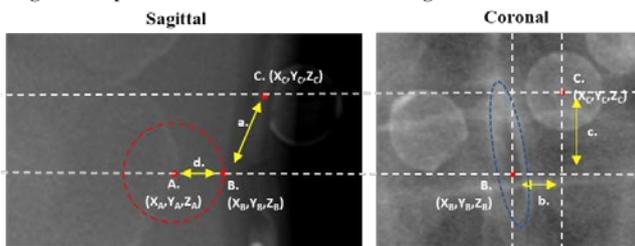

## Introduction

Measurement of spinal alignment within adult spinal deformity (ASD) research is currently shifting from mainly two-dimensional, static radiography, towards three-dimensional (3D), dynamic assessment, through the use of marker-based motion analysis. However, information is lacking on the accuracy of spinal marker placement (i.e. palpation error), one of the main sources of variability in kinematic results, and its effect on spinal alignment estimation, in both healthy and deformed spines.

## Methods

20 ASD and 10 control subjects underwent biplanar imaging with a spinal skin marker model attached. 3D spinous processes (SP) (T11, T12, L2, L3, L4) and corresponding 3D marker positions were extracted using custom software. The optimal marker position was obtained through a circle fitting method, defining the shortest distance from the respective spinous process to the skin surface. Palpation error was defined as the 3D Euclidean distance between the actual and optimal marker positions. Based hereon, also mediolateral (ML) and inferosuperior (IS) PE's were extracted. The 3D distance between the spinous process and the optimal marker position was used to quantify SP depth. PE was compared between ASD and controls and related to radiograph-based scoliosis and lordosis as well as body morphology (BMI and SP depth) through Spearman correlation ( $r_s$ ). (Figure 1)

Figure 1. Palpation error calculation and circle fitting

- A. Spinous process    B. Optimal marker position    C. Actual marker position
- a. 3D palpation error =  $\sqrt{(X_B - X_C)^2 + (Y_B - Y_C)^2 + (Z_B - Z_C)^2}$
- b. Mediolateral error =  $\text{Abs}(X_B - X_C)$     d. SP depth =  $\sqrt{(X_A - X_B)^2 + (Y_A - Y_B)^2 + (Z_A - Z_B)^2}$
- c. Inferosuperior error =  $\text{Abs}(Y_B - Y_C)$

To assess the effect of PE on marker-based spinal alignment measurement (lordosis and scoliosis), 10 ASD subjects were also measured in the motion lab. Lordosis and scoliosis were calculated by fitting a polynomial through both the uncorrected and palpation-error corrected marker positions [1]. The relation between these results and radiograph-based scoliosis and lordosis was investigated through Spearman correlation ( $r_s$ ) and root mean square errors (rmse).

## Results and Discussion

Table 1. Palpation error of ASD and control and impact on spinal curvature estimation using motion analysis

A. Palpation error quantification					
	ASD	Control	p-value		
3D PE <sub>mean</sub> (mm)	15.5 (9.2)	14.0 (5.8)	0.502		
ML PE <sub>mean</sub> (mm)	6.8 (9.1)	2.5 (1.9)	<b>0.002</b>		
IS PE <sub>mean</sub> (mm)	8.1 (9.2)	12.4 (6.1)	0.091		
Incorrect level	37%	32%			
B. Correlation analysis: Mediolateral PE vs radiography/body morphology					
	ASD		Control		
	$r_s$	p-value	$r_s$	p-value	
Lordosis (°)	0.34	0.141	-0.08	0.829	
Scoliosis (°)	0.77	<b>&lt;0.001</b>	N.A.		
BMI (kg/m <sup>2</sup> )	-0.08	0.734	0.78	<b>0.008</b>	
SP depth (mm)	0.33	0.158	0.66	<b>0.038</b>	
C. Spinal curvature estimation    Relation to Radiography					
1. Lordosis (°)	ASD		$r_s$	p	rmse
	Radiography	ASD			
Radiography	44.4 (41.7)				
Uncorrected markers	15.0 (26.9)	0.77	<b>0.009</b>		28.7
PE-corrected markers	25.8 (27.8)	0.69	<b>0.029</b>		23.2
2. Scoliosis (°)	ASD		$r_s$	p	rmse
	Radiography	ASD			
Radiography	55.8 (38.2)				
Uncorrected markers	11.3 (12.5)	0.44	0.152		44.3
PE-corrected markers	18.1 (21.5)	0.84	<b>&lt;0.001</b>		32.7

Median (interquartile ranges) are reported.  $\alpha=0.05$ .

Although spinal level identification and inferosuperior palpation error were not different between deformed and healthy spines, significantly increased mediolateral palpation error was observed in ASD. Significant correlation ( $r_s=0.77$ ) with radiographic scoliosis suggests a substantial contribution of the deformity itself, possibly due to the rotatory component of scoliosis, resulting in SP's directed towards the concave side of the curve. In contrast, PE in healthy spines was mainly related to body morphology. Correcting the marker positions towards their ideal position resulted in lordosis and scoliosis values, more similar to radiography (decreased rmse). For scoliosis, also a marked increase in correlation coefficient with radiography was observed.

## Conclusions

Palpation error is increased in deformed adult spines and relates to the severity of the deformity. Radiograph-based PE correction results in more accurate marker-based spinal alignment measurement, primarily in the coronal plane.

# Fear-avoidance beliefs are not related to stoop-squat-behavior during object lifting in healthy pain-free adults

Stefan Schmid<sup>1</sup>, Christian Bangerter<sup>1</sup>, Magdalena Suter<sup>2</sup>, Michael L. Meier<sup>2</sup>

<sup>1</sup>Spinal Movement Biomechanics Group, Bern University of Applied Sciences, Bern, Switzerland

<sup>2</sup>Integrative Spinal Research ISR, Balgrist University Hospital, Zurich, Switzerland

Email: [stefan.schmid@bfh.ch](mailto:stefan.schmid@bfh.ch)

## Summary

To investigate whether “fear of round-back-lifting” is related to stoop-squat-behavior during object lifting, we developed a novel lifting style index, applied it to the motion capture data of 57 healthy pain-free adults and correlated it with scores from a self-report questionnaire for assessing fear-avoidance beliefs. The results showed no associations between “fear of round-back-lifting” and lifting style, indicating that fear-avoidance beliefs might not directly affect whole body motor control strategies.

## Introduction

Although challenged by recent biomechanical evidence, many health care professionals still hold the opinion that lifting with a flexed spine (stoop lifting) is dangerous for the back and promote lifting with a neutral spine (squat lifting) as the safer way. In this regard, we previously showed that individuals with an elevated “fear of round-back-lifting” appear to reduce lumbar spine flexion during object lifting [1]. The question remains, however, whether this is related to lifting style in general (i.e. stoop or squat) or simply represents a localized motor control alteration.

In this study, we investigate the association between “fear of round-back-lifting” and lifting style in healthy individuals using a novel index for quantifying stoop-squat-behavior.

## Methods

A cohort of 57 healthy pain-free adults (m/f: 30/27; age: 29.5±7.0 years) participated in this study. After completing the Photograph Series of Daily Activities-Short electronic Version (PHODA-SeV) [2], they were equipped with 58 retro-reflective markers [3] and asked to lift up and put down a 5kg-box with their preferred lifting style.

To quantify the lifting style, we developed a novel index, the Stoop-Squat-Index (StSq), which describes the relationship between trunk forward lean and lower extremity joint flexion based on the following formula:

$$StSq = 100\% - \left( \frac{(Vert\_HJC_{Standing} - Vert\_HJC_{Bending}) * 100\%}{Vert\_C7_{Standing} - Vert\_C7_{Bending}} \right)$$

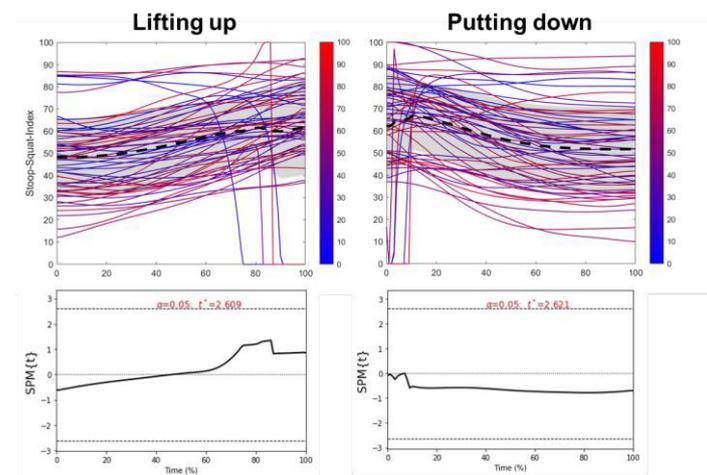

whereby *Vert\_HJC* and *Vert\_C7* represent the vertical positions of the hip joint center and the C7 marker, respectively, during standing and bending. Hip joint centers were thereby established using the Plug-in Gait full-body model. An index of 100% indicates full stoop lifting and 0% full squat lifting behavior.

The association between “fear of round-back-lifting” (sub-score of PHODA-SeV between 0 and 100 (PHODA-Lift)) and StSq over a full lifting cycle was investigated using

linear regression models, which were implemented by means of one-dimensional Statistical Parametric Mapping [4].

## Results and Discussion

Participants showed a large inter-subject variation of lifting styles (from almost full stoop to almost full squat lifting behavior), but no statistically significant associations between PHODA-Lift and StSq were found (Figure 1).

**Figure 1:** Stoop-Squat-Index for lifting up and putting down a 5kg-box and its relation to “fear of round-back-lifting” (PHODA-Lift).

Since this study only focused on lightweight objects, it remains unclear whether these results also apply for lifting heavier objects. Future studies might therefore use the newly introduced StSq to address this issue in more detail. If no motion capture information is accessible, the StSq might also be derived from conventional video recordings.

## Conclusions

Fear-avoidance beliefs, particularly the “fear of round-back-lifting”, appears not to be related to the stoop-squat-behavior during object lifting, indicating that fear-avoidance beliefs might not directly affect whole body motor control strategies.

# Cervical spine injuries observed in misdirected rugby tackles are not caused by a hyperflexion mechanism

Pavlos Silvestros<sup>1</sup>, Ezio Preatoni<sup>1</sup>, Harinderjit S. Gill<sup>2</sup>, **Dario Cazzola**<sup>1</sup>  
<sup>1</sup>Department for Health, University of Bath, Bath, United Kingdom  
<sup>2</sup>Department of Mechanical Engineering, University of Bath, United Kingdom  
 Email: d.cazzola@bath.ac.uk

## Summary

Rugby tackling carries with it a high proportion of all catastrophic cervical spine injuries in the game of rugby. In the literature, there is still an open debate on the injury mechanisms related to such injuries, with hyperflexion and buckling being under scrutiny. The aim of this study was to simulate the dynamic response of the cervical spine to loading conditions representative of misdirected rugby tackles injuries, and it was informed by experimental *in vivo* and *in vitro* data representing realistic rugby tackling conditions. Results showed that: i) neck flexion at the time of impact had the largest effect on neck internal loading; ii) the early generation of high compression, anterior shear and flexion loads provides additional evidence that hyperflexion is not the primary injury mechanism during rugby tackles.

## Introduction

In the literature, quasi-static and dynamic *in vitro* cadaveric experiments have been conducted to investigate cervical spine injuries during head first impacts [1]. However, from an injury prevention perspective, such experiments are not often deemed conclusive as they are highly controlled by nature and may greatly differ from the real *in vivo* dynamics of rugby tackles. Computer simulations have since proven a valuable method in being able to recreate with high fidelity the internal and external loading conditions, and can be informed or driven by *in vivo* kinematics, kinetics, and electromyography data. We conducted an *in silico* investigation, informed and driven by a combination of *in vitro* and *in vivo* data, to examine the dynamic response of the cervical spine to loading conditions representative of misdirected rugby tackles.

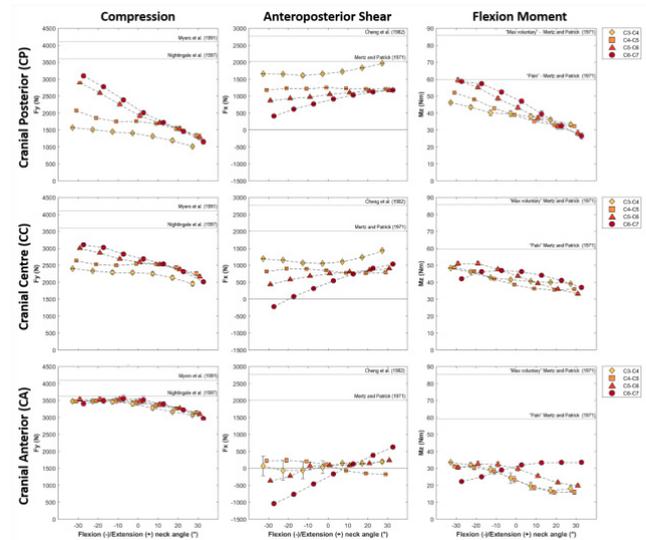

## Methods

One professional academy-level front-row rugby player (male, 22 years, 1.82 m, 113.7 kg) participated in this study. Experimental kinematics and neck muscles electromyography data was during staged rugby tackling trials, whilst external loading was collected during a set of head first impacts generated by accelerating a punch-bag against a dummy head. A subject-specific OpenSim musculoskeletal model [2] was firstly used in EMG-assisted inverse simulations to estimate neck muscles activation, and then in forward dynamics simulation (n=1638) where neck angles (n=117), loading conditions (n=7), and loading rate (n=2) were changed iteratively. The effects of initial neck angle and loading conditions were evaluated by analysing the maximal compressive loading, anteroposterior shear loading and flexion bending moment sustained during a 50 ms impact simulations.

## Results and Discussion

From a tackling technique perspective, neck flexion at the time of impact had the largest effect on neck internal loading, and confirmed that compressive loading increases with neck flexion angle also in rugby tackling (Figure 1).

From an injury mechanism analysis perspective, the early generation of high compression, anterior shear and flexion loads provides additional evidence that hyperflexion is not the primary injury mechanism during rugby tackles.

**Figure 1:** Mean and SD values for max compression and shear forces, and flexion moment of all initial neck angle conditions plotted against changes in neck flexion/extension angles for cranial loading conditions. Estimated injury thresholds from the literature for the entire cervical spine are also presented with horizontal lines.

## Conclusions

During misdirected rugby tackles, loading patterns associated with buckling and anterior facet dislocations are generated much earlier than when physiological neck flexion ranges are exceeded. This indicates that the cervical spine injuries observed in misdirected rugby tackles are not caused by a hyperflexion mechanism.

## Acknowledgments

The authors would like to thank the Rugby Football Union Injured Player Foundation for funding.

<sup>1</sup>Laboratory for Movement Biomechanics, Institute for Biomechanics, ETH Zürich, Switzerland

<sup>2</sup>Faculty of Technical Sciences Čačak, University of Kragujevac, Serbia

<sup>3</sup>University Children Hospital - UKBB Basel, Switzerland

Email: [sasa.cukovic@hest.ethz.ch](mailto:sasa.cukovic@hest.ethz.ch)

## Summary

To avoid repetitive harmful effects of X-ray exposure in patients with Adolescent Idiopathic Scoliosis (AIS), new non-invasive approaches have been developed, with the aim to replace or reduce the need for X-ray imaging, especially in follow-up and monitoring stages. We recently developed ScolioSIM1.0, a software tool that produces 3D visualizations of the patient-specific deformity model and allows evaluation of AIS in a non-invasive manner. As it enables spatial visualization of the deformity, numerous geometrical parameters can be evaluated in all 3 body planes in 2D or 3D. One parameter of clinical importance is the barycenter (BC) of the spine, which describes the center point of the surface that envelops a projected Middle Spinal Alignment (MSA) in the plane normal to the local spinal axis DM-C7, located at L5's lower plate point.

## Introduction

Traditional evaluation of AIS still relies on the 2D Cobb angle as a gold standard, which describes only one specific segment of the spinal curve in one plane, neglecting the 3D nature and spatial configuration of the deformity, especially axial projection of the MSA (Figure 1). In this study, we aim to determine transversal projections of the MSA and BC of the human spine using non-invasive optical techniques [1], as their shape and position can reveal important indicators of the deformity, as well as help clinicians to qualitatively describe a patient's posture [2].

## Methods

We performed retrospective analysis of 26 3D optical samples of AIS patients' back surfaces using the ScolioSIM1.0 diagnostic tool (18 females and 8 males;  $10.6 \pm 1.37$  and  $11.5 \pm 2.07$  years old). For each patient, the BC location and surface area were calculated, and contour shapes were considered. Depending on the position of the BC from the local spinal axis (0,0), deformity may be left or right shifted. In addition, the BC was used to determine if the subjects' back posture deformities were flat (ventral) or sway (dorsal). As scoliosis is a 3D deformity, the BC was then placed in different quadrants in order to allow the pathology to be classified as an anterior shift, posterior shift, right or left shifted, or combined. Depending on the shape of projected contour, deformity could be qualified as isophasic (narrow contour) and anisophasic (rounded) (Figure 1).

## Results and Discussion

Analysis of the collected datasets and parameters of BC points showed that the most dominant type of scoliosis in the

selected population of patients were right (84.6%) and posteriorly (57.7%) shifted. As datasets contained AIS patients only, all projected contours indicated mainly anisophasic deformities.

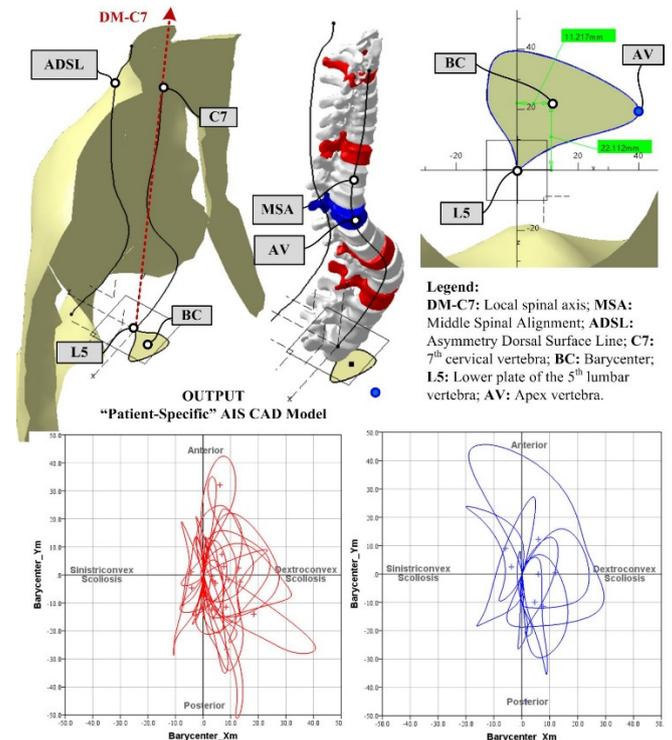

Figure 1: Barycenter points in pathological spines, presented for both female and male subjects

## Conclusions

In many studies and current clinical practice, AIS is mainly diagnosed based on 2D frontal and sagittal plane parameters. Axial projection of the MSA is of crucial importance, and can now be accessed using optical techniques, hence providing access to the BC. Such approaches can clearly show balance of the patient and pave the way towards a new non-invasive 3D classification of scoliosis.

### Summary

Previous modelling has suggested that the muscle forces required to stabilize the lumbar spine are related to its shape. In this study, we performed subject-specific modelling on a sample of 41 healthy participants using a simple two-dimensional model. The predicted muscle forces correlated significantly with the lumbar lordosis suggesting that muscle force is subject-specific and related to spinal shape.

### Introduction

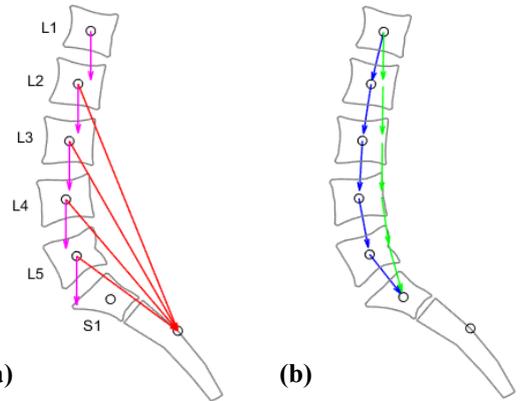

The muscle forces required to maintain a stable lumbar spine have been shown to relate to lumbar spine shape [1]. Previous studies, however, have focused on single or idealized anatomy which may miss interactions between lumbar shape and other parameters such as muscle angulation. The aim of our study was therefore to investigate muscle forces in a sample of healthy individuals using subject-specific models.

### Methods

Models were created using Matlab (R2020a, The MathWorks Inc.). The model geometry (Figure 1) was defined by the lumbar vertebrae and sacrum. Body forces (totaling 49 % of body weight) were distributed across the vertebrae according to [2]. Muscle forces were applied in directions defined by the vertebral body centroids and the sacrum.

The magnitude of the muscle forces and internal forces generated within the spine were determined using optimization for two cases (Figure 1b). In the 'optimum' case, the path of the internal forces was constrained to pass as close as possible to the vertebral body centroids. In the 'minimum' case the total muscle force was minimized without allowing the path of the internal forces to lie outside the vertebral bodies.

Subject-specific model data were derived from magnetic resonance images. The images were a subset of data from a study where participants had consented for their data to be used in subsequent research. The subset comprised 41 healthy female participants (26 to 46 years) with a body mass of  $72 \pm 13$  kg (mean  $\pm$  sd). Lumbar lordosis was calculated as the angle between the superior endplates of L1 and S1.

**Figure 1:** (a) Example model geometry with body forces (pink) and muscle forces (red) (b) Path of the resulting 'optimum' (blue) and 'minimum' (green) internal forces generated in the spine.

### Results and Discussion

Predicted muscle forces (Table 1) increased from L2 to L5 in both the optimum and minimum case. Lumbar lordosis ranged from 37 to 72 degrees. The Spearman correlation between lordosis angle and muscle force was statistically significant for all optimum muscle forces and for minimum muscle forces at L4 and L5 (Table 1). The internal force magnitudes at L4L5 were consistent with measurements of intradiscal pressure from the literature [3], giving confidence in model validity.

### Conclusions

The muscle forces required to maintain the upright lumbar spine in static equilibrium are subject-specific and are related to the curvature of the subject's lumbar spine.

### Acknowledgments

We thank the volunteers for their image data.

## Summary

Finite element (FE) software ABAQUS and FEBio have been used to model time-dependent responses of fibril-reinforced poroelastic and biphasic tissues (FRPE), such as articular cartilage. However, knee joint models with depth-wise and split-line collagen fibril orientations have been simulated only in ABAQUS. Here, we propose a novel fibril-reinforced biphasic hyperelastic material formulation in FEBio, implemented in a knee joint model under a gait cycle loading. Results were compared with a previous validated FRPE model in ABAQUS. The mechanical outputs between the models corresponded well through the gait cycle. To conclude, we suggest using the easily accessible and free FEBio software to simulate the complex mechanical behavior of cartilage in the knee joint during gait.

## Introduction

FRPE models of articular cartilage capture the mechanical interactions between tissue constituents (collagen fibrils, proteoglycans, interstitial fluid) and show how altered properties of the constituents in osteoarthritis affect tissue and joint mechanics [1]. These models have been implemented in FE software ABAQUS [2,3] and in the free open-source software FEBio [4,5]. However, FEBio models with the FRPE formulation of cartilage have not been generated for patient-specific knee joint geometries to simulate gait. Furthermore, the important split-lines patterns in a depth-dependent collagen network have not been incorporated in FEBio before, as has been done in ABAQUS. Thus, this study proposes a new material formulation of knee articular cartilage with a realistic orientation of collagen fibrils in FEBio. The results from the knee joint model during walking were then compared to those obtained from a corresponding model in ABAQUS.

## Methods

Figure 1 shows the workflow of the study: (a) knee geometry generation, (b) optimization of the material parameters in FEBio, (c) boundary and loading conditions, and (d) result comparisons. The geometry was generated from MRI data of a healthy subject, obtained from the Osteoarthritis Initiative. In FEBio, articular cartilage corresponded to a fibril-reinforced biphasic hyperelastic material. The depth-wise collagen network consisted of primary and secondary fibrils that follow split-lines patterns. We simulated simple cubic models under tension and confined and unconfined compression tests to optimize the mechanical parameters in FEBio based on the FRPE model in ABAQUS. At the joint-level modeling, a simplified stance phase of gait was implemented in FEBio and ABAQUS models by applying time-dependent axial load and flexion angle boundary

conditions to the rigid-body femur reference point (Figure 1). Finally, mechanical responses of the knee joint cartilage were compared between software.

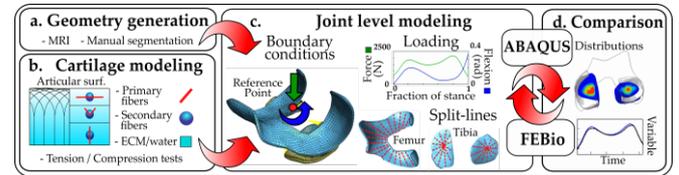

Figure 1: The workflow of the study.

## Results and Discussion

Quantitative and qualitative results (Figure 2) show similar fluid pressures, stresses, reaction forces, and strains between FEBio and ABAQUS models. Small differences may arise from the different fibril formulations we used in the models. The results agreed with previous studies on the effect of depth-wise orientation of collagen fibrils of cartilage in FEBio, using simpler geometries [5], and ABAQUS [3], using knee joint geometries. As FEBio is easier accessible than ABAQUS and free for researchers, this work encourages its use in the modeling of knee joint mechanics.

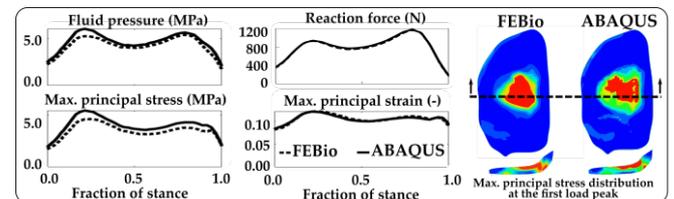

Figure 2: Mechanical responses in the medial tibial cartilage, modeled by fibril-reinforced biphasic and poroelastic material formulations, during simulated gait in FEBio and ABAQUS.

## Conclusions

This study presents an approach to generate a 3D fibril-reinforced biphasic knee joint model in FEBio with realistic collagen fibril orientations of cartilage. Similar mechanical responses of cartilage during gait in FEBio and ABAQUS suggests that easily accessible FEBio can be used in future applications.

### Summary

Recent developments in atlas-based finite element (FE) knee joint modeling have drastically reduced construction and computation time [1, 2]. However, that approach has been utilized only with magnetic resonance imaging (MRI) and computed tomography (CT) based imaging modalities. Radiographs of the knee joint are the most commonly used for knee osteoarthritis (OA) diagnosis. Hence, a capability to produce biomechanical knee joint models directly from radiographs would enable an efficient way to estimate knee cartilage failure and progression of knee OA. This study proposes an atlas-based FE modeling framework for an automatic model generation and simulation of knee joint cartilage mechanical responses using knee X-ray images. The developed framework was successfully verified against the simulation results obtained from MRI-based FE models.

### Introduction

Current atlas-based FE models are based on images obtained through MRI [1] or CT [2]. However, these imaging modalities are typically available in specialized healthcare centers and are not standard knee OA diagnostics methods. However, radiography (planar X-ray imaging) is an economic diagnostic imaging modality at the primary healthcare level. Hence, 3-D knee joint model generation from radiographs would increase the scalability of the FE modeling – an important factor for clinical use. Thus, this study aims to develop a radiography-based 3-D knee joint model generation framework that would be a clinically feasible method to simulate knee OA progression.

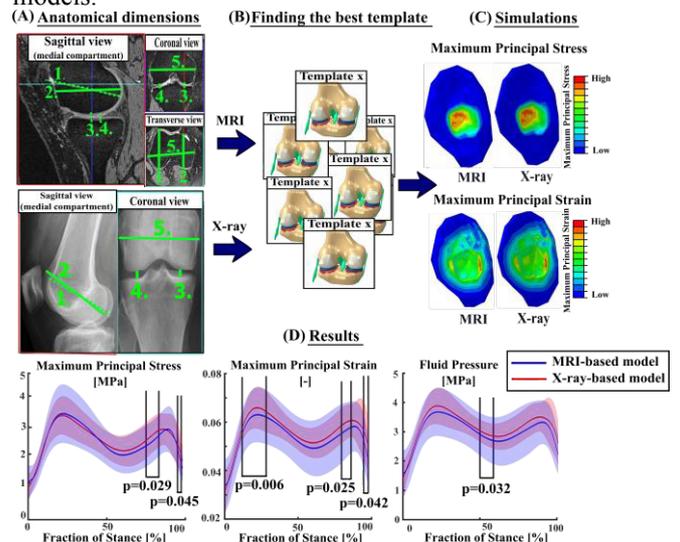

### Methods

Previously collected data from 28 patients (aged between 50 and 68 years) were used in the study [3]. In that study, each patient's knee MRI and X-ray images were acquired using clinical 3T MRI and X-ray devices, respectively. The X-ray images based FE modeling followed the previously developed atlas-based FE model generation method [1]. In order to generate FE models, the anatomical dimensions of the distal femur and tibiofemoral joint space widths were measured similarly from both imaging modalities (Figure 1A). To improve intra-observer reliability, the dimension measurements were repeated three times for each subject. Thereafter, the closest knee template to the patient's knee dimension measurements was selected from the knee atlas database (21 templates) and morphed to match the measured anatomical dimensions (Figure 1B). In total, 84 knee models for both modalities were constructed. Knee cartilages were modeled using fibril-reinforced poroviscoelastic material, and physiologically relevant time-dependent gait loading (stance phase) was applied to knee models in Abaqus (v2018) [1]. The model outputs (i.e., average values of maximum principal stress, strain and fluid pressure of tibial

cartilage obtained from the tibiofemoral contact area) of MRI and X-ray-based models were compared using a 1-D statistical parametric mapping.

### Results and Discussion

In terms of the biomechanical responses, X-ray based approach offered similar outcomes compared with MRI based approach (Figure 1D). The maximum principal stress was different in the models in a narrow timeframe between the midstance and 2nd peak load as well as at the end of the stance (Figure 1D). The maximum principal strain was different at the loading response and at the same locations as the maximum principal stress. The fluid pressure was different only in a narrow timeframe along the midstance. These results suggest that to estimate knee cartilage mechanics and possible failure points, X-ray-based knee joint models can simulate similar results as MRI-based models.

**Figure 1:** (A, B) Workflow of the atlas-based method for model generation, (C) the simulated maximum principal stress and strain distributions of a single subject in medial tibial cartilage in both X-ray and MRI-based models. (D) Mean and standard deviation (28 subjects, 84 models for both imaging modalities) of model outputs.

### Conclusions

The presented modeling approach can offer a fast and cost-effective approach for simulation of biomechanical risks for the onset and progression of OA that could potentially be also used at the primary healthcare level.

### Summary

Vibration-induced low Wall Shear Stress (WSS) flow inside digital arteries may cause arterial growth and remodeling. In this study, we propose an agent-based model of the WSS-modulated growth, supposedly induced by an intimal hyperplasia phenomenon. The modelled mechanisms depend on the Platelet-derived growth factor BB chain (PDGF-BB) secreted by endothelial cells (ECs) upon exposure to vibration. The PDGF-BB concentrations were obtained from flow experiments on cultured human umbilical vein ECs (HUVECs) exposed to a physiological level of WSS = 3 Pa and a vibration-induced level of WSS = 1 Pa. Results showed higher PDGF-BB level for WSS = 1 Pa. The arterial lumen narrowed around 50% when simulating a vibration exposure of 4 hours a day for 5 years (WSS = 1 Pa).

### Introduction

A chronic exposure to Hand-Arm transmitted Vibration (HAV) can cause an arterial growth and remodeling inside digital arteries. In our study, we suppose that the growth is induced by a WSS-modulated intimal hyperplasia phenomenon (IH). Studies have shown that an acute exposure to HAV can decrease the WSS exerted by the blood on the arterial endothelium [1]. A low WSS can promote the EC-secretion of certain mitogens and chemoattractant acting on smooth muscle cells (SMCs), such as the PDGF-BB [2]. We suppose that this secreted PDGF-BB, will alter the dynamics of SMCs. On the long term, this can lead to the development of IH. In this present study, we propose an agent-based model that describes the SMCs dynamics inside the arterial wall during physiological state and for a low WSS resulting from vibration exposure. The secretion of PDGF-BB for different WSS values was investigated using in-vitro flow experiments on HUVECs. The results of the model will allow understanding the effects of the HAV on the onset of vascular pathologies.

### Methods

The agent-based model, implemented in NetLogo<sup>®</sup>, is based on biological laws derived from literature on ECs behaviors when exposed to low WSS. The initial geometry is a normal muscular artery including the endothelium (ECs) and the media layer (SMCs and Extracellular Matrix (ECMs)). The SMCs dynamics were modelled using probabilistic equations that describe biological mechanisms such as the proliferation/apoptosis, the migration and ECMs synthesis/degradation. Starting from an equilibrium state, the model was then disturbed by a WSS value resulting from a

vibration exposure. Our model took into account the acute cellular changes and simulated the chronic SMCs dynamics. Experimental data of the PDGF-BB concentrations secreted by HUVECs when exposed to a low WSS were used as input parameters for our model.

### Results and Discussion

Results of the cellular tests on HUVECs showed that the ECs secreted almost 50% more PDGF-BB for WSS = 1 Pa ( $27.93 \pm 5.14$  pg/ml) than for WSS = 3 Pa ( $18.50 \pm 7.97$  pg/ml) ( $p < 0.05$ ,  $n = 7$ ). In addition, our model succeeded in simulating the physiological state, in the absence of vibration and the arterial growth resulting from vibration exposure (Figure 1).

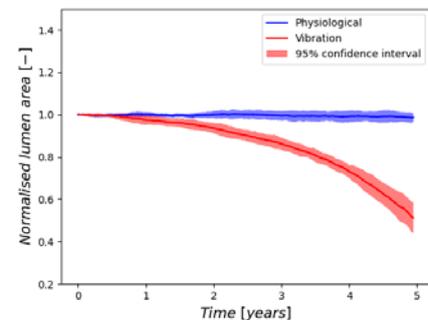

Figure 1. Change in lumen area for physiological and vibration exposure states (average of 5 simulations).

Figure 1 shows a 50% decrease in lumen area upon exposure to vibration, describing the arterial growth after 5 years of 4 hours exposure per day. We only took into account the change in ECs-secretion of PDGF-BB when exposed to a low WSS. However, other mitogens might be released from the SMCs as well and then modulate their dynamics. Our model offers the possibility to include more cellular mechanisms and to study other work conditions with different exposure times.

### Conclusions

We presented an agent-based model of the vibration-induced intimal hyperplasia, enriched with experimental data. The model was able to describe the physiological state and predict the arterial growth resulting from vibration exposure.

# The effect of soft tissue modeling on tibiofemoral stress distribution in models of high tibial osteotomy and its importance for making simulation-based clinical decisions

Elaheh Elyasi<sup>1</sup>, Antoine Perrier<sup>1</sup>, Yohan Payan<sup>1</sup>

<sup>1</sup>Univ. Grenoble Alpes, CNRS, TIMC-IMAG, 38000 Grenoble, France

Email: elyasi.elaheh@gmail.com

## Summary

High tibial osteotomy (HTO) is a surgical procedure to treat unicompartmental osteoarthritis through correcting the lower limb alignment. Biomechanical models have been used for making simulation based decisions on the optimal alignment correction to achieve during HTO. However, in many models generated with this aim, the role of soft tissues has been neglected. Our objective was to investigate the impact that the connective tissues can have on simulation-based decisions.

## Introduction

High tibial osteotomy (HTO) is a common surgical procedure used to relieve pain and improve joint function in patients with early-stage unicompartmental osteoarthritis. Its goal is to reduce the pressure of the damaged knee compartment by correcting the limb alignment. However, finding the required correction for each patient is challenging as indicated in the follow-up studies [1]. To overcome this challenge, biomechanical numerical simulations have been used, aiming to find the optimal correction that balances the contact force between knee compartments [2,3]. To our observation, these studies tend to oversimplify the problem by neglecting the impact of HTO on moments produced by the soft tissues. Our objective is to investigate the importance of realistically modelling the connective tissues impacted by HTO on the stress distribution in the cartilages. We propose to study the role of the superficial Medial Collateral Ligament (MCL) that is one of the most important soft tissue in this perspective.

## Methods

MRI and CT images of a healthy subject were used to reconstruct the bone and soft tissue geometries through manual segmentation in Amira software. A model of the tibiofemoral joint at 25° flexion was generated in the Artisynth combined FE-multibody platform [4]. Virtual open-wedge HTO was performed on this model to simulate the HTO surgery with a 10° wedge opening. The model included the femoral and tibial cartilages and menisci all modeled with FE components and meshed with hexahedral dominant elements. Anterior and posterior cruciate ligaments, MCL with a deep and superficial layer, lateral collateral ligament, and the knee anterolateral ligament were modeled with bundles of nonlinear springs. An axial load along the mechanical axis of the limb was applied to the tibia at the center of the ankle while the femur was fully constrained and the knee flexion angle was fixed.

During HTO model generation, the superficial bundles of MCL were treated in three different ways: 1) Their length and tension were affected by wedge opening. 2) Their length and tension were not affected by wedge opening. 3) The superficial MCL was released after wedge opening.

## Results and Discussion

Maximal principal stress distribution on tibial cartilages was observed in models with the three options for representing the superficial bundles of MCL, as presented in Figure 1. The results indicate that the approach we take towards modelling the MCL after HTO can significantly impact the stress distribution on the tibiofemoral compartments. Assuming that the insertion of superficial MCL is lower than the HTO cut and thus wedge opening results in increasing its length and tension, the maximum principal stress values (medial: -2.29, lateral: 1.40 MPa) show that the medial cartilage is noticeably under higher compression compared to the lateral cartilage. This means that the objective of HTO surgery is not achieved even after 10° wedge opening in this case. The stress in the medial cartilage is reduced to 48% of this value assuming that the superficial MCL is not impacted by surgery. Furthermore, releasing the superficial MCL reduces the medial stress to 34% of this value. This is while the lateral side experiences the highest stress values among the three models. As a result, it seems important to define the approach towards the MCL attachment/release when generating models of HTO as it can significantly impact the stress balance between compartments.

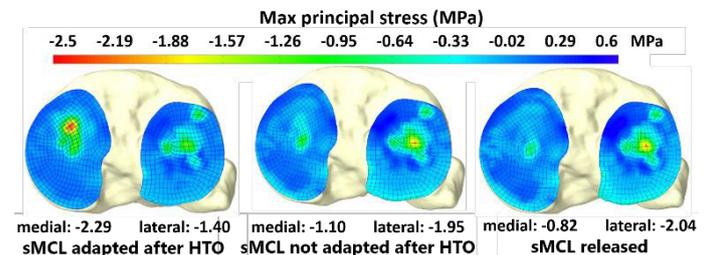

Figure 1: Maximum principal stress distribution on the tibial cartilages after 10° wedge opening.

## Conclusions

Our results show that a clear approach towards the MCL in models of the HTO has to be defined to be able to propose relevant simulation-based decisions on the optimal lower limb alignment correction.

## Numerical discretization of trabecular bone based on Voronoi tessellation

Y. Zhou, P. Isaksson, C. Persson

Department of Materials Science and Engineering, Uppsala University, Sweden

Email: [yijun.zhou@angstrom.uu.se](mailto:yijun.zhou@angstrom.uu.se)

### Summary

Discrete cellular three-dimensional structures were developed for numerical simulation of porous materials. The algorithms are based on Voronoi tessellation techniques and the morphometrical properties of the final structures are similar to trabecular human bone. Numerical and experimental evaluations of the mechanical behaviour of the structures reveal a reasonable agreement with human bone.

### Introduction

The complexity of natural cellular structures, such as trabecular bone, imposes difficulties when discretizing them for numerical simulations. Although a good representation of the microstructure can be achieved with e.g. micro-CT imaging, it is limited to one specific specimen and does not permit for a rapid representation of structures from different sites and ages, which can display large variations in structural features. In recent years, several porous models have been proposed [e.g. 1,2], however, they are often based on repeated unit cells, assembled to form a macroscopic homogenized structure, limiting stochastic features. In this study, a Voronoi tessellation technique was utilized to numerically discretize structures with mechanical and topological properties very close to those of human trabecular bone. The discretized geometries were numerically analyzed in finite element structural models and contrasted to compression tests on 3D-printed structures.

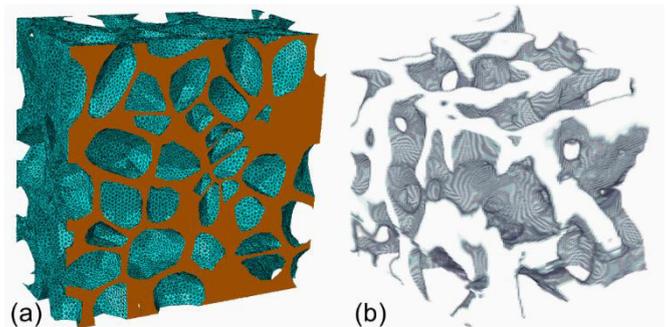

### Methods

The basic steps in Voronoi tessellation to numerically generate a porous structure are well reported in the literature [e.g. 3,4]. In contrast to previous studies, the discretized “core structure” was herein subdivided and scaled to achieve a smooth surface and the desired porosity. The discretized structures were compared to human and rabbit trabecular bone data to demonstrate the representability. Several numerical models were implemented in a commercial finite element software (ABAQUS). To validate the results, 3D-printed specimens were tested in quasi-static compression with a material testing machine.

### Results and Discussion

One of the most important features of the derived algorithm is that it combines both open and closed cells. The different topologies are controlled by the relative porosity - a higher porosity results in higher connectivity between pores. Another important feature of the algorithm is that stochasticity is naturally included in the discretization process. Other important features, such as porosity, specific bone surface, trabecular thickness, or trabecular separation can easily be controlled in the algorithm to represent different types of bone [e.g.5]. Thus, several structural features of bone can be included in the algorithm, which demonstrates the universality

of the model. An example of discretized structures with roughly 60% porosity compared with a human trabecular bone is shown in Fig. 1.

**Figure 1:** A part of finite element mesh with 200 randomly distributed pores (a), and a human trabecular bone (b).

When comparing the finite element models to the mechanical test results on 3D-printed structures, the stiffness was in general 25% higher in the finite element models. The main reasons could be differences in boundary conditions, test system compliance and defects resulting from the printing not being captured in the model.

### Conclusions

An algorithm based on a Voronoi tessellation technique has been developed to numerically discretize trabecular bone tissue having different inherent properties such as relative porosity, orthotropy, connectivity, specific bone surface, etc. The mechanical testing shows reasonable agreements between numerical simulations and experimental results, suggesting that the discretized geometries may be utilized as test material for the development of new implants, e.g. in screw attachment tests.

Email: [david.rusaw@ju.se](mailto:david.rusaw@ju.se)

## Summary

Investigations of balance and postural control in prosthesis users are often based on an implicit assumption that upright stance can be modelled as a single inverted pendulum. However, the validity of this assumption been shown to be questionable in this group. The current study suggests that a model incorporating the independent function of both the intact and prosthetic limbs better represents postural control in unilateral prosthesis users.

## Introduction

Previous research has shown that the kinetic validity of the inverted pendulum model does not reflect the behaviour of the body during quiet standing for transtibial prosthesis users (TPU) [1].

The aim of the current study was to develop and to assess the efficacy of a biomechanical model representing the control of upright posture in unilateral TPUs, specifically by: (1) empirically establishing how closely the predicted outcomes of upright postural control from a theoretical model matched the measured outcomes from a group of unilateral TPUs and a group able-bodied individuals with mechanical constraints on the centre of pressure (CoP); and (2) assessing how closely matched the measured outcomes of upright postural control were between a group of unilateral TPUs and a group able-bodied individuals with mechanical constraints on the centre of pressure.

## Methods

Two groups of participants were recruited (unilateral transtibial prosthesis users (TPU) (n=8) and controls (CON) (n=8). Participants stood quietly for 60 seconds on two parallel forceplates while full-body kinematics and kinetics data were collected. The CON group stood on a device which constrained the CoP to a fixed point. (CoP, centre-of-mass (CoM) and centre-of-mass acceleration (CoMacc) were extracted. Pearson

product-moment correlation coefficients ( $r$ ) were calculated for the CoP-CoM ( $m$ ) vs. (CoMacc) ( $m/s^2$ ) for each foot and the resultant CoP in the ML- and AP-direction under three sensory conditions (eyes-open (EO), eyes-closed (EC), weightbearing feedback (FB)).

A three-way mixed ANOVA was used to compare mean coefficient for CoM-CoP distance under each foot/combined CoP and the CoM acceleration (CoM<sub>Acc</sub>) in the mediolateral and anteroposterior directions.

## Results and Discussion

There was no statistically significant three-way interaction between Group-Condition-Limb for the AP ( $F(2.374, 30.858)=2.511, p=.089, \text{partial } \eta^2=.086, \epsilon=.593.$ ) or ML ( $F(2.016, 26.212)=1.216, p=.313, \text{partial } \eta^2=.086$ ) direction.

There was one two-way interaction effect involving the group variable in the AP direction ( $F(1.735, 30.858)=9.400, p=.002$ ) indicating increased positive correlation coefficients associated with the prosthetic/constrained limb factor vs. intact/unconstrained and total limb factors, particularly in the AB group.

## Conclusions

For the intact and unconstrained limbs, coupling of CoM acceleration and CoP were stronger when contrasted against prosthetic and constrained limbs and suggest that both TPUs and constrained able-bodied individuals' postural control conforms well to that predicted by a unilaterally-constrained pin-controller model. These effects held independent of visual manipulation and weight-bearing asymmetry, suggesting that the proposed model has implications for the fundamental control of posture in transtibial prosthesis users.

## Summary

In the optimization of a specific follower load (FL) path, usually only intervertebral rotations are minimized. In this study, we investigate the sensitivity of mechanical responses of a lumbosacral spine when including facet joint contact forces in the optimizations of FL paths. This consideration of load distributions results in substantial variations in FL paths and lumbosacral mechanical responses.

## Introduction

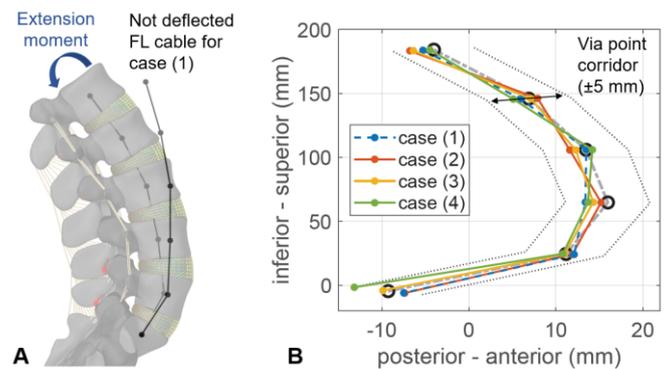

Intervertebral disks and facet joints (FJ) of the lordotic lumbosacral spine (LSS) share compressive load in upright standing position [1]. Changes in their load sharing (LS) are associated with early degeneration and pain [2]. When modeling a LSS without muscles, a follower load (FL) is used to account for the axial compressive load from standing upright [3]. In the optimization of a specific FL path, however, usually only intervertebral rotations (IVR) are minimized [4]. FJ contact forces are excluded which omits possible effects of LS. We assume that this additional criterion has an impact on the FL path and mechanical responses of a LSS model. In this study, we investigate these effects and address the question of whether LS should be considered in future FL path optimizations.

## Methods

We use a calibrated and validated passive hybrid model [5] of the ligamentous LSS built in ArtiSynth [6]. The LSS model consists of L1-S1 rigid vertebrae interconnected with fiber-reinforced finite element disks, ligaments, and idealized frictionless FJ with an initial gap width of 0.5 mm. Two sagittal symmetric tension-only cables implement the FL which is set to 600 N. The cables run through via-points attached to each vertebra. During optimization, via-point positions are automatically varied in a corridor (Figure 1B) starting at the approximate sideways centers of the vertebral bodies. In vivo estimations of FJ contact forces vary widely and may be influenced by the lumbar level or IVR [1]. Therefore, we compare the results of four different cases of objective functions used to optimize the FL path. They are minimized in MatLab® by PatternSearch with global search settings. Weighted objectives are the summarized absolute IVR and the targeted FJ forces as percentage of LS. The functions differ in the percentage of LS and in the lumbar levels for which the objectives are minimized: (1) minimize (min.) IVR; (2) min. IVR and 0% LS; (3) min. IVR (L1-L3) and 2% LS (L4-S1); (4) min. IVR (L1-L3) and 4% LS (L4-S1). For downstream LSS deflections, vertebra L1 is additionally loaded with  $\pm 7.5$  Nm in all principal directions.

## Results and Discussion

Optimizations converge after 531-706 function evaluations. Calculated displacements (mean  $\pm$  SD) of the via points from the geometric centers in mm are  $-0.25 \pm 1.80$ ,  $-0.22 \pm 2.05$ ,  $-1.04 \pm 1.03$ , and  $-1.43 \pm 2.54$ . IVR with FL are  $0.00^\circ$  in (1) and  $0.11 \pm 0.169^\circ$  in (2). IVR is maximal in (4) for L5 with  $4.15^\circ$ . Minimized IVR in (1) cause a FJ contact in L4/5 (5.2% LS). Lordosis and ROM of vertebra L1 ( $0.39^\circ$ ,  $0.02^\circ$ ,  $2.36^\circ$ , and  $3.44^\circ$ ) correlate with the mean FJ forces, which are lowest in (2) with  $0.02 \pm 0.03$  N. Less the L1 ROM due to the FL, L1 ROM in flexion is maximal in (2) with  $22.53^\circ$  and min. in (4) with  $20.37^\circ$ . However, mean FJ force in extension is  $105.31 \pm 77.84$  N in (1), highest in (2) with  $112.2 \pm 66.78$  N and lowest in (4) with  $102.9 \pm 76.25$  N. Coupled motion in axial rotation are altered by up to  $4.5^\circ$ .

**Figure 1:** (A) LSS in extension for (1) plus the initial FL cable. (B) Vertebral body centers (O) and via point positions in sagittal plane.

## Conclusions

Consideration of LS in FL optimization results in varying mechanical responses and FL paths. For better comparability of biomechanical data, even small LS ( $<5\%$ ) due to FL should be discussed. Furthermore, influences of deviating anatomies, such as lordosis angle and facet joints, should be investigated in the future. Moreover, our study illustrates the sensitivity of LSS models to the defined boundary conditions, which will be particularly relevant in the context of a hybrid model extension with active skeletal muscles.

### Summary

Little is known about how older persons balance during stand-to-sit transitions even though this poses a higher risk for falls than walking. Compared to the young, we found older adults to be more statically balanced during both sit-down and stand-up. During sit-down, younger adults were unstable and fell into the chair. In contrast, older adults remained dynamically balanced but positioned more forward. This poses a risk for falling that could be addressed during fall training.

### Introduction

The ability to get up from a chair is degraded in over 60% of long-term care residents, posing a risk of falling and affecting their independence [1]. To enable the assessment of balance during sit transitions, we recently presented an analysis of static versus dynamic balance, expressed relative to the person's base-of-support and using the foot-placement-estimator, thus taking into account the considerable linear and angular momenta during these movements [4]. Using this analysis, we found that older adults stay closer to being statically balanced than younger adults during stand-up.

Since nearly as many falls occur during stand-down [2,3], here we present the first analysis of the balance of younger and older adults during stand-to-sit.

### Methods

Eight older adults (79±8 yrs; Short Physical Performance Battery 7-12 score) and 9 younger adults (28±5 yrs) stood up and sat down 5 consecutive times at comfortable speed with 2s rest in between. Full body motion capture and ground reaction force data were collected. Analyses focused on seat-on and seat-off, based on a >1N change in force measured under the stool (adjusted to knee-height), given the typically high velocities and instabilities at these moments.

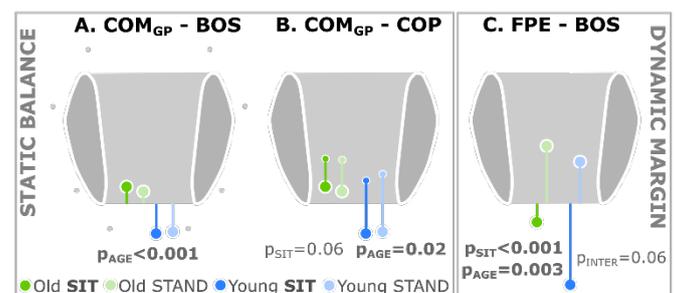

Both static and dynamic balance were analyzed using the person's base-of-support (BOS), center-of-mass-ground-projection (COM<sub>GP</sub>, IOR model Visual3D), center-of-pressure (COP), and the model-based foot-placement-estimator (FPE). The BOS was defined as the convex hull enclosing the area people could move the COP around in during flat foot standing [4]. A 2-factor mixed-model ANOVA (age vs. motion) was performed using SPSS.

### Results and Discussion

Both age groups took more time to sit down compared to standing up ( $p_{SIT} < 0.001$ ), but the older adults more so ( $p_{INTER} = 0.02$ ;  $\Delta Y = 0.47 \pm 0.39s$ ;  $\Delta O = 1.61 \pm 1.25s$ ).

Being more conservatively statically balanced was defined as the COM<sub>GP</sub> further within the BOS and closer to the COP, with lower COM speed. All 3 metrics indicated that older adults were more conservatively statically balanced compared to young, similarly during both tasks except for an even lower COM speed in older adults during sit-down (Figure 1A&B).

Being more conservatively dynamically balanced was defined as the FPE further within the BOS (larger dynamic balance margin); if the FPE is outside the BOS the person will need to take a step, or be caught by a chair, to prevent a fall. Both age groups were less dynamically balanced during sit-down compared to stand-up, with the younger adults becoming unstable (FPE far outside BOS; Figure 1C) and effectively falling onto the stool.

**Figure 1:** Static balance metrics and dynamic balance margin, with BOS hull and markers (A) in gray. Age effect, effect of sit vs. stand ( $P_{PAGE}$ ) and interaction effect ( $P_{INTER}$ ) are given ( $p < 0.05$  significant).

### Discussion

We showed that the balance dynamics between sit-down and stand-up motions are differently affected by age. While older adults sit down slower and more statically, younger adults fall into the chair. Paradoxically, the cautious approach of older adults might place them at a higher fall risk by leaning too far forward. Further research aims to relate balance in more frail older adults to typical falls seen in long-term care residents.

## Forefoot or Ankle – Which really affects Balancing Skills?

Lena I. G. Fennen<sup>1</sup>, Rosemary Dubbeldam<sup>1</sup>, Heiko Wagner<sup>1</sup>

<sup>1</sup>Department of Movement Science, Sport Institute, Faculty of Sport and Psychology, University of Münster, Germany  
Email: lena.fennen@uni-muenster.de

### Summary

The idea of interpreting our foot as a simple connection to the ground during balancing is underrepresenting the foot's complexity and importance for posture [1,2,3]. Evolutional studies pinpointed the complexity of the foot and determined the medial longitudinal arch as a particularly unique part of human feet compared to the animal kingdom [1]. In this study, three-dimensional balance analysis with a multi-segment foot model showed that the segments midfoot and medial forefoot present extraordinary high movement activity during different balancing tasks. In contrast, rearfoot movements were much less. Hence, the role of mid- and forefoot in balancing should be reconsidered. Moreover, these findings suggest a re-evaluation of the so-called hip and ankle balance strategy. The insights may benefit rehabilitation.

### Introduction

One of the common balance theories states that balancing is mostly managed by two joints: the hip and ankle [2]. Equivalently, in many biomechanical models, the human foot (26 bones, 20 muscles) is represented as one single segment [2,3]. But is this an accurate representation? Few approaches have been made to represent the foot's structures by multi-segment kinematic foot models [4]. Using such a model, assessing balance may reveal those foot segments, which influence balance abilities most. Such novel insights could be used to adjust rehabilitation approaches after, e.g., an ankle sprain. This study analyses the motion of the 6 foot segments from the Gent Foot Model (GFM) during balance tasks [4]. Additionally, so-called ankle joint motion was assessed using a 1-segment foot. The hypothesis is that not the rearfoot-tibia joint of GFM or the ankle joint present the highest amount of motion, but the midfoot and medial forefoot.

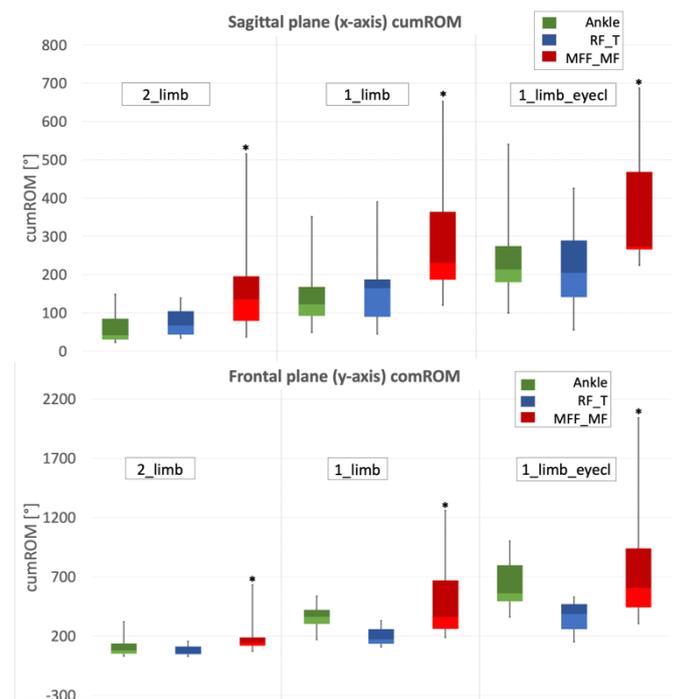

### Methods

17 healthy subjects ( $M_{age} = 24$  year,  $SD \pm 5$ ) have been equipped with 21 infrared retro-reflective markers on the right foot [4]. Three balancing tasks were recorded using a 3-dimensional movement analysis system: two-limb stance, one-limb stance and one-limb stance with eyes closed. All tasks were performed for 60 seconds and repeated twice. The GFM's 6 segment angles, as well as the ankle joint angle (assuming the foot is one segment), were assessed in 3 dimensions. Cumulative ROM (cumROM) was calculated for each trial to derive the amount of movement over time (Figure 1). A linear mixed model was used to compare joint motion in all tasks for each joint and dimension.

### Results and Discussion

The midfoot-medial forefoot joint is more active in

comparison to the rearfoot-tibia joint or the ankle joint, which difference further increases with increasing task difficulty (Figure 1). Task difficulty significantly predicted the joint's cumROM,  $F(10, 491) = 3.7$ ,  $p < 0.001$ . When incorporating all 3 dimensions, significant changes remained,  $F(20, 1324) = 5.94$ ,  $p < 0.001$ . The findings suggest that representing the foot by one rigid segment overestimates the role of the so-called ankle joint, and is not able to represent the role of the mid- and forefoot.

**Figure 1:** CumROM values with SD of two-limb (2\_limb), one-limb (1\_limb) and one-limb stance with eyes closed (1\_limb\_eyecld) of the ankle (Ankle), rearfoot-tibia (RF\_T) and medial forefoot-midfoot (MFF\_MF) joint on the sagittal and frontal plane.

### Conclusions

New knowledge about the importance of the foot's segments motion while balancing provides an opportunity to redefine training interventions to increase balance abilities. Further, the assumption that the mid- and medial forefoot are of special importance can be confirmed. This can foster a different view on the foot and its influence on the body, which it is carrying.

# Concurrent Assessment of Posture and Saccades with Visual Stimulation using Virtual Reality Technology; Construct Validity Testing in Healthy Older Adults

Y. Imaoka<sup>1</sup>, A. Flury<sup>1</sup>, E. D. de Bruin<sup>1,2</sup>

<sup>1</sup> Motor Control & Learning Laboratory, Department of Health Sciences and Technology, ETH Zurich, Zurich, Switzerland  
<sup>2</sup> Division of Physiotherapy, Department of Neurobiology, Care Sciences and Society, Karolinska Institute, Stockholm, Sweden  
 Email: [yu.imaoka@hest.ethz.ch](mailto:yu.imaoka@hest.ethz.ch)

## Summary

With the aim of early detection of dementia, a comprehensive assessment system with virtual reality (VR) technology was developed to measure posture and saccades simultaneously. Construct validity was evaluated with 14 healthy older adults (OA). We measured postural sway speed and saccade latency, provoking movements of posture and eyes with VR. Visual stimuli significantly affected on posture if saccade task was absent ( $P=.01$ , effect size (ES) = .66), and on saccade latency ( $P>.002$ ,  $ES<.78$ ).

## Introduction

OA prone to mild cognitive impairment (MCI) can express dysfunction in posture and saccadic eye movement compared with healthy OA [1, 2]. Vestibular impairment is prevalent amongst people with MCI and is associated with poorer spatial cognitive skills [3]. Concurrent assessment of posture and saccades, provoking vestibular deficits, could broaden our understandings of mechanisms underlying MCI. Following prior studies, we integrated eye-trackers with our VR-based stabilometer and assess the validity of our construct in healthy OA [4]. We hypothesised that VR visual stimuli would more affect postural sway and cause longer saccade movement generation reaction times.

## Methods

14 healthy OA (7 men / 7 women, mean age  $71.9 \pm 4.6$  years) participated. We screened all participants using the Montreal Cognitive Assessment (MoCA). We measured postural sway and eye movement simultaneously with a newly developed VR-based stabilometer (GP-5000, ANIMA Corp. & VIVE Pro Eye VR headset, HTC Corp.), recording centre of pressure and gaze direction under 11 test conditions (eyes-open and -closed without VR; gaze, pro- and anti-saccade tests in 3 VR environments: black background (2D), non-oscillating stripes (NonOSC), oscillating stripes (OSC) in anterior-posterior (AP) direction). We started with non-VR tests and then randomised the other tests. Participants wore the VR headset while standing on the stabilometer with their feet at comfortable position. We measured both eye movements and posture for 60 seconds with 30 saccade trials per condition. We evaluated the effects of 1) visual stimuli by VR and 2) saccade types on postural sway speed and saccade latency by comparing the parameters between the test conditions.

## Results and Discussion

The participants achieved MoCA scores of  $27.5 \pm 1.6$ . We compared saccade latency between 2D and the other VR environments, and postural sway speed between 2D Gaze and

the other conditions. For mean saccade latency, we found significant differences between saccade types ( $P<.001$ ,  $ES=.88$ ), and between VR environments ( $P>.002$ ,  $ES<.78$ ). For posture, we observed significant difference only between 2D Gaze and OSC Gaze in AP direction ( $P=.01$ ,  $ES=.66$ ).

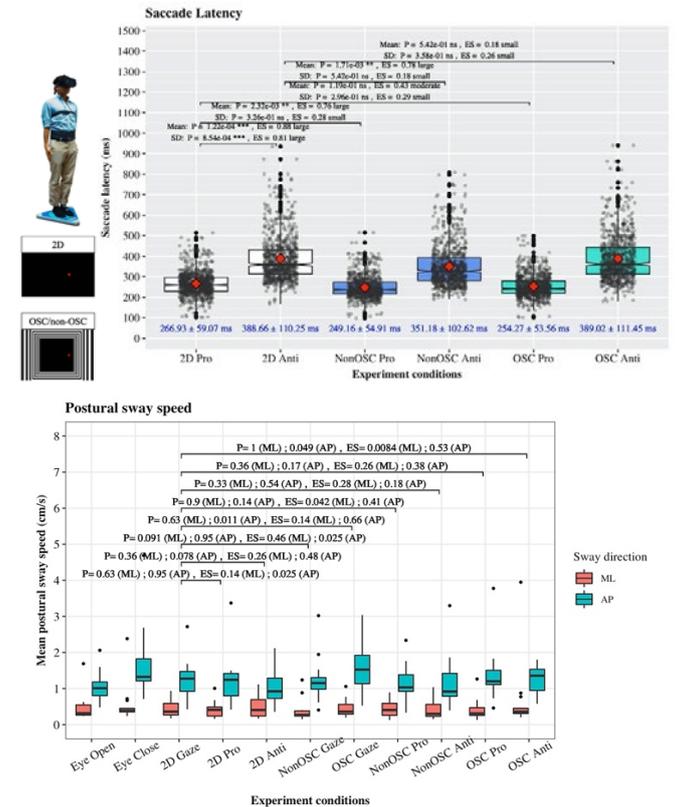

Figure 1: Distribution of saccade latency and postural sway speed

## Conclusions

The results imply that OSC visual stimuli without saccade tasks induced more postural sway in healthy OA as hypothesised. OA had enough attentional resources to perform additional saccade tasks while lessening their postural sway in the OSC condition. Concurrent evaluation of posture and saccadic eye movements using VR might support assessing people with dementia more comprehensively and the results warrant further research where OA with and without MCI should be compared.

### Summary

We examined whether muscle-wise differences in passive elasticity, measured using shear wave elastography, are associated with non-uniformity in Achilles tendon displacement. In total 52 young athletes (18.3±3.2 years, 178±13.7 cm, 72±15.8 kg) were measured for soleus, medial and lateral gastrocnemius passive muscle elasticity during slow dorsiflexion. During submaximal isometric contraction, Achilles tendon internal displacement from the distal tendon was measured using B-mode ultrasonography and analysed by speckle tracking. Results showed that passive muscle elasticity was greatest in MG muscle and lowest in SOL without differences between sports or sex. Differences in absolute passive elasticity, measured as differential shear modulus between muscles did not correlate with tendon non-uniformity. Interestingly, female sex was the only significant predictor for greater non-uniformity in tendon displacement in this sample of young athletes.

### Introduction

Athletes have 7.7 times greater chance of getting Achilles tendon (AT) rupture and 4.7 times greater chance for AT tendinopathy than controls [1]. AT injuries maybe long lasting and the factors leading to better recovery are still poorly understood. In healthy AT, non-uniform displacement is considered a healthy sign while in injury the non-uniformity is nearly nonexistent [2]. In search for functional factors influencing this phenomenon, we tested the hypothesis that non-uniform AT displacement is associated with non-uniformities in calf muscle passive elasticity in adolescent athletic population. We also examined if results were different between males and females or athletes in different sports.

### Methods

Young athletes were recruited from local Sports Academy and training room -project. Total of 35 males (mean 18.5 yrs, 186 cm, 79 kg) and 17 females (17.8 yrs, 163 cm, 58 kg) from basketball (18), track and field (16) and gymnastics (18) visited laboratory for biomechanical assessments. Study had been approved by ethics committee and participants signed an informed consent.

Muscle elasticity was assessed using Supersonic shear wave elastography (SSI, France) when participants were sitting on an ankle dynamometer with knee fully extended. When relaxed, ankle joint was rotated from 40° plantarflexion to maximum of 20° dorsiflexion at 2°/s. These passive movements were repeated when imaging soleus (SOL), medial (MG) and lateral gastrocnemius (LG) muscle bellies in random order. Inter- and intrarater reliability was ICC>0.96 Shear modulus was extracted using ElastoGUI software.

AT proximo-distal displacements within a sagittal section of distal tendon were acquired with B-mode

ultrasonography (SSI, France) when participants were performing isometric ramp contractions up to 50 Nm target level. Displacements were assessed using 2D speckle tracking (Slane & Thelen 2015) in 6 locations across the tendon. Maximal nonuniformity was calculated as maximum-minimum displacement within the tendon cross-section. Correlations between maximal tendon non-uniformity and absolute differences in passive stiffness between muscles (MG-SOL, LG-SOL, MG-LG) were calculated. Results are presented from right leg. A linear stepwise regression to predict tendon non-uniformity was performed.

### Results and Discussion

Passive muscle elasticity at maximal dorsiflexion was different between muscles (SOL 16.9±9.4 kPa, MG 89.2±25.2 kPa, LG 50.8±14.4 kPa, all p<0.001) but no differences were observed between sports or sex. Tendon displacement varied from 4.0. to 11.4 mm in the dorso-ventral plane, peak non-uniformity being non-significantly lower in males (7.0±2.9 mm) than females (9.3±5.0 mm) without differences between sports.

There were no bivariate correlations between non-uniformity in shear modulus of muscles and tendon displacement. While MG muscle had a much greater passive elastic modulus than SOL, the magnitude of elasticity difference did not correlate with the non-uniformity in AT displacement. It may be that active muscle dynamics plays the most important role in AT subtendon movement [3].

The regression model where differences in passive muscle elasticity and sex were included into the model revealed that females had more non-uniformity (standardized  $\beta$  0.323, p=0.027). This novel finding needs further study in relation with the knowledge that males have more Achilles tendon ruptures [4].

### Conclusion

Differential passive muscle properties were not associated with differential tendon displacement during isometric contraction. Female sex was the only significant predictor of AT non-uniformity in young athletes.

## Modulating Achilles Tendon Loading during Gait with a Resistive Soft Ankle Exosuit

### Summary

This study combines shear-wave tensiometry with a soft exosuit to track Achilles tendon loading during exosuit-applied ankle resistance during gait. The results demonstrate the unique potential to actively modulate and track internal muscle-tendon loading during resistive training.

### Introduction

Resistive training during gait rehabilitation in individuals with neuromotor disorders (e.g. cerebral palsy (CP), stroke) is often used to increase task intensity, which can improve retention of functional outcomes such as walking speed [1]. For post-stroke gait rehabilitation, one goal is to increase ankle push-off in the paretic limb, enhancing propulsion and walking speed. While clinics often use elastic bands to apply resistance and increase intensity, these methods do not directly target the paretic joint. Recent work showed that exoskeletons applying plantarflexor (PF) resistive torques increased PF muscle activity in patients with CP [2]. Still, it remains unknown how this translates into increased muscle-tendon (MT) loading, and how MT loading is modulated by the magnitude of applied resistance. The recent development of shear-wave tensiometry [3] enables noninvasive measures of tendon loading *in vivo* during dynamic movement, which has the potential to isolate the contributions of the triceps surae to net ankle torque. This is a distinction that cannot be made using traditional methods such as inverse dynamics, which only provide an estimate of the PF ankle torque. Here we demonstrate the feasibility of using shear-wave tensiometry to track modulations of Achilles tendon loading across a range of exosuit-applied resistances during gait.

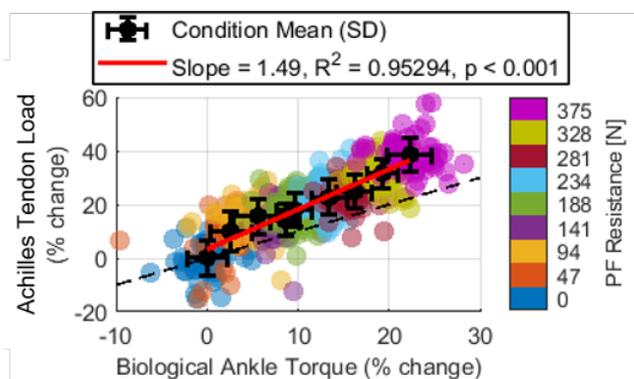

### Methods

One young healthy subject walked continuously for 9 minutes on an instrumented treadmill while wearing a unilateral soft exosuit on the left leg [4]. We collected data from optical motion capture, force plates, onboard exosuit sensors, and a tensiometer. The exosuit applied PF resistive force during the mid-late stance phase, such that the peak force increased monotonically each minute from 0N (slack) to 375N in 9 equidistant increments. The last 30 seconds of each condition was used for analysis. Net biological ankle torque was computed as the difference between exosuit-applied torque and net torque from inverse dynamics. Tendon loading is proportional to tendon shear wave speed squared, as measured by the tensiometer [3].

### Results and Discussion

The peak exosuit resistance torque increased from 0 to 0.4 Nm/kg over the 9-minute walking trial. The corresponding

peak net biological ankle torque increased from 1.61 $\pm$ 0.04 to 1.97 $\pm$ 0.04 Nm/kg (+22%). Peak Achilles tendon wave speed increased from 50.1 to 58.9 m/s (+18%) over the trial, which we estimate to correspond to a 38.6% increase in tendon loading. A significant linear relation between tendon load and net biological ankle torque was observed, with the percent change in load exceeding the percent change in biological torque (ratio=1.49,  $R^2 = 0.9529$ ,  $p < 0.001$ , Fig. 1). The strong correlation of tendon loading with resistance gives confidence that the tensiometer tracked modulations effectively. The deviation from a unity slope relationship suggests that estimations of net biological torque are insufficient to fully describe the modulation of individual muscle contributions.

**Figure 1:** Relative change in peak biological ankle torque and peak Achilles tendon load with respect to slack walking ( $F_{pk}=0$ ) across nine exosuit resistance magnitudes.

### Conclusions

This study demonstrates that shear-wave tensiometry provides a unique methodology for directly assessing the effects of active exosuit resistance on MT loading during walking. The methodology obviates the need for a motion analysis laboratory, and hence is easily transferable to clinical environments. We believe that the coupled technologies could provide an objective approach to actively modulating MT loading during gait rehabilitation.

## Summary

This study investigates the interplay of the serial elastic and the contractile component of the muscle-tendon-unit (MTU) during pure shortening and stretch-shortening contractions among varying contraction velocity and range of motion. Thereby, we used nerve muscle stimulation, ultrasound, motion capture, and dynamometry. Our results suggest that a change in contraction intensity only affects the absolute concentric MTU work but does not lead to an increased SSC-effect.

## Introduction

Stretch-shortening contractions (SSC) are the most common muscle action in sports or daily locomotion. During the concentric phase of a SSC, muscle force, work and power are increased by up to 50% when compared to pure concentric (CON) contractions [1]. This so-called SSC-Effect is discussed to be related to elastic energy preservation, reflex activity, activation dynamics or residual force enhancement (rFE) [2]. Thereby, the influence of contraction intensity on these performance-enhancing mechanisms is still rather poorly understood [3]. The aim of this study was to investigate how different contraction intensities influence the interplay of the serial elastic and the contractile component of the MTU during SSCs with varying range of motion (ROM) and contraction velocity.

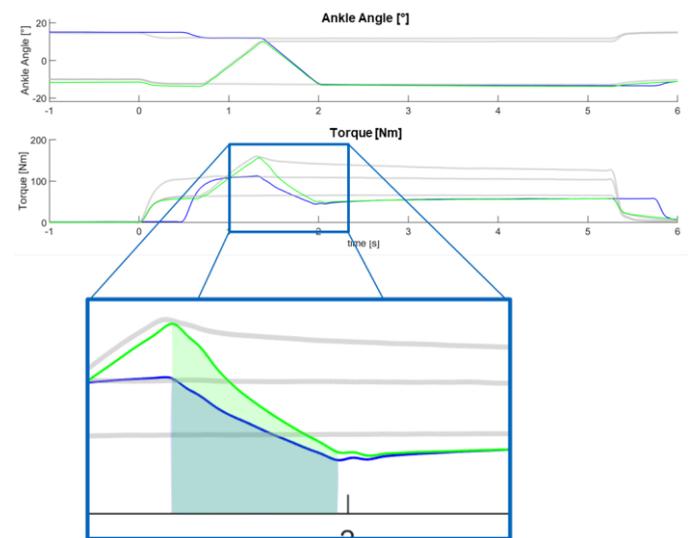

## Methods

Eleven participants performed submaximal plantar flexion contractions on a dynamometer using electrical nerve stimulation, including isometric, CON and SSC contractions at 30% and 60% of individual maximum voluntary torque (velocities: 40 & 120°/s; ROM: 15 & 25°). 3D motion capturing was used to track leg kinematics. In addition, two synchronized ultrasound probes were used to track changes in fascicle length of the gastrocnemius medialis and Achilles tendon, and to determine the dynamic Achilles tendon moment arm. The analysis focuses on the SSC-effect, defined as the ratio between the concentric phase of the SSC and CON contraction (Figure 1), using a repeated analysis of variance with the factors ROM, contraction speed and intensity.

## Results and Discussion

The SSC-effect was confirmed as MTU work was significantly increased by 5-33% during SSC contractions ( $p < 0.05$ ). The SSC-effect was unaffected by intensity as no change in MTU work ratio was found ( $p = 0.096$ ). Contraction intensity changes had no effect on the relative behavior of the

series elastic and contractile component, as the ratio of Achilles tendon length change ( $p = 0.242$ ), fascicle length change ( $p = 0.549$ ), and fascicle and Achilles tendon shortening velocity ( $p = 0.452$  and  $p = 0.218$ , respectively) was unaltered. Thus, intensity changes had no influence on fascicle work ratio ( $p = 0.091$ ). Due to the measurement setup, reflex activity and activation dynamics should not have influenced the SSC-effect.

**Figure 1:** Exemplary ankle joint angle and torque of CON (blue), SSC (green), and isometric (grey) plantar flexions. During SSC contractions concentric work (green area under curve) was increased when compared to CON contractions (blue area under curve) throughout all contraction conditions (varying speed, ROM and intensity).

## Conclusions

While the absolute values for all analyzed parameters were clearly affected by contraction intensity, these changes seemed to apply to SSC and CON contractions in a similar fashion so that the SSC-effect was unaffected. We did not find intensity-dependent changes in the contributions of the serial elastic and the contractile component of the MTU to the net SSC-effects. Further analysis focusses on rFE-related mechanisms that are not yet presented in this abstract.

## Comparing Eight Normalization Methods for Net Joint Moment Data in the Single-Leg Squat

Steven M. Hirsch, Christopher J. Chapman, Tyson A.C. Beach  
 Faculty of Kinesiology and Physical Education, University of Toronto, Toronto, Canada  
 Email: [steven.hirsch@mail.utoronto.ca](mailto:steven.hirsch@mail.utoronto.ca)

### Summary

Recent ISB recommendations raise the question of whether the variance in kinetic data due to confounding anthropometric factors between groups (e.g., males vs. females) should be controlled by using statistical adjustments or (ratio) normalization techniques [1]. Although normalization facilitates between-group comparisons, certain techniques may misrepresent the relationship between kinetic and anthropometric data [2], fail to remove the correlation between them, or provide different interpretations to adjusted linear models. The purpose of this investigation was to assess eight normalization techniques using body mass, height, and limb length to normalize net joint moment (NJM) magnitudes. Normalizing NJMs by mass\*height or mass\*leg-length were the only methods that did not misrepresent the relationship between NJM and anthropometric data, removed the correlation between these data, and provided similar interpretations to adjusted linear models. Therefore, dividing NJM magnitudes by mass\*height or mass\*leg length is recommended to facilitate between-group comparisons.

### Introduction

Anthropometric variables such as body mass, height, or limb length can influence the magnitude of NJMs. There is no consensus as to how, if at all, NJM data should be analyzed to account for differences in anthropometrics [1]. Commonly used ratio normalization techniques, where the NJM is divided by a "control" variable (e.g., body mass, height, or limb length), can potentially misrepresent the underlying relationship between NJM and anthropometric data if the regression line between these variables does not pass through the origin [2]. Further, it is unclear which methods successfully remove the correlation between the NJM and anthropometric variables while maintaining similar statistical interpretations to adjusted linear models (i.e., covariate analyses). Therefore, it is essential to consider how or if NJM data were normalized when interpreting research results, as it may affect the conclusions drawn. The purpose of this investigation was to compare the effects of eight different normalization techniques that involved dividing NJMs by various (combinations of) body mass, height, and limb length metrics during a single-leg squat (SLS) movement.

### Methods

Sixteen males and 16 females performed five SLSs with their non-stance foot held back behind their body. A bottom-up inverse dynamical linked-segment modelling approach was used to quantify knee NJMs using standard methods. The data analyzed here were a subset of those reported elsewhere [3].

Net moments about the knee joint mediolateral axis were extracted when the knee was maximally flexed, and were then

divided by body mass, allometric mass ( $\text{mass}^{0.67}$ ), height, limb length, mass\*height, mass\*limb length, allometric mass\*height, and allometric mass\*limb length.

Three methods were used to assess normalization techniques: 1) intercept analysis; 2) correlations between normalized NJM and anthropometric data; and 3) "mock" experimental analysis comparing normalized NJMs between males and females. The first method was used to assess the implicit assumption that the regression line between the NJM and anthropometric variables passed through the origin. If the regression line did not pass through the origin (i.e., the intercepts were significantly different from zero), then the ratio was deemed to misrepresent the relationship between these variables. The second method assessed the assumption that normalization removes the correlation between the NJM and anthropometric variables. The third method assessed the similarity of statistical interpretations when comparing NJMs between males and females using each normalization method relative to a statistically adjusted linear model.

### Results and Discussion

The regression lines between NJMs and mass, mass\*height, mass\*limb length, allometric mass\*height, and allometric mass\*limb length passed through the origin (i.e.,  $p > 0.05$  for all intercepts). Correlations between NJMs and anthropometric data were only removed when normalizing by mass\*height ( $r = 0.04-0.19$ ), mass\*limb length ( $r = 0.06-0.11$ ), allometric mass\*height ( $r = 0.29-0.31$ ), and allometric mass\*limb length ( $r = 0.23-0.33$ ) (all  $p > 0.05$ ). When comparing NJMs between males and females, only normalizing with mass\*height and mass\*leg length yielded similar statistical interpretations to an adjusted linear model.

### Conclusions

Dividing NJMs by mass\*height or mass\*leg length is recommended to facilitate comparisons between groups. The traditional method of normalizing kinetic data based solely on body mass should be avoided for knee NJMs during a SLS.

# Can electrical noise stimulation improve the perception of vibration stimuli in patients with diabetes mellitus?

Claudio Zippenfennig<sup>1</sup>, Tina J. Drechsel<sup>1</sup>, Daniel Schmidt<sup>1</sup>, Thomas L. Milani<sup>1</sup>

<sup>1</sup>Chemnitz University of Technology, Department of Human Locomotion, Chemnitz, Germany

Email: claudio.zippenfennig@hsw.tu-chemnitz.de

## Summary

This study investigated the influence of an electrical noise stimulation (ENS) on plantar vibration perception thresholds (VPT) of 43 patients with diabetes mellitus (DM). ENS application was randomized during VPT measurements at 30 and 200 Hz. Although no significant differences were found, there were trends supporting a possible effect of ENS.

## Introduction

Diabetic neuropathy is an incurable disease and mostly only symptomatic treatment with various drugs is available [1]. VPT are used to assess sensory deficits caused by DM; they are even used to assess neuropathy and ulcer risk [2]. A recent study showed that VPT can be enhanced by plantar mechanical noise stimulation (MNS) [2]. The phenomenon behind MNS is called stochastic resonance, which is the same for ENS [3,4]. To our knowledge, there are no studies investigating the effects of an ENS at the plantar foot on VPT in DM. Therefore, the present study investigated the effects of an ENS at the plantar foot on VPT in DM. Based on previous results, we hypothesized improved VPT due to ENS [2]. Furthermore, we hypothesized that ENS led to a reduction in the variability (CoV) of VPT.

## Methods

43 DM subjects (27 ♂, 16 ♀; mean ± sd: 64.6 ± 9.3 yrs, 171.0 ± 9.8 cm, 88.9 ± 17.7 kg, 13.9 ± 10.6 yrs since diagnosis) participated in this study. VPT were measured at the first metatarsal head (MET I) at 30 and 200 Hz using a customized vibration exciter (type 4180, Brüel & Kjaer Vibro GmbH, Germany). ENS (white noise) was applied by an isolated bipolar constant current stimulator (Digitimer DS5, Digitimer Ltd, UK). Electrodes were placed at the plantar metatarsal heads and the dorsum of the toes/foot. Through a hole (∅ 10 mm) in the plantar electrode, the vibrating probe (∅ 7.8 mm) was positioned at MET I. VPT were measured three times with and without ENS (randomized). The stimulation intensity was 90% of the individual absolute current perception threshold.

## Results and Discussion

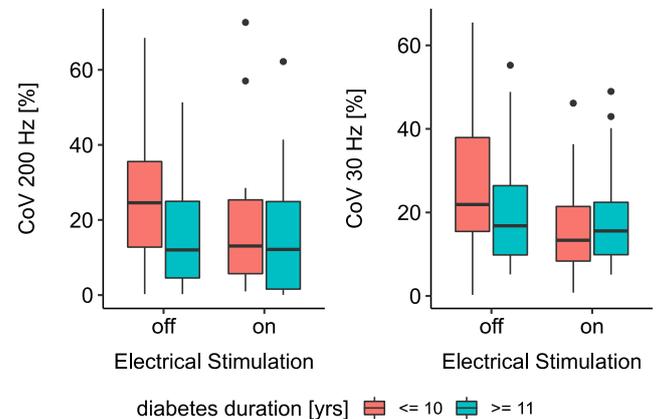

Due to strict exclusion criteria, ENS was only performed on 38 DM subjects. Wilcoxon signed-rank tests showed no significant changes of VPT and CoV due to ENS (Table 1).

**Table 1:** Mean ± standard deviation of vibration perception thresholds (VPT) and coefficients of variation (CoV) for 30 and 200 Hz

	n = 38	stimulation off	stimulation on
VPT [ $\mu$ m]	200 Hz	34.1 ± 22.1	34.7 ± 22.4
	30 Hz	89.5 ± 88.6	82.3 ± 78.5
CoV [%]	200 Hz	20.8 ± 17.2	17.0 ± 17.7
	30 Hz	22.7 ± 15.1	17.8 ± 12.9

VPT:  $p_{200\text{Hz}} = 0.753$ ,  $p_{30\text{Hz}} = 0.100$ ; CoV:  $p_{200\text{Hz}} = 0.144$ ,  $p_{30\text{Hz}} = 0.157$

Descriptively, DM with a diabetes duration  $\leq 10$  yrs showed an average improvement of  $\sim 6\text{-}9\%$  of their CoV. Although this was not significant, it shows a trend of variability reduction (Figure 1).

**Figure 1:** Coefficients of variation (CoV) for 30/200 Hz subdivided by diabetes duration (p range: 0.079 – 0.785).

Our results are in contrast to [2], but in line with the results of a previous study with healthy elderly subjects [3]. While MNS primarily acts on the receptors themselves, it is assumed that ENS modulates the nerve fiber [4]. This hypothesis is supported by improved VPT after ENS of the tibial nerve [5]. In contrast to MNS, skin properties play a major role in ENS, which are highly altered in DM. Since current seeks the path of least resistance, it is uncertain if the measured MET I area was also electrically stimulated, which could explain the lack of improvement in VPT.

## Conclusions

Although our hypothesis was not confirmed, there seems to be a possible effect of ENS when considering diabetes duration and VPT variability. Hence, further studies are needed to provide evidence of the effect of ENS on VPT in DM patients.

### Summary

Gross taper failure (GTF) is a rare but dramatic failure mode of the head-stem-taper connection of modular hip prostheses. The present study shows that the second stage of the GTF process - once initiated by bottoming-out - is associated with a linear increase in the wear of the stem taper and little further wear of the head taper caused by abrasive wear. The volume-time relationship is dependent on head length; with higher material loss for shorter heads.

### Introduction

Gross taper failure (GTF) is a rare but dramatic failure mode of the head-stem-taper connection of modular hip prostheses, accompanied by massive material loss of the stem and head. GTF is suspected to be a two-stage process initiated by the corrosion-induced failure of the force locked taper, 'bottoming-out', leading to severe abrasive wear due to the subsequent rotation of the head on the stem taper.[1,2]

The objective of this study was to test the hypothesis of abrasive wear in the second stage in-vitro and to determine the time-material loss relationship.

### Methods

Six cobalt-chromium alloy (CoCr) heads (36mm, 12/14 taper) with three different lengths ("S": -4mm, "M": 0mm, "L": +8mm) were assembled to stem taper replicas made from titanium-aluminium-niobium alloy (TiAl6Nb7). A small steel plug (S37) was used to simulate bottoming out. Dynamic gait loading according to ISO 14242-1 was applied for 2 million cycles using a hip simulator. Gravimetric wear was determined every 0.5 million cycles during serum exchange and volumetric wear was calculated with density of  $\rho_{\text{CoCr}}=8,4\text{mg/mm}^3$  and  $\rho_{\text{TiAl6Nb7}}=4,52\text{mg/mm}^3$ .

### Results and Discussion

Each stem taper surface developed a characteristic, head length-specific abrasive wear pattern (Figure1), comparable to those found in explants. At the time of serum exchange, the position of all heads was rotated to varying degrees from the initial position.

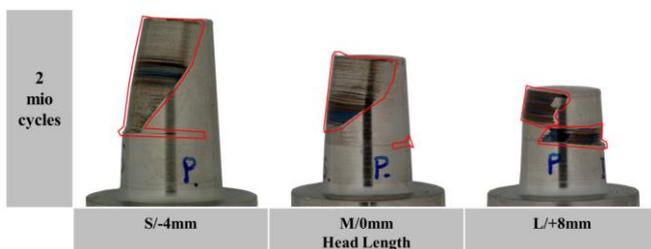

Figure 1: Taper wear after 2 million cycles. Red: Wear edges

Stem taper wear increased linearly with load cycles ( $p<0.001$ ) and resulted in a mean volumetric material loss of  $129\text{mm}^3/43\text{mm}^3/10\text{mm}^3$  per million cycles for head lengths S/M/L. The wear rate after 2 million cycles was significantly greater for the S head than for the M and L heads ( $p=0.01$ ).

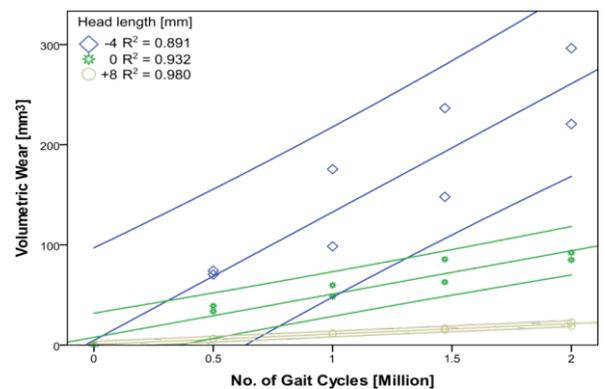

Figure 2: Volumetric wear of the stem tapers grouped by head length indicating a linear wear increase with time (Regression line with 95% confidence interval CI).

The head taper wear rates for the S/M/L head lengths were  $2.5\text{mm}^3/2.6\text{mm}^3/4.1\text{mm}^3$  per million cycles. Only wear for the L head increased significantly with loading cycles ( $p=0.016$ ). No difference was observed with respect to head lengths after 2 million cycles ( $p=0.61$ ).

### Conclusions

The present study shows that the second stage of the GTF process - once initiated by bottoming-out - is associated with a linear increase in the wear of the stem taper and little further wear of the head taper caused by abrasive wear. The volume-time relationship is dependent on head length; with higher material loss for shorter heads. Clinically, GTF is more common in association with longer heads [2]. This leads to the assumption that the total duration of the GTF process consists mainly of the first stage, where corrosion dominates, which is greater for longer heads [3,4] and thus leads to bottoming-out more quickly.

### Acknowledgments

Materials were provided by Waldemar LINK GmbH and EndoLab provided the simulator time.

## Fatigue resistance of nitinol stents subjected to walk-induced femoropopliteal artery motion

Ran He<sup>1</sup>, Liguo Zhao<sup>1</sup>, Vadim V. Silberschmidt<sup>1</sup>, Helen Willcock<sup>2</sup>

<sup>1</sup>Wolfson School of Mechanical, Electrical and Manufacturing Engineering, Loughborough University, Loughborough, UK

<sup>2</sup>Department of Materials, Loughborough University, Loughborough, UK

Email: L.Zhao@lboro.ac.uk

### Summary

Fatigue resistance of nitinol stents implanted in femoropopliteal arteries is a critical issue because of their harsh biomechanical environment. Limb flexions due to daily walk expose the femoropopliteal arteries and, subsequently, the implanted stents to large cyclic deformations, which may cause fatigue failure of the smart self-expandable stents. For the first time, this study utilised the up-to-date measurements of walk-induced motion of human femoropopliteal artery to investigate the fatigue behaviour of nitinol stent after implantation. The study was carried out by modelling the processes of angioplasty, stent crimping, self-expansion and deformation under repetitive bending, torsion and axial compression as well as their combination. The highest risk of fatigue failure of the nitinol stent occurs under a combined loading condition, with the bending contributing the most, followed by compression and torsion. The work is significant for understanding and improving the fatigue performance of nitinol stents through innovative design and procedural optimisation.

### Introduction

Peripheral artery disease, narrowing of the peripheral arteries, is caused by the build-up of plaque on the inner wall of a blood vessel, which restricts the blood flow through the lower limbs. Peripheral artery disease is most found in the leg arteries, i.e., femoropopliteal arteries. Self-expandable nitinol stents were developed, which have excellent flexibility and can recover from deformation thanks to their unique superelastic behaviour. However, fracture of nitinol stents was frequently observed during follow-up examinations [1,2], which is directly associated with the repetitive external forces, i.e., fatigue loading, exerted on the stents during normal walk [3]. In this study, advanced finite-element simulations were carried out to investigate the fatigue resistance of nitinol stents subjected to walk-induced motion of an femoropopliteal artery.

### Methods

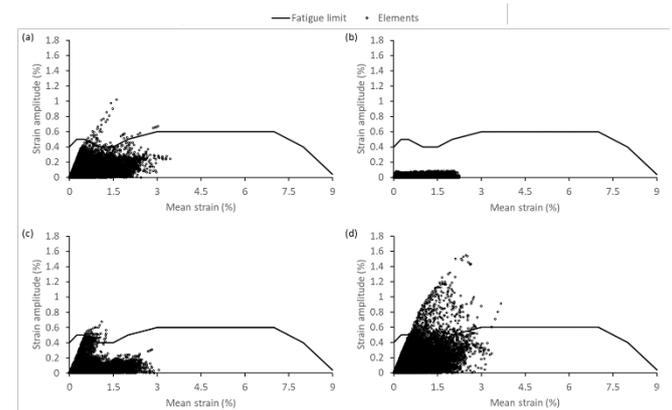

In our numerical studies, a two-layer femoropopliteal artery, with an overall wall thickness of 1.15 mm, an inner diameter of 4 mm and a length of 50 mm, was modelled. The plaque was modelled as a symmetric layer inside the artery, with a length of 18 mm and a stenosis of 50% (i.e., an inner diameter of 2 mm). Finite-element model for the Zilver Flex® Vascular Self-Expanding Stent (Cook Medical, USA) was built using Abaqus CAE, with a length of 20 mm, an outer diameter of 5 mm and a strut thickness of 125 µm. A linear-elastic tube was

created in the numerical model to crimp and release the Zilver stent in the diseased artery. To simulate angioplasty, a three-folded non-compliant balloon model was also created, with a length of 21 mm and a nominal diameter of 4 mm.

Angioplasty was simulated before stenting, with a peak inflating pressure of 1.8 MPa applied to the inner surface of the balloon. The process of stent deployment in the diseased artery consisted of crimping and releasing steps. Following the stent deployment, its in-service fatigue behaviour was studied under a combined bending, torsion and axial compression fatigue caused by walking-induced artery motion.

### Results and Discussion

In the constant-life's diagrams (Figure 1), the stent under combined loadings has the most elements in the dangerous zone above the fatigue strain limit line, indicating the highest risk of fatigue failure among all loading scenarios.

**Figure 1:** Constant-life diagrams for (a) bending, (b) torsion, (c) axial compression and (d) their combination.

### Conclusions

The combined loadings imposed the highest risk to stent's fatigue failure, to which the main contribution was from bending, followed by axial compression and torsion.

# Comparison of total ankle replacement designs using a dynamic computational model of the foot and ankle

Maria Ruiz<sup>1</sup>, Rostam S. Kojouri<sup>1</sup>, Sorin Siegler<sup>1</sup>

<sup>1</sup>Biomechanics Lab, Department of Mechanical Engineering, Drexel University, Philadelphia, PA

Email: [mr3393@drexel.edu](mailto:mr3393@drexel.edu)

## Summary

Two different types of Total Ankle Replacement (TARs) are compared with a dynamic computational model of the foot. The foot is set to rotate in its three main directions in order to see the effect the implant designs have on the behavior of the ankle and subtalar joint. The saddle-shaped design approximates the anatomical surface of the bones, shows a better congruency and follows joint kinematics more realistically than the uniaxial design.

## Introduction

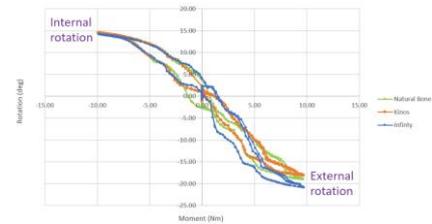

TARs are used as a replacement of damaged cartilage and bone surfaces due to arthritis. These devices are getting more popular as their improved designs continue to accomplish better clinical results and good survival rates. While several Finite Element studies have been carried out to analyze critical stress concentrations due to wear [1], barely any project has managed to replicate *in vivo* motions of the ankle in a computational simulation. This study uses a validated numerical model [2] in order to compare the behavior of two TAR designs. One of the devices has a more constrained design, which mainly allows for uniaxial rotation (dorsiflexion/plantarflexion), such as the Infinity™ TAR. The other design instead, approximates the anatomical structure of the joint, thus making it more mobile, allowing the foot to rotate in all directions. A new implant (the Kinos™ TAR) is used as a representation of this second type of design. The study evaluates foot kinematics in the ankle complex, the talocrural joint and the subtalar joint.

## Methods

The computational model used for this study includes the complete tibia and fibula bones, as well as the hindfoot and midfoot bones up to the metatarsals. These are considered 3D rigid bodies that were initially obtained from CT scans. The ligaments are modelled as tension-only springs with non-linear strain properties. The midfoot bones are also interconnected using specific springs with stiffness values in the 6 degrees of freedom. The articulating surfaces of the bones were offset for cartilage compensation, and the contact between them was considered frictionless. Regarding the implants, the talar dome and tibial tray were fixed to their respective bones, and the polymer component was attached to the tibial tray. The contact between the talar dome and the polymer is also assumed to have no friction. All the bones are completely free to move in any direction, only having the ligaments as constraints. In the simulations, the tibia was held fixed and rotational moments of 10Nm were applied to the calcaneus in dorsiflexion/plantarflexion, inversion/eversion and external/internal rotation. Also, a load of half-body weight was applied upwards as ground reaction force.

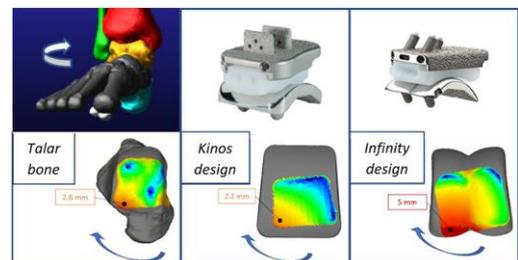

## Results and Discussion

The results of these simulations show that the behavior of the two implants is very similar during dorsiflexion/plantarflexion, but larger differences can be seen during eversion/inversion and external/internal rotation (Figure 1). The Kinos implant is able to follow a very similar pattern to the natural joint, the Infinity design deviates more during those rotations.

**Figure 1:** Rotation of the Ankle Joint Complex against the moment applied during External/Internal Rotation

Additionally, the distance between the interacting surfaces of the implants (the talar dome and the poly component) were studied using color maps. While the Kinos design showed good congruency, larger gaps between the surfaces were found in Infinity, as well as small areas of contact. This could lead in the future to stress concentration and wear.

**Figure 2:** Distance mapping of the talus to the tibia, and the talar domes to the poly components, during External rotation

## Conclusions

The dynamic computational foot/ankle model is a useful tool to compare the performance of different TAR designs. The saddle shaped implant, which approximates the anatomical joint surface, provides a better stress distribution, higher congruency and similar mechanics to that of the natural joint. This may suggest that such a replacement may provide less long-term wear and reduce failure rates.

## Summary

Cranial implants aim to provide cerebral protection after neurosurgery or skull trauma. With the increased use of patient-specific cranial implants, the mechanical response of each implant cannot be characterized experimentally in a practical way. However, computational models provide an excellent possibility to efficiently predict their mechanical response. This study developed finite element models of titanium-reinforced calcium phosphate (CaP-Ti) implants, the models predicted the mechanical response at both quasi-static and impact loading rates.

## Introduction

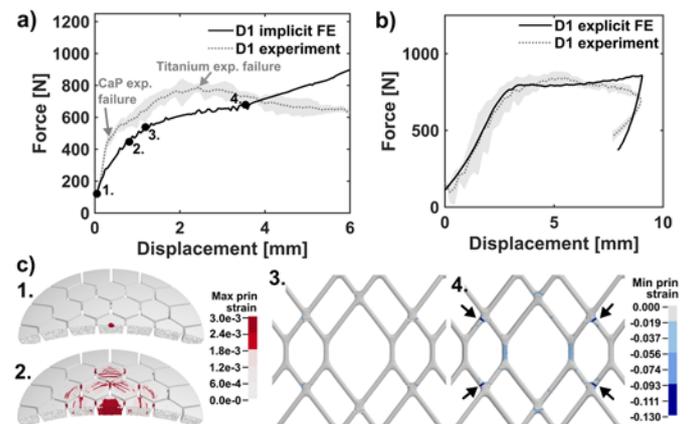

Reconstruction of cranial defects with synthetic implants has a high clinical complication rate (~20%). Infection is the most frequent complication [1]. Most cranial implants have commonly been constructed from bioinert materials e.g. PMMA. The outcome could potentially be improved by using osteoconductive and bioactive materials. Promising clinical results have been reported for one such patient-specific calcium phosphate-titanium (CaP-Ti) implant, which consists of an additively manufactured titanium structure, covered by CaP tiles [2]. An important function of cranial implants is to provide cerebral protection. Recently, the mechanical behavior of generic CaP-Ti implants were experimentally investigated at quasi-static (QS) and impact loading rates [3]. However, computational models are required for investigating patient-specific designs. The primary aim of the present study was to develop a finite element modelling approach for CaP-Ti implants, and to validate it against experimental data of two implant designs at impact and quasi-static loading rates [4].

## Methods

In the experiments, generically shaped implants were rigidly supported at the implant circumference and tested under QS (1 mm/min) or impact loading (5 kg, 1.52 m/s) [3]. Implant models were discretized (Ansa 17.1.0, Beta CAE Systems), and the boundary conditions were set to replicate the experiments. A rubber sheet (soft tissue surrogate) was used in the experiments, but only modelled in the impact model. The models were solved using implicit (QS) or explicit (impact) solvers (LS-Dyna R11.0.0, Livermore). For the CaP, a material model with tension-compression asymmetry was used. In the explicit model, damage was also implemented in the material model since CaP fractures had been observed experimentally. The material properties were determined by material testing or based on literature.

## Results and Discussion

The FE models showed good agreement with experimental force-displacement data (Figure 1a-b). The failures indicated in the strain plots were observed at similar locations as in the experiments (Figure 1c). Initial peak loads were predicted with  $\leq 11\%$  for implicit models, and  $\leq 5\%$  difference for explicit models. The maximum displacement was predicted by the explicit models with  $\leq 4\%$  difference.

**Figure 1:** Force-displacement data for one implant design, QS (a) and impact (b). Implicit FE strain plots (c): CaP tiles (1, 2), red show failure. The titanium below the applied load (3, 4), blue show yield and failure. The strain plot locations are marked in a).

## Conclusions

As demonstrated by this study on two implant designs, the mechanical response of CaP-Ti composite implants can be predicted by FE models at both quasi-static and impact loading rates. The models could be a valuable tool for the design and evaluation of patient-specific CaP-Ti cranial implants to optimize their performance and assure their safety. The framework developed for modelling the CaP-Ti implant used only literature based input and matched boundary conditions, hence it could be used in future studies for modelling CaP materials in other composite implants.

### Summary

High Flow Nasal Canula (HFNC) oxygen therapy can provide an effective treatment option in the early phase of respiratory insufficiency (e.g. for COVID-19 patients). Innovatively designed HFNC devices can be operated independently from medical O<sub>2</sub> supply infrastructure. In this study we present a simple, safe and cost effective HFNC system built with commonly available components utilizing membrane separation technology, which can support up to 10 patients in parallel depending on the clinically relevant flow rate.

### Introduction

High Flow Nasal Cannula (HFNC) and Noninvasive Intermittent Positive Pressure Ventilation (NIPPV) via mask may have an advantage over controlled mechanical ventilation (CMV) [1]. Utilizing membrane separation technology in these noninvasive devices, O<sub>2</sub>-enriched respiratory gas is directly produced via membrane separation from ambient air. An advantage permitting it for worldwide use due to the independence from medical O<sub>2</sub> supply infrastructure. For operation, only ambient air, an electrical power supply and water for humidification are required.

### Methods

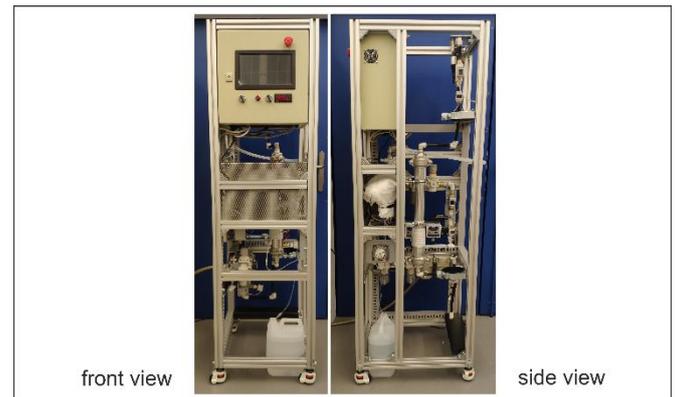

Based on a numerical model for the gas separation process, we designed an O<sub>2</sub>-enrichment device for HFNC therapy. Key component of the device is an O<sub>2</sub>-selective membrane module, in which pressurized and filtered ambient air (feed) is guided through the lumen of the hollow fiber membranes. O<sub>2</sub>-enriched air is thereby separated as low pressure permeate and N<sub>2</sub>-enriched gas is retained as high pressure retentate.

Pressure controllers ensure appropriate pressure levels and flow distribution in the flow paths of the system. We utilized an Arduino Mega 2560 with a TFT display as well as sensors for control and visualization of process parameters. Additionally, we developed a humidifier for the respiratory gas, comprising a pipe heating for the air flow combined with an evaporator.

### Results and Discussion

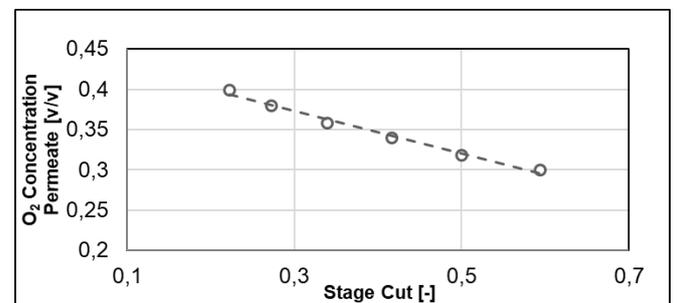

The built prototype of the O<sub>2</sub>-enrichment device measures 170 x 50 x 60 cm (height x width x depth). It provides respiratory gas with a O<sub>2</sub> concentration of 30 to 40 % for HFNC treatment of up to 10 patients in parallel depending on the clinically relevant flow rate. In order to generate a particle-free respiratory gas flow, the pressurized feed flow is first conditioned with a multistage filter unit. The permeate is then filtered in a second stage and subsequently heated and humidified. O<sub>2</sub> concentration is controlled via a pressure

control valve at the retentate exhaust. All described components are placed within an aluminum frame (Figure 1). Our prototype supports a working pressure of up to 10 barg on the feed side and a permeate flow of up to 200 L/min O<sub>2</sub>-enriched respiratory gas for the patients.

**Figure 1:** Lab prototype of the O<sub>2</sub>-enrichment device

Figure 2 shows the dependency of O<sub>2</sub> concentration on the stage cut (permeate flow/feed flow) at a pressure of 7 barg in the feed stream.

**Figure 2:** O<sub>2</sub> concentration in dependency on stage cut.

### Conclusions

In this work we present a simple device for HFNC therapy of up to 10 patients suffering from respiratory failure (e.g. for COVID-19 patients) in parallel. The device is assembled using standard commercially available components and allows to provide HFNC therapy independently from medical O<sub>2</sub> infrastructure.

## Quantifying the hip-ankle synergy in short-term maximal cycling

Louise Burnie<sup>1,2,3</sup>, Paul Barratt<sup>4</sup>, Keith Davids<sup>2</sup>, Paul Worsfold<sup>3,5</sup>, Jon Wheat<sup>2</sup>

<sup>1</sup> Applied Sports, Technology, Exercise and Medicine Research Centre, Swansea University, Swansea, UK; <sup>2</sup> Sport and Physical Activity Research Centre, Sheffield Hallam University, Sheffield, UK; <sup>3</sup> Biomechanics, English Institute of Sport, Manchester, UK; <sup>4</sup> Team INEOS, Manchester, UK; <sup>5</sup> Sports and Exercise Sciences, University of Chester, Chester, UK;

Email: [l.a.burnie@swansea.ac.uk](mailto:l.a.burnie@swansea.ac.uk)

### Summary

A key mechanical feature of maximal cycling is hip and ankle joints working in synergy during the downstroke to enable the ankle to transfer power produced by the hip extensors to the crank. This study applied a modified vector coding technique to quantify the strength of the hip-ankle moment synergy in the downstroke during maximal cycling at varying pedaling rates: 60 and 135 rpm. There was a significantly stronger hip-ankle synergy for sprints at 60 rpm compared to 135 rpm, suggesting that as the task complexity increases (increase in pedaling rate) it is more difficult to coordinate the joint actions. Results suggest that this method could be used to assess riders' pedaling techniques and monitor effects of training or equipment interventions on coordination patterns.

### Introduction

Musculoskeletal simulation studies have demonstrated during maximal cycling that the hip and ankle joints need to work in synergy through the downstroke, to enable the ankle to transfer power produced by the hip extensor muscles to the crank [1,2]. Consequently, the hip and ankle joints working in synergy during the downstroke is a key mechanical feature that represents functional maximal cycling coordination patterns. Therefore, developing a method to quantify the strength of this synergy in participant-based studies is important when investigating the stability of coordination behaviors in maximal cycling. The aim of this study was to apply a modified vector coding technique to quantify the strength of the hip-ankle moment synergy in the downstroke during short-term maximal cycling, and to compare the strength of the synergy to performance variations such as pedaling at differing rates of 60 and 135 rpm.

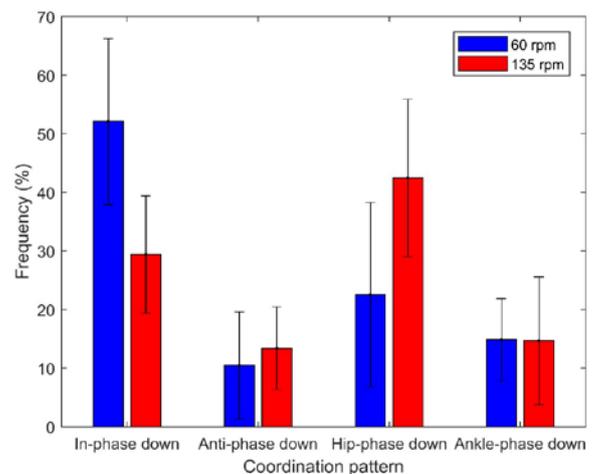

### Methods

Twelve track sprint cyclists (4 males and 8 females,  $24.1 \pm 13.8$  yrs,  $68.2 \pm 11.1$  kg), performed 3 x 4 s seated sprints at 135 rpm, interspersed with 2 x 4 s seated sprints at a 60 rpm on an isokinetic ergometer. Joint moments were calculated via inverse dynamics, using measured pedal forces and limb kinematics, and interpolated to 100 points around the crank cycle. The hip-ankle moment synergy was quantified using a modified vector coding method [3]. First, the coupling angle was calculated from the hip-ankle moment-moment diagrams for each point on the crank cycle, with circular statistics used to calculate the mean coupling angles for each participant. The mean coupling angle was categorised into four coordination phases: in-phase, anti-phase, hip-phase and ankle-phase based on the system proposed by Chang and colleagues [3]. The frequency the mean coupling angle lay within each of these coordination patterns during the downstroke (0 to 180°) was calculated for each participant at each pedalling rate. Strength

of the hip-ankle synergy was quantified by the frequency of in-phase coordination pattern between the hip and ankle moments in the downstroke. Differences between coordination phase frequencies of the hip-ankle moments during the downstroke between sprints at 60 and 135 rpm were assessed using Wilcoxon matched-pairs tests.

### Results and Discussion

In-phase coordination between the hip and ankle moments was significantly more frequent at 60 rpm compared to 135 rpm (Figure 1). Hip-phase coordination was significantly more frequent at 135 rpm compared to 60 rpm (Figure 1).

**Figure 1:** Hip-ankle moment coordination patterns during downstroke for sprints at 60 and 135 rpm. The  $P$  values for coordination patterns between sprints at 60 and 135 rpm: In-phase:  $P = 0.001^*$ , Anti-phase:  $P = 0.119$ , Hip-phase:  $P = 0.005^*$ , Ankle-phase:  $P = 0.970$ . \*Indicates significant difference ( $P < 0.01$ )

There was a significantly stronger hip-ankle synergy for sprints at 60 rpm compared to 135 rpm, which might be due to the increased time available in the downstroke to coordinate the joint actions at 60 rpm. At 60 rpm, the ankle plantarflexion moment started to be produced just before TDC which was earlier than at 135 rpm, which meant it was increasing in conjunction with the hip extension moment, resulting in the stronger synergy at 60 rpm.

### Conclusions

Results demonstrated that a modified vector coding technique can be used to quantify the strength of the hip-ankle moment synergy during the downstroke, and that the strength of the synergy is influenced by pedaling rate.

## Summary

We have developed and validated an open-source algorithm to automatically label optical motion capture markers. The algorithm uses deep learning and can be trained on existing data or simulated marker trajectories. We found that the algorithm had an accuracy of 99.6% when trained on existing data and 92.8% when trained on simulated trajectories. However, the later could be increased to 97.1% by applying transfer learning to existing data from a single participant. The algorithm and the provided user interface can help to reduce the time and effort required to label motion capture data, especially for those who have limited access to commercial software.

## Introduction

Optical motion capture is a valuable tool for quantifying human movement. However, assigning labels to the 3D coordinate data in passive motion capture systems can be a tedious and time-consuming process. Previous methods have been proposed using machine learning to automate this process [1,2]; however, this typically requires a large dataset of ground truth data for training and some methods are negatively affected by extraneous or missing markers. Furthermore, few have made their algorithms publicly available. Therefore, our aim was to develop and share a deep learning-based algorithm that can be trained on existing or simulated marker trajectories to automatically label motion capture data.

## Methods

In the proposed algorithm, a neural network based on long short-term memory units is used to predict label probabilities for unlabelled marker trajectories. Labels are assigned using the Hungarian algorithm, and corrections are made based on a pre-defined OpenSim marker set.

The algorithm was first trained on an existing dataset of 100 participants performing athletic movements and tested on a set of 42 participants performing the same movements. Simulated trajectories were then generated for a different marker set based on the motion of those 100 participants. The algorithm was trained on the simulated trajectories and tested on the data of nine participants that used this new marker and performed the athletic tasks and some other movements not included in the training set. The algorithm was updated using transfer learning on data from one participant and the accuracy was tested again. Labelling performance was compared to the commercial software Nexus (Vicon, Oxford, UK).

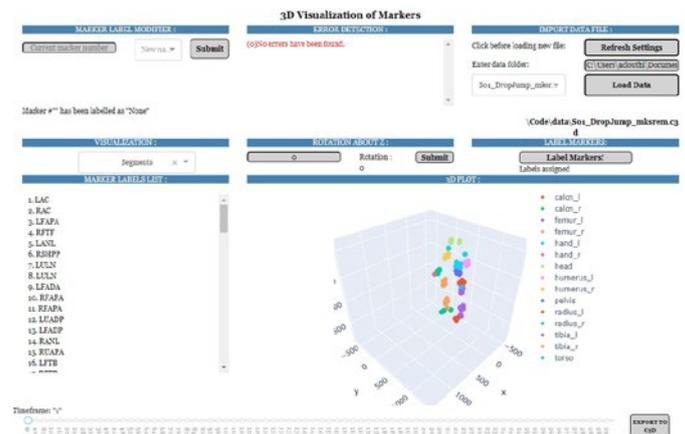

## Results and Discussion

When trained on existing labelled data, the labelling accuracy was 99.6%. When trained on simulated trajectories, the

accuracy was 92.8%, but could be increased to 97.1% by updating the algorithm through transfer learning on labelled data from one participant. Performance was comparable to the commercial software, Vicon Nexus.

The labelling accuracy was better for movements contained in the training set of simulated marker trajectories (97.2%) than for those that were not (87.0%). However, the accuracy on unknown movements was increased to 95% following transfer learning. Additionally, markers were labelled successfully in the presence of missing and/or extraneous markers, although a large number of missing or extraneous markers did decrease the accuracy.

The Python code and data required to generate simulated trajectories for a custom marker set and to train the algorithm on existing or simulated trajectories is available at <https://github.com/aclouthier/auto-marker-label>. We have also created a graphical user interface to perform the labelling and make manual corrections as necessary (Figure 1).

**Figure 1:** User interface that performs automatic labelling and allows user to make any necessary corrections.

## Conclusions

The proposed marker labelling algorithm is able to accurately label motion capture markers without requiring any participant-specific model calibration and can be improved as data are collected, labelled, and used to update the algorithm. The algorithm and provided user interface have the potential to reduce the time and effort required to label motion capture data, especially for those with limited access to commercial software.

# The Performance of Open-Source Pose Estimation Algorithms During Walking, Running and Jumping

Laurie Needham<sup>1</sup>, Murray Evans<sup>1</sup>, Darren P. Cosker<sup>1</sup>, Logan Wade<sup>1</sup>, Polly M. McGuigan<sup>1</sup>, James L. Bilzon<sup>1</sup>, Steffi L. Colyer<sup>1</sup>

## Summary

Several deep learning-based pose estimation methods (OpenPose, AlphaPose and DeepLabCut) were bench-marked against full-body marker-based motion capture. Joint centre locations between systems were evaluated during walking, running and jumping.

## Introduction

Biomechanics research traditionally relies on vision-based motion capture tools, either using regular video data and manually annotating points of interest or using maker-based motion capture systems. Deep learning-based pose estimation methods are beginning to provide viable, non-invasive alternatives to traditional motion capture. However, markerless pose estimation methods were not developed specifically for biomechanics applications, thus there is a need to understand their performance in such settings against more established techniques, such as marker-based motion capture. The aim of this study was to evaluate the performance of several open-source pose estimation algorithms against maker-based motion capture during walking, running and jumping.

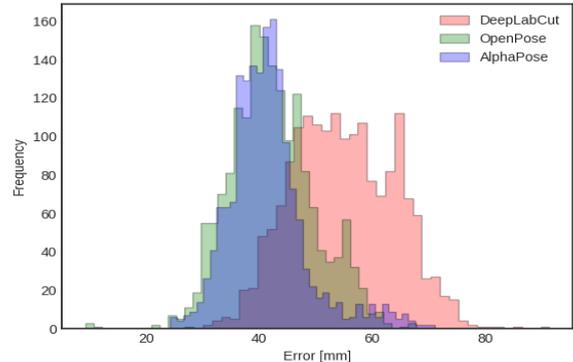

## Methods

Fifteen participants performed walking, running and jumping activities wearing a full-body markerset (44 + clusters). Marker data were captured using a 15 camera Qualisys system (200 Hz) which was synchronised with 9 machine-vision cameras (200 Hz). Image data from each machine-vision camera were processed using OpenPose[1], AlphaPose[2] and DeepLabCut[3]. 2D image plane coordinates from each pose estimation method were back-projected into the 3D space, where the intersect of the back projected rays were taken to represent the 3D joint centre locations. Differences (mean  $\pm$  SD) in joint centre locations were determined by computing the 3D Euclidean distances between the marker-based (regressed from markers on the segment) and markerless joint centres. Additionally, 95% limits of agreement (LoA) values were computed for the differences in hip, knee and ankle joint centre positions.

## Results and Discussion

For all three activities and methods, joint centre locations with the lowest mean differences and SD were observed at the ankle followed by the knee and hip, respectively (e.g., running in Table 1). A large portion of these differences were systematic in nature and likely represent systematic mis-

labeling of joint locations in the training data of the markerless pose estimation methods. Additionally, the large random errors that occurred were typically due to false positive detections of joint centres or erroneous switching of contralateral limbs by all pose estimation methods.

**Figure 1:** Hip joint location error distributions for each method during all activities.

The lowest mean differences were observed using AlphaPose, followed by OpenPose and then DeepLabCut (Table 1 & Figure 1). These results align with each method's performance on common computer vision benchmarks (COCO, MPII). Further processing of pose estimation results, e.g., outlier detection and inverse kinematics modelling, may be required before acceptable results can be obtained for biomechanics research applications.

## Conclusions

OpenPose, AlphaPose and DeepLabCut were benchmarked against marker-based motion capture. Large systematic and random differences were observed for all methods but AlphaPose exhibited the lowest mean errors. Researchers should consider the accuracy and precision requirements of their research applications before implementing these markerless motion capture techniques.

## Under-shoe hydrodynamics correlate with film thickness predictions based on worn tread geometry

Email: [slh148@pitt.edu](mailto:slh148@pitt.edu)

### Summary

Greater shoe tread wear leads to increased slip risk. There is a need to standardize shoe replacement recommendations, but shoe wear is complex as the rate at which shoes wear varies across individual and shoe. This study found that the shoe's ability to disperse under-shoe fluids was positively associated with the shoe outsole wear geometry, independent of shoe type or individual. As such, shoe wear geometry may be a good indicator for shoe replacement across workplaces.

### Introduction

Slips, trips, and falls are a major problem accounting for 28% of occupational injuries [1]. Footwear and particularly shoe outsole design are important factors for reducing slip risk [2]. Previous work has shown that the rate at which shoe tread becomes unsafe varies across individuals and shoe type [3]. This may prevent the distance walked in shoes from being an efficacious replacement recommendation. Therefore, replacement guidelines based on the condition of the shoe may be more advantageous.

Previous work by our group has applied lubrication theory to worn shoes to predict under-shoe hydrodynamics (film thickness) based on the worn region dimensions [4]. This approach provided valid predictions for the hydrodynamics for shoes worn via a controlled mechanical wear experiment [4]. The aim of this research is to extend that work to determine whether lubrication theory can predict changes in under-shoe hydrodynamics for *naturally* worn shoes.

### Methods

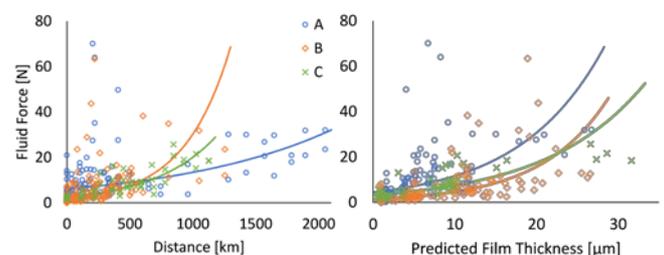

Fifteen participants were each provided with two out of three types of slip-resistant shoes (shoes A and: B or C). A pedometer on the shoes tracked the distance walked. The under-shoe hydrodynamics (referred to as fluid force hereafter) were tested at baseline and after each month worn in the workplace. Fluid force was quantified from a robotic slip tester that applied a simulated slip under fluid-contaminated conditions (90% glycerol), while the load supported by the fluid was measured with fluid pressures sensors [5]. The shoe wear geometry was measured as the longest and widest regions of continuous wear. The under-shoe predicted film thickness (PFT) was calculated based on the wear geometry length and width, fluid viscosity, sliding speed, and vertical force [4].

Two repeated measures ANOVAs were used to assess predictors of fluid force. The primary predictor in model 1 was distance walked (current wear standard), and in model 2 was PFT (based on lubrication theory/wear geometry). Shoe type (A, B, C), and its interaction with distance walked/PFT were also independent variables. Distance walked was

square root-transformed and fluid force was natural log-transformed.

### Results and Discussion

Participants walked 103-2053 km in the shoes across 1-11 months (199 total subject-months). Fluid force increased with the distance walked ( $F_{1,276}=140.0$ ,  $p<.001$ ) and PFT ( $F_{1,205}=112.4$ ,  $p<.001$ ). The shoe type was significant in both analyses ( $F_{2,239}=29.2$ ,  $p<.001$ ), ( $F_{2,102}=29.2$ ,  $p<.001$ ). An interaction was observed between shoe type and distance walked indicating the rate at which fluid force increased varied per shoe type ( $F_{2,273}=7.5$ ,  $p<.001$ ). This effect was not seen in the model with PFT ( $F_{2,255}=2.0$ ,  $p=0.141$ ).

**Figure 1:** Fluid force vs. distance walked (left) and PFT (right) for the three shoe types with exponential trendlines.

Film thickness predictions based on the shoe outsole wear geometry consistently predicted increase in the fluid force across shoe types. The distance shoes are worn predicts fluid force though with greater variation across shoe type. Our results suggest lubrication theory, based on wear geometry, to be more versatile in predicting under-shoe hydrodynamics across multiple settings, shoes, and individuals than distance.

### Conclusions

PFT based on outsole wear geometry was found to be a valid tool for assessing loss in fluid drainage capacity in naturally worn regions. Thus, this study shows that the previously developed models [4] are valid in the context of natural wear. This adds to the growing body of evidence for monitoring shoe wear based on the dimensions of the worn region rather than a time or distance walked measurement.

## Can Leap Motion Controller replace conventional marker-based motion capture systems ?

Amartya Ganguly<sup>1</sup>, Gabriel Rashidi<sup>1</sup>, Katja Mombaur<sup>2</sup>

<sup>1</sup>Optimization, Robotics and Biomechanics, Institute of Computer Engineering, Heidelberg University

<sup>2</sup>Chair in Human-Centred Robotics & Machine Intelligence, University of Waterloo

### Summary

Over the last few years, the Leap Motion Controller (LMC) is progressively used in clinical environments to track hands, wrist and forearm positions as an alternative to the gold-standard motion capture systems. We compared performance of the LMC against gold-standard motion capture system to validate reliability of LMC. The two systems were time synchronised and performance validation was conducted for static as well as dynamic conditions i.e flexion and extension movements for all fingers. The study shows that currently, the LMC, is not yet suitable to replace gold-standard motion capture systems in clinical settings.

### Introduction

The LMC device is a portable, marker-less motion capture system, and is often used as a low-cost alternative to standard marker-based motion capture systems, specially in clinical environments. The LMC is designed to track elbow, wrist, and finger joint positions. Few studies have attempted to validate the LMC against standard marker-based motion capture systems [1-3]. It is evident that the LMC is being used in a variety of applications, however, there is a lack of validation and replication studies with regards to clinical acceptance of this low-cost marker-less device. Specifically, there is a gap in evaluation of performance of LMC with respect to finger kinematics, as well as, lack of synchronised validation of LMC with a gold-standard motion capture system.

### Methods

Ten right-handed subjects (6 male and 4 female) of mean age of 26.8 years were recruited for this study. The experimental protocol was completed successfully.

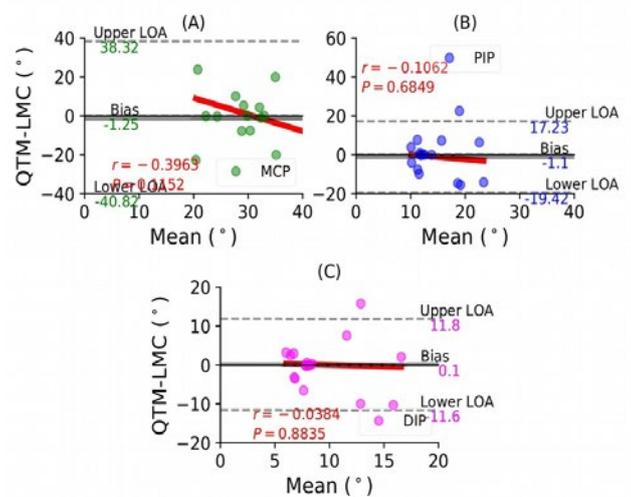

Ten Oqus 500 motion capture cameras (QTM; Qualisys, Goeteborg, Sweden) placed at appropriate locations, were used at a frame rate of 150Hz. The LMC generally is pre-calibrated, however, it was calibrated again with a calibration score of 95. Higher calibration score yields better stable measurements.

The two data acquisition systems were time synchronised as each system streams data with different sampling frequency. All participants performed a static trial and series of flexion/extension tasks. Instructions were prompted on the screen and all tasks were randomised. Two trials per subject were conducted. In each trial, the subjects performed flexion/extension movements three times. Overall, there were 10 successful static trials, and 120 dynamic trials.

### Results and Discussion

The figure 1(A) shows a BA plot for MCP joint with a negative bias of 1.25° with  $r = -0.3963$ ,  $P = 0.1152$ . Panel 1(B) shows a negative bias of 1.1° with  $r = -0.1062$ ,  $P = 0.6894$  of PIP joint. Lastly, Panel 1(C) shows a positive bias of 0.1° with  $r = -0.0384$ ,  $P = 0.8835$  of the DIP joint. During the index finger flexion movement, none of the joints demonstrated a positive correlation between the two measurement systems [4].

**Figure 1:** Bland-Altman plot for Index finger flexion, (A) MCP

joint, (B) PIP joint and (C) DIP joint

### Conclusions

The LMC device has the potential to replace marker-based motion capture technology, however, it requires significant programming knowledge to extract data from the device for offline analysis. The variable sampling frequency is still a major problem with LMC when conducting such validation studies. At this juncture, we conclude that the LMC is acceptable in static conditions, however, for dynamic cases further validation studies are warranted.

### Summary

The intrinsic stiffness and damping of muscle are of great importance for force generation and stability. We present a muscle model with a force response dominated by a spring-damper in the short term but converges to a Hill model over time. The spring-like quality of the proposed model results in a gain and phase response that more closely follows biological muscle in the frequency domain than a Hill model.

### Introduction

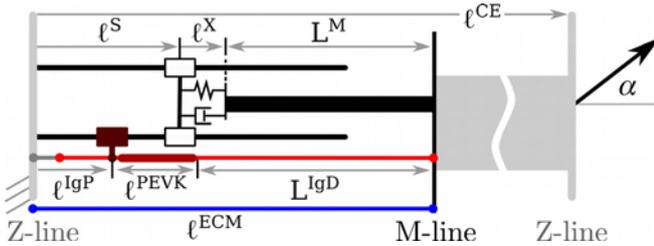

The intrinsic stiffness and damping of muscle vary linearly with activation [1] and are used by the central nervous system to stabilize the body's posture [2]. In this work, we present a muscle model that can reproduce the force-velocity [3] and force-length [4] properties by construction, and has stiffness and damping similar to biological muscle.

### Methods

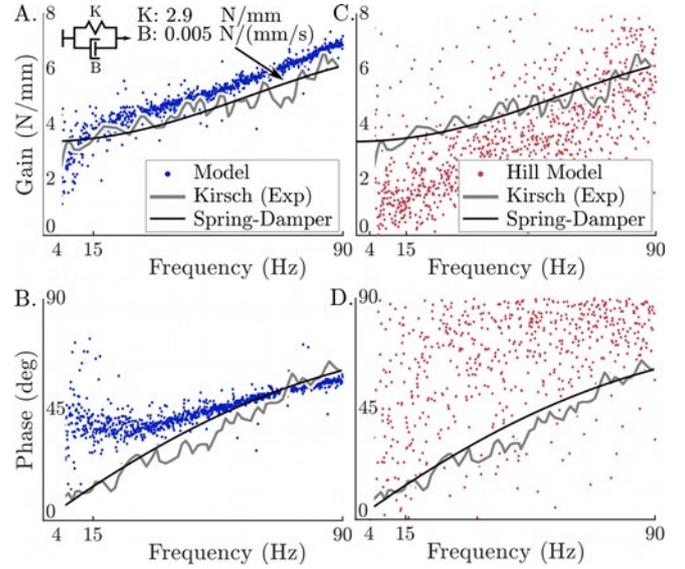

We model the musculotendon unit as a scaled half-sarcomere acting at a pennation angle of  $\alpha$  to a rigid tendon (Fig. 1). The myosin filament attaches to the actin filament through a single lumped cross-bridge that attaches to the actin filament at a distance of  $\ell^S$  from the Z-line. The intrinsic stiffness ( $K^X$ ) and damping ( $\beta^X$ ) of the lumped cross-bridge varies linearly with activation and the amount of overlap between the actin-myosin filaments. The attachment point  $\ell^S$ , is driven at the acceleration-level primarily by the force imbalance between the spring damper and a Hill-type muscle model

$$dv^S/dt = [K^X \ell^X + \beta^X v^X - a f^L(\ell^S + L^M) f^V(v^S)]/T^S - \beta^S v^S \quad (1)$$

where 'v' stands for velocity, and  $T^S$  is a time constant. Given enough time, Eqn. 1 will drive  $\ell^S$  to a length, velocity, and force consistent with the embedded Hill model. In the short term, the finite value of  $T^S$  ensures that the spring-damper system dominates the model's force response. We

**Figure 1:** The proposed muscle model with a lumped cross-bridge

**Figure 2:** The frequency response of the models, Kirch et al.'s [1] processed data, and the spring-damper of best fit to the data.

simulate the experiments of Kirch et al. [1] and compare frequency domain responses of our proposed model and a Hill model [5] to Kirch et al.'s [1] results.

### Results and Discussion

The gain and phase of both the proposed model and Kirch et al.'s analysis feline soleus [1] resemble the gain and phase curves of a spring-damper (Fig. 2A & 2B). In contrast, the gain and phase coefficients of the Hill model are scattered, due to the non-linearity of the model, and differ widely from Kirch et al.'s [1] observations (Fig. 2C & 2D).

### Summary

Numerous articles and Hill-type muscle-tendon (MLT) models have been proposed in the past fifty years providing a rich but dense and thus hard-to-explore literature. This work presents the findings of a systematic review on skeletal MLT Hill-type phenomenological models. Current underdeveloped modelling aspects and other limiting factors for the field, such as inter-study inconsistency in terminology and notations, or scarcity of open-source models, are identified and discussed.

### Introduction

Hill-type models [1,2] are computationally fast and fairly accurate models of muscle dynamics that are currently included in all biomechanical simulation platforms. As their popularity has increased in the last 50 years, they have become the subject of a dense literature that would gain from a contemporary assessment of the state-of-the-art, since the last milestone reviews date back 20-30 years [2,3]. This work offers such assessment by presenting the conclusions of a systematic review on phenomenological MLT Hill-type modelling aiming to identify current limitations and evaluate if updated recommendations would be beneficial to the field.

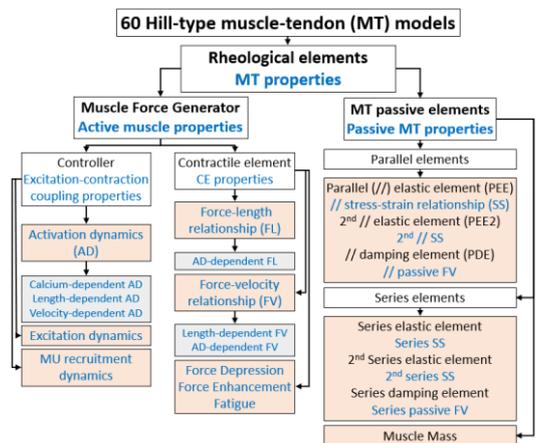

### Methods

A systematic search of 20 key terms was performed on four online databases (PubMed, Web of Science, MedLine, EMBase). The eligible studies retained for review contained skeletal MLT Hill-type models including at least components for the neural controller, active and passive MLT properties and one methodological contribution (no duplicates). Each eligible model was first assessed for completeness against 23 possible phenomenological properties (Figure 1), for each of which inheritance diagrams representing the time-evolution of the published modelling approaches were created. The studies were finally scored on their methods for MLT model validation, calibration, reusability, and modelling strategy.

### Results and Discussion

The systematic search yielded 478 studies including a Hill-type model among which 60 were eligible studies. Around 75% of the eligible models did not deviate from the traditional Hill-type modelling approach outlined in few classic studies [1-6]. Most used a linear activation-scaling of activation-independent Force-Length (FL) and Force-Velocity (FV) relationships [4], a first-order two-parameter differential equation for the activation dynamics [5], an instantaneous FL property with descending limb instability, exponential passive properties [4], and Hill's concentric and Mashima's eccentric instantaneous hyperbolic FV relationships [1,6]. Most models

did not account for accuracy-sensitive mechanisms such as time-history dependent properties (20% of the eligible models), motor unit recruitment dynamics (20%), or activation-dependency of the optimal fibre length (3%). We interpreted this as symptomatic of the limited reusability of the eligible models due to inter-study inconsistencies in the terminology and the notations, scarcity of open-source models (10%) and lack of good practices like validating simulations against experimental data (50%), providing objective quantitative or statistical analyses of the results (40%) or calibrating parameters using subject-specific data (50%).

**Figure 1:** Rheological elements and their properties included in the 60 eligible Hill-type models. Black font: elements; blue font: properties; orange: main properties; grey: state-variable dependency

### Conclusions

A review of 60 representative Hill-type muscle models unveiled that most models did not build upon previous advances, limiting further modelling innovations and the reassessment of older models. Recommendations aiming to standardize notation and terminology, clarify modelling assumptions and promoting model validation and sharing, could prove beneficial to the field.

## Motor-units matter: enriching continuum-mechanical skeletal muscle models with neuromuscular information

### Summary

Motor-unit (MU) physiology is fundamental to understanding skeletal muscle function and human movement. Continuum-mechanical, macroscopic muscle models often provide insights not practically obtainable via experimental techniques. Most of these models, however, neglect the spatial distribution of MUs and therefore may oversimplify muscle function. Here, we present a method to generate and incorporate physiological MU information within such models and demonstrate it via a prototype musculoskeletal model. We found that muscle deformation, pressure, and joint force were highly sensitive to MU distribution. This exploratory study highlights the importance of MU distribution in predicting muscle and joint function.

### Introduction

Motor-units (MUs) are often restricted to sub-regions of a skeletal muscle, and their selective recruitment is partly responsible for the functional heterogeneity of muscles. That is, the same muscle may produce various “lines of action” depending on the subset of recruited MUs. To capture this phenomenon, we first present a method to incorporate micromechanically based MU activity and distribution within continuum-mechanical muscle models and second, to demonstrate the method via a prototype model of the masticatory system.

### Methods

*Constitutive modelling of skeletal muscles.* The mechanical behaviour of the skeletal muscle is based on [1] and additively splits the active stress  $\mathbf{S}_{ACT}(\alpha_M)$  from the passive response. The muscle activation parameter  $\alpha_M \in [1,0]$  is decomposed according to  $\alpha_M(t, \mathbf{X}) = \sum_i^{N_{MU}} \alpha_i(t) \kappa_i(\mathbf{X})$ , where  $\alpha_i$  and  $\kappa_i$  are, respectively, the temporal activity and spatial (fractional) distribution of MU  $i$ , and  $N_{MU}$  is the number of MUs.

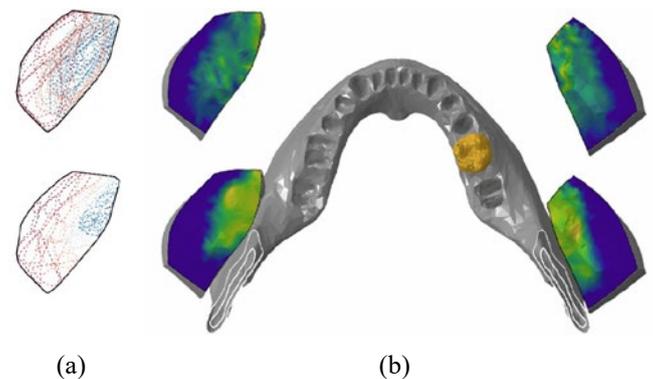

*Computing & integrating motor-unit information.* Taking a scalar excitatory drive as an input to the MU pool, individual MU activities  $\alpha_i$  are computed via a recruitment model coupled with cross-bridge and calcium dynamics models, e.g. [2]. MU distributions are computed by (i) reconstructing the microstructure in the muscle, (ii) assigning the (reconstructed) fibres to MUs via a novel algorithm (to control MU position, overlap, size, etc.) and (iii) homogenising the innervated microstructure within the FE mesh to obtain the fractional distribution  $\kappa_i(\mathbf{X})$  of the MU.

*Simulation trials.* A masticatory system model, including the mandible and masseters, was used to simulate sub-maximal (34/50 MUs recruited) static bites. Only the MU distribution

was varied between trials, and the bite forces were used to quantify variations in motor-output. An additional simulation with spatially uniform MUs was carried out, representing the traditional modelling approach.

### Results and Discussion

The distribution of the recruited MUs dictated active muscle stress (Figure 1). The range in peak bite forces for all MU distributions was 5N with a mean of 146N. Bite force angle (in the horizontal plane) exhibited a more drastic variation, with a range of 40° and a mean of -86° (-90° is oriented to the left). Such changes in the bite force can be explained by MU territory and masseter architecture. Since masseter fibre orientation and geometry are not uniform, changes in regional contraction influence the bite force. The traditional modelling approach yielded a steadier force, directed along the “average” fibre orientation of the masseters.

**Figure 1:** (a) MU territories in right masseter; MU 1 (dark blue) to 50 (dark red); recall only MUs 1-34 are active. (b)  $\mathbf{S}_{ACT}$  over the masseter cross-section at the same time instance; 0MPa (blue) to 1MPa (yellow)

### Conclusions

Our method to enrich a continuum-mechanical model with MUs captured nuances in motor-output that were not possible with a traditional modelling approach.

# Muscle-Specific Intramuscular Passive Properties are Required to Accurately Scale Passive Muscle Mechanics

Benjamin I Binder-Markey<sup>1</sup> and Richard L Lieber<sup>1,2,3</sup>

<sup>1</sup>Department of Physical Therapy and Rehabilitation Science, Drexel University, Philadelphia, PA, USA, <sup>2</sup>Shirley Ryan AbilityLab & <sup>3</sup>Department of Physical Medicine and Rehabilitation, Northwestern University, Chicago, IL, USA

## Summary

Unlike whole muscle active length-tension properties, passive mechanical properties do not scale from the sarcomere to the whole muscle level. The source of this non-linear scaling is largely unknown. Thus, the purpose of this study was to directly measure muscle passive mechanical properties and then use modeling to identify potential sources contributing to non-linear scaling from fascicle to whole muscle. This study demonstrates that to accurately model muscle passive mechanical properties muscle-specific intramuscular model parameters must be included within models. Unfortunately, the actual structures that represent these mathematical terms are not currently clear.

## Introduction

Generic whole muscle active length-tension properties with architecture parameters accurately scale from the sarcomere to the whole muscle level [1], but interestingly, in mammalian muscle, passive mechanical properties do not [1,2,3]. Recent work in rabbit muscle demonstrated that fiber, fiber bundle and fascicle mechanics did not simply scale to whole muscle mechanics [3]. We believe that this non-linear scaling is due to the poorly appreciated intramuscular connective tissues that increase with increasing scale. Thus, the purpose of this study was to measure whole muscle passive mechanical properties and use modeling to identify potential sources contributing to the non-linear scaling observed from fascicle to whole muscle.

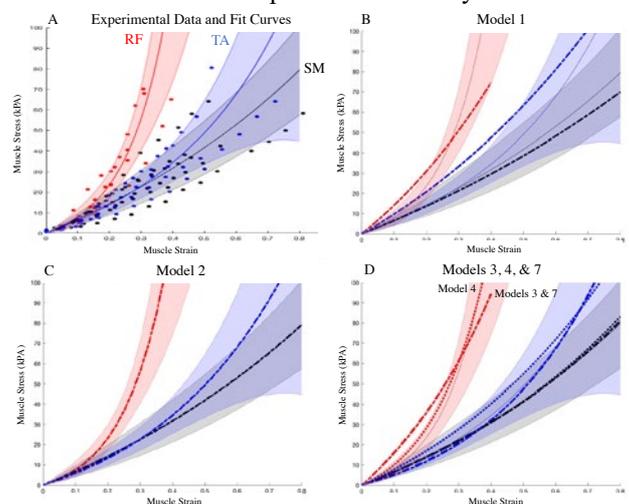

## Methods

Passive mechanical properties from three muscles of varying architecture and function were measured in 12-week C57Bl6 mice: rectus femoris (RF; n=6), semimembranosus (SM; n=6), and tibialis anterior (TA; n=5). Muscles were dissected, attached to a small 1N force transducer, and lengthened in static ~0.5mm increments. Muscle passive force was normalized to physiological cross-sectional area and muscle deformation converted to strain. These data were exponentially fit and curves were averaged to create a single exponential describing each muscle's passive stress-strain relationship (Fig. 1A).

To investigate potential sources contributing to the passive mechanics of muscle, we developed nine different Hill-type models of progressively increasing complexity. These models were created by sequentially including the fascicle passive property in the form of  $\frac{a}{b}(e^{be} - 1)$ , a parallel element elastic element ( $c_m$ ) across the whole muscle, and an inter-fascicular shear factor ( $\tau_m$ ) resisting fascicle rotation, that were either generic or muscle specific (Table 1). For each model, parameters ( $a$ ,  $b$ ,  $c_m$ , and  $\tau_m$ ) were optimized in MATLAB to minimize the sum of the squared error (SSE) between the muscles' modeled stress-strain curve and the experimentally fit curve (Table 1).

## Results and Discussion

Model 1 replicates most current muscle models that use a generic fascicle stress-strain curve scaled by architecture (Fig 1B). It provides a first approximation of each muscle's passive properties. However, it is clear that, to accurately replicate each muscle's mechanics, additional muscle-specific parameters are needed. Model 2 with muscle-specific fascicle properties had the lowest SSE and was able to replicate the previously fit curves (Fig 1C). However when incorporating other potentially physiologic relevant parameters we observe the best fits across muscles for models 3, 4, and 7 (Figs. 1D). Apart from model 2, the next best fit was model 4, using both muscle specific fascicle and parallel connective structure properties. To our surprise, the addition of shear did not improve the fit of any model.

**Figure 1:** A) Stress-Strain data and fit curves average (solid lines)  $\pm$ SD (shaded region) for RF (red), SM (black), and TA (blue). Stress-strain fit curves with B) Model 1, C) Model 2, and D) Models 3, 4, and 7 in dashed lines, with experimentally fit curve in solid lines  $\pm$ SD in shaded regions.

## Conclusion

These results demonstrate that, to accurately model muscle passive mechanical properties, muscle-specific intramuscular model parameters must be included. To a first approximation, architectural parameters helps, but in order to provide high resolution properties, additional terms are needed. Unfortunately, the precise structures that represent these mathematical terms are not currently clear and are the subject of ongoing investigations.

### Summary

The aim of this study was to investigate length and lever arm (LA) variations of scalenus anterior (SAnt), medius (SMed) and sternocleidomastoid (SM) muscles in respiratory movement. We used a 3D modelling approach combining in vivo costovertebral joints kinematics from 12 asymptomatic adults and a generic model of the cervical spine (GMCS) scaled to in vivo data. Absolute and relative change in muscles length and LA relative to the helical axis of the first costovertebral joint was computed. Quantitative data and related 3D representation of the biomechanical features were obtained. Results showed that all muscles shortened during inspiration while LA increased.

### Introduction

SAnt, SMed and SM muscles may be involved in various musculoskeletal and/or respiratory disorders. Biomechanical features such as moment generating capacity of these muscles were previously explored during cervical movements [1] but the effect of respiratory motion on length and LA is still to be determined. Therefore, the aim of the present study was to determine length and LA of the muscles of interest using 3D modelling approach.

### Methods

Previously published kinematic data [2] computed from CTscan performed at three different lung volumes (TLC: total lung capacity, MIC: middle of inspiratory capacity and FRC: functional residual capacity) were used in the present study. 3D bone models and breathing kinematic data (ranges of motion, mean helical axis (HA) location and orientation) were combined to a GMCS. With LHPFusionBox software (<http://lhpfusionbox.org>), anatomical landmarks (AL) were positioned on each 3D bone model for registration and at the insertion sites of each muscle of interest for measurements on the first rib and on the sternum. The GMCS was then registered on the individual first thoracic vertebra of each subject using similarity transformation. (Figure 1 A). Finally, length muscle and LA according to the HA of the first costovertebral joint were computed (Figure 1 B) using direct method [3]. The relative variations were calculated as a percentage of the FRC reference position.

### Results and Discussion

Globally, all muscles displayed an increasing length associated to a shortening of the LA from TLC to FRC. Absolute length variation was greater for SM ( $9.1 \pm 4.1$ mm) and smaller for SMed ( $7.1 \pm 3$ mm). The maximal relative length variation ranged between  $5.3 \pm 2.5\%$  for SAnt and  $-8.9 \pm 3.6\%$  for SM. Besides, LA ranged between 30.2 and 41.3mm at TLC and from 25.1 to 32.5mm at FRC for SAnt and SM respectively. LA displayed also the maximal change

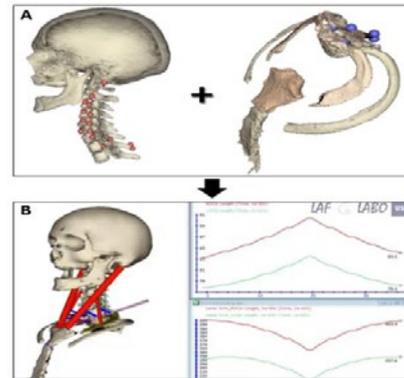

Figure 1: A: Left: GMCS with ALs on insertion sites and Th1; Right: Upper thorax model with ALs on Th1. B: 3D visualization of SAnt and SM with results of length and LA over the breathing cycle (right).

for SM ( $8.8 \pm 4.9$ mm) and minimal for SMed ( $5.1 \pm 2.5$ mm). The relative LA variations ranged between  $22 \pm 18.3\%$  and  $35 \pm 38.7\%$  for SAnt and SMed respectively. Note that the greatest variations of both length and LA occurred between MIC and FRC (i.e under 50% of the inspiratory capacity) and can be explained by the greater range of rib motion during this phase [2]. Considering the relative change in muscle length, this result combining a GMCS and in vivo rib kinematics are in line with previously published results [4]. Prior work [1] reported scalene muscles maximal LA close to 20mm for lateral bending of the cervical spine while the present study showed a minimum of 25.1mm for respiratory contribution. About the SM, the present minimal LA of 32.5mm represent approximately 50% of the value obtained for lateral bending of the cervical spine (55mm) and 200% of the value reported for axial rotation (15mm).

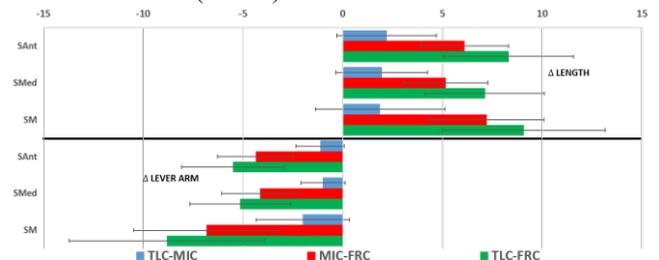

Figure 2: Mean difference in length/LA in millimeter of each muscle of interest between each respiratory position.

### Conclusions

Length and LA changes of SAnt, SMed, and SM muscles during respiratory movement were quantified using a modelling approach. All muscles shortened during inspiration while LA increased. Further research will explore interaction of respiratory mechanics in clinical conditions.

## Towards real-time estimation of joint moments during fast sidestepping

Sina David<sup>1</sup>, Marion Mundt<sup>2</sup>

<sup>1</sup>Department of Human Movement Sciences, Vrije Universiteit Amsterdam, Amsterdam, The Netherlands

<sup>2</sup>School of Human Science, The University of Western Australia, Perth, Australia

Email: s.david@vu.nl

### Summary

This abstract presents the estimation results of lower limb joint moments using a long short-term memory neural network. The network was trained using linear accelerations and angular rates of the lower limb segments on predicting hip, knee and ankle joint moments during fast sidestepping. Data were obtained from 3D motion analysis. The average prediction accuracy is  $> 0.8$ . The results are promising and indicate the possibility to apply neural networks for real-time feedback.

### Introduction

A majority of collected biomechanical data from clinical and sports research is used to retrospectively analyze a participant's movement and the associated joint loading. Hence, direct feedback to the participant is limited due to the time arising from postprocessing and running musculoskeletal models. The application of neural networks and the development of inertial measurement units (IMUs) with direct output of linear acceleration and angular rate could provide the opportunity to estimate joint loading in real-time since no such data processing is needed. Long short-term memory (LSTM) neural networks are processing time series successively. This eliminates the need for time normalization, which is key for real-time applications. This study aimed to evaluate the ability of an LSTM neural network to predict joint moments from simulated IMU data in real-time.

### Methods

Due to the limited availability of IMU data, linear acceleration and angular rate were simulated from a marker-based motion analysis study. Training a neural network based on these allows for the direct transition to measured IMU data when applicable [1]. The dataset consists of the 3D kinematics and kinetics of 67 healthy athletes (631 trials in total) during full effort 90° sidestepping [2]. To train the LSTM the linear acceleration and angular rate of the lower limbs was simulated and 3D joint moments from the touch-down of the execution to the take-off of the depart contact were extracted.

The dataset was split subject-wise into training (50 athletes), validation (8 athletes), and test set (9 athletes) for five-fold cross-validation. An LSTM neural network was trained on the time series. Different network architectures and hyperparameters were tested using a hyperband search [3].

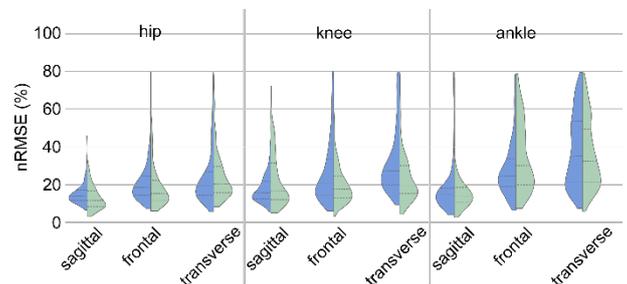

The prediction accuracy of the network was evaluated on the test set only, assuring that these data were unknown to the network, and was measured using the root mean square error normalized to the range of the data (nRMSE) and the correlation coefficient. For this purpose, the time series were

split into execution and depart contact and normalized to the stance phase.

### Results and Discussion

The hyperband search resulted in a single layer with 1024 LSTM cells to perform best. The initial learning rate was set to 0.0003, the activation function tanh, and dropout to 0.7.

The mean nRMSE of the execution step was 21.0% and 19.6% for the depart contact. The correlation coefficients were 0.8 and 0.9, respectively. Higher prediction accuracy was reached for the sagittal plane motion. The ankle joint rotation shows a low accuracy. The prediction accuracy for the depart contact is generally higher (Figure 1). These results are in accordance with previous studies [4,5]. The prediction accuracy in the main motion plane is generally higher due to the lower variance. Additionally, the minor motion planes do not necessarily show consistent behaviour in joint moment progression throughout all participants, which makes the prediction more difficult, especially based on a small dataset. As LSTM networks learn datasets successively, the first frames, which are part of the execution contact, are more difficult to predict than later ones, resulting in higher prediction accuracy of the depart contact.

**Figure 1:** Violin plots of the nRMSE for all lower limb joints and motion planes for the execution (blue) and depart (green) contact.

### Conclusions

Although further reduction of the prediction error needs to be achieved, the results are promising and show the general power of neural networks to develop motion analysis towards feedback applications.

## Muscle synergies enable accurate joint moment prediction using few EMGs

Yixing Liu<sup>1,2</sup>, Gunnar Ingi Fridriksson<sup>1</sup>, and Elena M.Gutierrez-Farewik<sup>1,2,3</sup>

Email: lyixing@kth.se

### Summary

In this study, we predicted knee joint moments during walking from as few as 4 EMG sensors with a long short-term memory (LSTM) neural network by taking advantage of lower extremity muscle synergies. Results indicate that predicting joint moments from muscle synergies can reduce the number of EMG inputs required, with lower prediction error than predicting directly from EMG signals.

### Introduction

Wearable sensors, i.e., electromyography (EMG) and inertial measurement units, can facilitate real-time detection of movement intention, estimation of appropriate torques in assistance-as-needed exoskeleton control, and even remote monitoring of patients' motor function, i.e., estimating joint torques and observing muscle activations during rehabilitation [1]. In these settings, it is important to minimize the required number of sensors in order to achieve practical applicability. To this end, the concept of muscle synergies has been useful in predicting unmeasured EMG signals within a measured subset [2] as well as in exoskeleton feedforward control [3]. The objective of this study was to identify and use muscle synergies to predict knee joint moment during walking in an LSTM network using a minimal number of EMG sensors.

### Methods

Ten EMG signals (gluteus maximum, vastus medialis and lateralis, semitendinosus, biceps femoris, medial and lateral gastrocnemius, soleus, tibialis anterior, and rectus femoris) and knee joint moments during normal gait in six able-bodied subjects were collected through motion capture (Vicon cameras, AMTI force plates, Myon nano EMGs). Between 4 and 6 muscle synergies ( $n_{ms}$ ) were identified from the 10 EMG signals using a non-negative matrix factorization (NNMF) algorithm. Two outputs were generated after NNMF – a weights matrix  $W_{n_{emg} \times n_{ms}}$  and time-dependent synergy action signals  $H_{n_{ms} \times n_{time}}$ . The synergy action signals were then used as inputs to train an LSTM neural network prediction model. After training, the synergy action signals were then estimated with 4-7 EMG signals and the weights matrix using a non-negative least squares algorithm, and then used as inputs to evaluate the prediction performance. Four different testing conditions were conducted; predicting knee moments using the synergies-trained LSTM network from 1a) synergies estimated from all 10 EMG signals, 1b) synergies estimated from 4-7 EMG signals, as well as predicting knee moments using an LSTM network that was trained on the EMG signals directly, i.e., not trained with synergies, from 2a) all 10 EMG signals directly, and 2b) between 4-7 EMG signals. For

different EMG subsets, performance from both synergies-based and EMG-based predictions were compared with measured knee moments. Root-mean-square error (RMSE) of knee moment, as a percent of knee joint moment range, was used to assess the error between predicted and measured knee joint torques.

### Results and Discussion

The model that takes advantage of muscle synergies predicted knee moments accurately (Figure 1) and with lower prediction error than the model that used EMG signals directly. In the synergies-trained LSTM model, when as few as 4

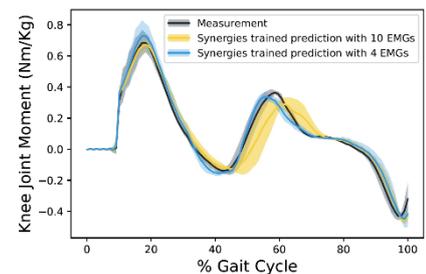

Figure 1. Measured and synergies trained predicted knee moments in 1 subject

EMG signals were used as inputs, knee moments were predicted with lower prediction error when predicting from 4 muscle synergies than that predicting from 5 and 6 muscle synergies (Table I), i.e., in an LSTM trained on 4 muscle synergies identified from 10 EMGs, knee moment could be accurately predicted using as few as 4 EMGs sensors.

Table I Average prediction RMSEs (% knee moment range)

	10 EMGs	7 EMGs	6 EMGs	5 EMGs	4 EMGs
4 synergies	5.85	4.35	4.42	4.48	4.48
5 synergies	5.67	5.07	5.17	5.71	7.48
6 synergies	4.70	4.54	4.73	5.85	7.85
No synergies	6.04	5.63	6.05	5.84	5.74

### Conclusions

Taking advantage of muscle synergies can result in accurate joint moment prediction with fewer EMG sensors. By training an LSTM to predict joint moments from muscle synergies, rather than from EMG signals as independent observations, accurate prediction can be achieved with fewer EMG sensors. We believe this method can facilitate exoskeleton control and rehabilitation devices in daily uses by achieving accurate moment prediction with a minimum of wearable sensors.

# Automated and personalized pose registration from x-ray images using convolutional networks

Florian Vogl<sup>1</sup>, Pascal Schütz<sup>1</sup>, Barbara Postolka<sup>1</sup>, Renate List<sup>1</sup>, William Taylor<sup>1</sup>

<sup>1</sup>Laboratory for Movement Biomechanics, Institute for Biomechanics, ETH Zürich, Switzerland

Email: fv@ethz.com

## Summary

Measuring joint kinematics is a key requirement for a variety of biomechanical research and applications. While x-ray systems avoid the soft-tissue artefacts arising in optical systems, extracting an object's pose (translation and rotation) from the images is time-consuming, expensive, and operator-dependent. Based on 106'000 annotated images of knee implants collected using our moving fluoroscope during activities of daily living, we trained a deep-learning model to automatically estimate the poses for both implant components. By pretraining one stage of our architecture on renderings of the implant geometries, our approach offers predictions for unseen subjects personalized to their specific implants. In 90% of the test set, which included heavily occluded samples, our approach predicted both components' poses better than 2mm (in-plane translation), 25mm (out-of-plane translation), and between 1.5° and 3° (all Euler-angle rotations) without any additional user intervention.

## Introduction

X-ray systems directly measure the skeletal structure and yield a series of x-ray images, from which the 3D kinematics are conventionally estimated by acquiring the 3D information and manually adjusting the object's pose until its projection matches the image. Even for high-contrast structures such as joint replacements, this process is time-intensive, expensive, and operator-dependent.

While automation methods for this task have been developed, their need for approximate poses means that extensive manual work is still required in practice [1,2]. Deep learning has recently achieved impressive results for pose estimation tasks, but requires large datasets including the annotated poses. With the aim to develop an accurate, automated, and personalized approach for 2D-3D registration, this study aims to take advantage of our unique dataset of 106'000 annotated images [3] to a) apply deep learning to pose estimation of knee replacements from x-ray images and b) personalize this process by considering the subject's particular implant geometries.

## Methods

We split the 53 tibia/femur combinations in our dataset into a training- (90%) and test-set (10%). The network (Figure 1) consisted of a) a generic "shadow" network to extract the implant shadows from the image and b) a personalized "synthnet" network to estimate the poses from these shadows. Here, the intuition is that a human could extract the shadow solely by noting the components' absorption and recognizing the surrounding structures, while estimating the pose from this shadow requires the implant geometry. By pretraining a synthnet for each implant geometry on renderings in varying

poses, the synthnets learn what landmarks indicate what pose for a certain implant. Next, we trained the shadownet on our training-set by loading the correct synthnet with frozen weights for each sample, and performing backpropagation.

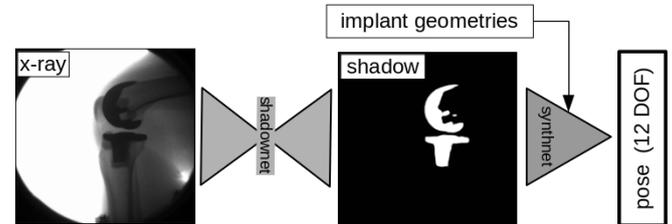

Figure 1: The network architecture. The synthnet is pretrained on renderings of the implant geometries in varying poses.

## Results and Discussion

In-plane translations were predicted to within 2mm (about 3 pixels) in 90% of testsamples, while out-of-plane translations were only predicted to within 25mm because a change in this component only leads to a small change due to perspective (Figure 2). Because our approach struggled to extract the shadow from occluded images, we propose to iteratively feed the rendered shadows based on the estimated poses back into the shadownet to provide approximate information on the shadow it should be looking for.

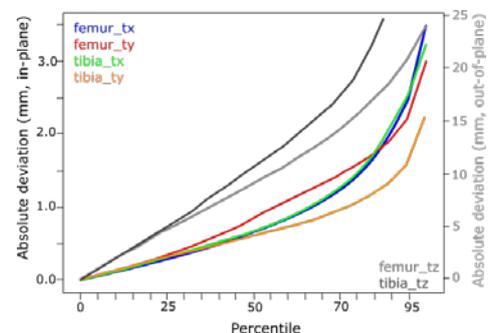

Figure 2: Testset-error between predicted and true translations

## Conclusions

Our approach can either provide starting poses to other algorithms [1,2] or can be used directly to estimate poses from x-ray images in a personalized and automated manner, thus avoiding the laborious and expensive task of manually estimating the poses for each image.

# Assessment of a novel deep learning-based marker-less motion capture system for clinical gait analysis

Saman Vafadar<sup>1</sup>, Laurent Gajny<sup>1,\*</sup>, Wafa Skalli<sup>1</sup>

<sup>1</sup>Institut de Biomécanique Humaine Georges Charpak, Arts et Métiers, Institute of Technology, Paris, France.

\*Email: laurent.gajny@ensam.eu

## Summary

A marker-less motion capture system designed based on four digital video cameras, novel deep learning techniques, and a dedicated dataset, is evaluated against a marker-based system in terms of spatiotemporal and kinematic gait parameters. The results indicate that the marker-less system is highly accurate for measuring spatiotemporal parameters; however, further improvement is required for some kinematic parameters if clinical applications are targeted.

## Introduction

The effectiveness of clinical gait analysis is supported by the literature [1]. The gold standard systems are marker-based. However, their routine clinical use is limited to a few specialized centers mainly because of equipment and operating costs. Marker-less systems could be cost-effective alternatives. Deep learning techniques have demonstrated their potential on publicly available datasets for marker-less motion capture [2]. However, these techniques have not yet been adapted and assessed for 3D marker-less gait analysis. We aimed to design a marker-less system based on deep learning techniques and assess its performances in terms of gait outcomes.

## Materials and Methods

The marker-less system was designed based on four calibrated and synchronized digital video cameras and a convolutional neural network (CNN) [2] that could estimate sixteen joints' 3D position. A novel dataset dedicated for gait study, was collected to train the CNN and test the marker-less system. Twenty-two asymptomatic, two adults with spinal disorder and seven children with bone disease, aged from 6-44 years performed ten walking trials, while being recorded by the marker-less and a reference marker-based system (VICON<sup>®</sup>). Biplanar radiographs (EOS<sup>®</sup>) were also acquired to improve the accuracy of anatomical frames determination according to the protocol published in [3].

The marker-less system was assessed on the test set (12 subjects including 4 pathological) in terms of gait parameters. A gait event detection algorithm [4], designed for marker-based systems, was adapted for the marker-less system. Then, spatiotemporal parameters were computed based on detected gait events. For kinematic parameters, since the marker-less system could only estimate one axis for each bony segment, to form an anatomical frame, the second axis was determined

using a priori knowledge – the gait data of sixty-six subjects, independent from the training and test sets, were used.

## Results and Discussion

The difference between the gait parameters obtained by the marker-less and the reference systems is shown in Table 1. The biases of the spatiotemporal parameters were close to zero (<0.1 cm or sec), and the limits of agreement were smaller than the minimum detectable changes reported in [5] (e.g., step length: 1.56 < 6 cm). Thus, the designed system is accurate enough for measuring spatiotemporal parameters. Regarding kinematic ones, the limits of agreement of the joint-based (JB) knee extension-flexion angle, *i.e.*, the angle between the femoral and tibial segments was below 5°. However, knee and hip extension-flexion were higher than 5°. Indeed, the main limitation of the marker-less system was that it could only estimate the joint positions. Work is in progress to further develop the system to accurately determine anatomical frames, paving the way for using marker-less systems in clinical gait study.

Figure 1: Joint positions by the reference and marker-less systems.

## Summary

Conventionally, detecting gait events, such as initial contact (IC) and toe-off (TO), from kinematic data is performed through manual annotation or kinematic algorithms – both of which are operator-dependent and require substantial user-intervention. While Machine learning (ML) offers a data-driven alternative for detecting gait events in an automated manner, little is known about the performance for specific gait patterns, such as toe-walking. This study examined how well ML was able to detect gait events for different gait patterns by using a variety of foot-markers. Over 95% of the test-set, **our approach detected gait events to within 15ms (IC) and 23ms (TO)** when using the hallux and heel markers. While performance across all gait patterns did not improve when using other markers, **performance on individual gait patterns varied up to 8ms**. Thus, depending on the target population, different marker-sets are required to detect gait events in a repeatable and fully-automated manner.

## Introduction

Clinical gait analysis is used to diagnose neuromotor deficits in pathologies such as Cerebral Palsy. This analysis requires the accurate detection of gait events, particularly IC and TO. In current clinical practice, experts have to manually detect these events based on kinetic (requiring force plates) or kinematic data, which is laborious, expensive, and operator-dependent. While ML techniques [1] have recently demonstrated promising results for detecting gait events using 3-D kinematic data, little is known about their performance in individual gait patterns (e.g. toe-walking). Furthermore, the effect of using different markers as inputs for the detection algorithms also remains unclear, which has significant practical relevancy as the number of kinematic markers and their locations can vary considerably.

Therefore, the goal of this study was to investigate a) how well ML is able to detect gait events in various gait patterns from foot-marker kinematics, and b) what combination of marker inputs optimises the performance for each gait pattern?

## Methods

3-D kinematic and kinetic data were collected from **363 adolescent participants** (Age: 11.76±3.16 years) who performed barefoot walking at a local hospital. The true events were found by setting a threshold of 20N for the vertical ground reaction force. This notably differs from similar works [1], in which the true events were identified by

manual annotation. To avoid overfitting, we assigned 80% of the data to the training-set, 10% to the validation-set used for hyperparameter tuning, and 10% to the test-set. Each gait event was categorised based on whether the heel, midfoot, or forefoot touched the ground first, yielding **5340 IC and 4937 TO events** with a ratio of about 4:2:1 between categories. The network consisted of a bidirectional long short-term memory (LSTM), a fully connected output layer, and a sigmoid activation function. The time-series of marker positions and velocities were cut to a length of 165 frames around the true event with a random offset and used as inputs to train the model with an ADAM optimiser (learning rate=0, momentum=0) and a binary-weighted cross-entropy loss.

## Results and Discussion

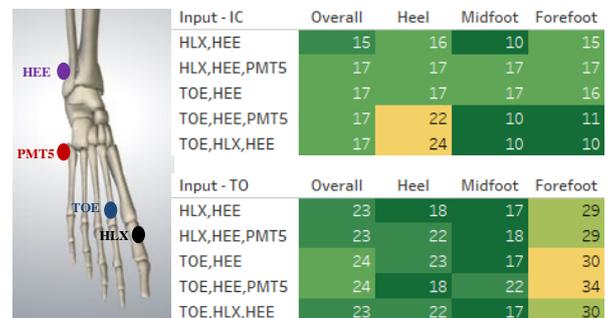

Figure 1: Marker placement on foot (left), Heat-map distribution of detection error in milliseconds (right)

Over 95% of the test-set, our approach detected gait events to within 15ms (IC) and 23ms (TO) when using only the hallux and heel markers (Fig. 1). These values are to be compared with an inter-rater variability of 25ms for manual annotations [1] and of 33ms for kinematic event detection [2]. While the use of other markers did not improve performance over all gait patterns, performance on individual patterns varied up to 8ms. Our results thus suggest that gait event detection could be improved by first identifying the gait pattern, and then choosing the optimal markers for this specific pattern and applying the appropriate detection algorithm. By training specialised algorithms for each gait pattern, the performance could be increased even further, thus ultimately providing optimal gait event detection in a repeatable and fully-automated manner.

## Should Major League Baseball Adjust the Mound Height?

<sup>1</sup>The American Sports Medicine Institute, Birmingham AL, USA

<sup>2</sup>Concordia University of Chicago, River Forest, Illinois, USA

Email: megan.s.stewart19@gmail.com

### Summary

With a decrease in runs scored, Major League Baseball (MLB) commissioned the American Sports Medicine Institute to conduct a biomechanical study looking at a potential change to height of the pitching mound.

### Introduction

In 1903, the pitching mound was restricted to a maximum height of 15in. Following the 1968 season (“The Year of the Pitcher”), MLB lowered the mound to 10in in hopes of boosting run scoring<sup>1,2</sup>. This seemed to work, as the number of runs scored bumped up in 1969 and remained relatively constant through the rest of the 20<sup>th</sup> century. However, from 2000-2014, there was a steady decrease leading to thoughts that the mound should be lowered again to boost scoring. Not only did scoring decrease during these years, but the number of pitching injuries and surgeries rose exponentially throughout professional and amateur baseball. Some baseball and medical experts suggested that lowering the mound may also reduce stress on the throwing arm and the number of injuries.

### Methods

The research study was approved by the Institutional Review Board at St. Vincent’s Health System (Birmingham, AL, USA). Twenty collegiate pitchers were recruited from universities in the area of Raleigh, NC. All of the testing was performed at the USA Baseball Training Complex in Cary, NC where four custom dirt mounds with differing heights (6in, 8in, 10in, 12in) were built outdoors and covered by a tent.

Pitchers were instructed to throw 10 full effort pitches from each condition to a catcher. Three-dimensional pitching biomechanics were tracked with an 11-camera Motion Analysis System (Motion Analysis Corporation, Santa Rosa, CA) at 240 frames/second. Ball velocity was tracked with Rapsodo (Rapsodo Inc). All of the mounds were constructed with the same slope according to MLB specifications, starting at six inches in front of the pitching rubber the mound sloped downward at a rate of one inch per one foot over a distance of six feet. There were two 11-camera motion capture systems (Motion Analysis Corporation, Santa Rosa, CA) set up each surrounding a pair of mounds. For each of the mounds, homeplate was positioned 60.5 ft away and a ball tracking system was positioned 6 ft behind homeplate (Rapsodo Baseball System, Rapsodo Inc. Fishers, IN). The baseball tracking system utilized a high-speed video sampling at 240 frames per second and radar technology sampling at 50KHz to calculate ball movement

and spin. 40 pitches were collected, where the pitchers were instructed to throw five full-effort fastballs and five full-effort curveballs from each of the mounds in a randomized order. For all trials, three-dimensional motion data were collected at 240 Hz while the ball tracking system captured the ball speed, break, and spin. From the motion capture data, 31 kinematic and kinetic variables were calculated for each pitch as previously described.

For each of the eight testing conditions (four mound heights and two pitch types), the magnitudes of ball movement and biomechanical parameters were averaged by participant. Repeated measures analysis of variance (ANOVA) was utilized to determine significant differences in the mound heights for fastballs and curveballs separately. When a significant difference ( $p < 0.05$ ) was found, a pairwise difference was analyzed with a Tukey post-hoc test ( $p < 0.05$ ).

### Results and Discussion

The pitchers were (mean $\pm$ SD) 19.7 $\pm$ 1.2 years old, 73 $\pm$ 2 in tall, and had a weight of 205 $\pm$ 19 lbs. There were no significant differences seen for ball velocity, movement, or spin when pitching from the four mound heights for both the curveball and fastball. The mean ball velocity for the fastball and curveball was 88.4 $\pm$ 6.06 mph and 70.2 $\pm$ 5.95 mph respectively. There were twelve biomechanical variables (seven kinematic variables and five kinetic variables) that were found to be significantly different when comparing the mound height for the fastball pitches. When comparing mound height and curveballs, there were eight kinematic variables shown to be significantly different.

### Conclusions

The results from these two studies indicate that lowering the pitching mound may not increase run scoring, as there were no changes in fastball and curveball velocity, spin or movement. The differences seen in pitching kinematics with mound height variations were small and may lack practical significance. The shoulder and elbow kinetics of the fastball may be slightly lower with a lowered mound, which may reduce the risk of pitching injury.

## The influence of bicycle lean on maximal power output during sprint cycling

Ross D. Wilkinson and Rodger Kram

Locomotion Laboratory, The University of Colorado, Boulder, CO, USA

Email: ross.wilkinson@colorado.edu

### Summary

We used a modified cycle ergometer to investigate if leaning (or not leaning) a bicycle side-to-side affects sprint power output. We found that leaning the ergometer *ad libitum* did not enhance maximal 1-s crank power compared to a locked condition. However, trying to minimize ergometer lean decreased maximal 1-s crank power by 5% compared to leaning *ad libitum*.

### Introduction

Competitive cyclists typically sprint out of the saddle and alternately lean their bikes from side-to-side, away from the down-stroke pedal [1]. Yet, there is no direct evidence as to whether leaning the bicycle, or conversely, attempting to minimize lean, affects maximal power output during sprint cycling. Here, we investigated two questions related to maximal 1-s power output during non-seated, sprint cycling: 1) Does *ad libitum* lean affect maximal power output compared to a traditional stationary ergometer? and 2) Does trying to minimize lean affect maximal power output compared to *ad libitum* lean? To address these questions, we modified a cycle ergometer so that it could lean from side-to-side or be locked to prevent lean. This modified ergometer made it possible for riders to sprint under three different conditions: locked (no lean), *ad libitum* lean, and minimal lean. In the minimal lean condition, the ergometer could lean but we asked the subjects to try to minimize lean. Our first hypothesis (null) was that *ad libitum* lean would result in the same maximal 1-s crank power as the locked condition. Our second hypothesis was that trying to minimize lean would decrease maximal 1-s crank power compared to the *ad-lib* and locked conditions.

### Methods

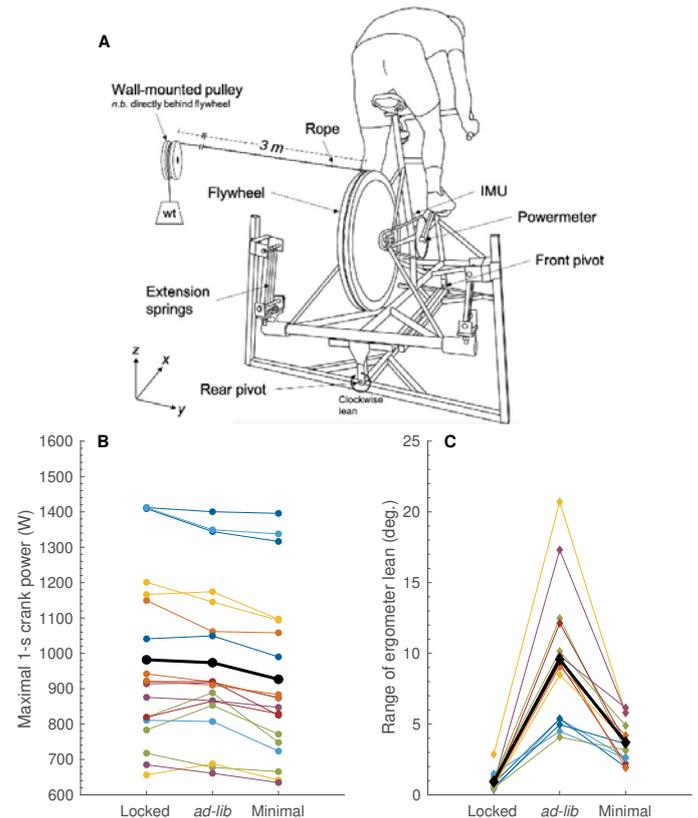

Nineteen healthy recreational cyclists (13M/6W,  $28 \pm 6$  y,  $1.75 \pm 0.09$  m,  $69 \pm 10$  kg, mean $\pm$ SD) pedaled a friction-loaded ergometer mounted atop a hinged chassis. The ergometer was equipped with a crank-based mechanical power meter (Quarq DZero, SRAM, Corp, Chicago, IL, USA) and a Monark 827E flywheel. In the *ad-lib* lean and minimal lean conditions, springs attached to the rear legs of the ergometer provided a restoring torque proportional to lean angle. In the locked condition, aluminum struts prevented lean. Subjects performed 9 maximal 5-s sprints from rest in a non-seated posture—3 locked, 3 *ad-lib* lean, and 3 minimal lean. We derived crank angle and ergometer lean angle from IMU acceleration data recorded at 500 Hz.

### Results and discussion

**Maximal 1-s crank power:** In support of our first hypothesis, maximal 1-s crank power in the *ad-lib* condition ( $974 \pm 33$  W) was similar to the locked condition ( $982 \pm 30$  W),  $p = 0.8$ ,  $ES = 0.2$ . In support of our second hypothesis, crank power was re-

duced by 47 W (5%) in the minimal lean condition ( $927 \pm 32$  W), compared to the *ad-lib* condition,  $p < 0.001$ ,  $ES = 1.3$ .

**Range of ergometer lean:** The range of lean in the *ad-lib* condition ( $9.6 \pm 2.3$  deg.) was more than ten-times the locked condition ( $0.8 \pm 0.3$  deg.),  $p < 0.001$ ,  $ES = 1.7$ , and more than twice the minimal lean condition ( $3.9 \pm 1.0$  deg.),  $p < 0.001$ ,  $ES = 1.3$ .

**Figure 1:** A. Diagram of modified cycle ergometer. B-C. Individual (color) and group mean (black) maximal 1-s crank power and range of ergometer lean, respectively.

### Conclusion

Leaning the bicycle *ad libitum* did not enhance maximal 1-s crank power compared to a traditional stationary ergometer. Trying to minimize bicycle lean decreased maximal 1-s crank power by 5% compared to leaning *ad libitum*.

**Summary**

Golf is a multimodal-activity that should be considered when designing training programs for older adults. This study quantified the lower extremity (LE) demands of the golf swing in healthy older adults (OAS) who acquired the skill through a 10-week golf training program. The average peak net extensor-(PEM) and support-moments (SM) of the lower extremity were calculated via 3D motion capture. PEM were found greater at the right hip and left knee compared to their contralateral counterparts, while no differences were found in the PEM of the ankles and SM. The LE demands of the golf swing were similar to common stepping activities in OAS. Understanding the demands associated with the physical tasks specific to golf will inform the design of safe and effective golf training programs in older adults.

**Introduction**

Proper exercise prescription is integral to quality of life in OAS [1]. Golf is a multimodal-activity that offers physical, psychosocial, cognitive, and health benefits [2, 3]. However, the physical demands associated with golfing activities have not been well characterized, and compared to other common exercises. The purpose of this study was to: 1) quantify the LE joint demands of the golf swing in OAS novel to golf after a 10-week golf training program, 2) examine the demand differences between limbs, and 3) to compare the demands to common stepping activities.

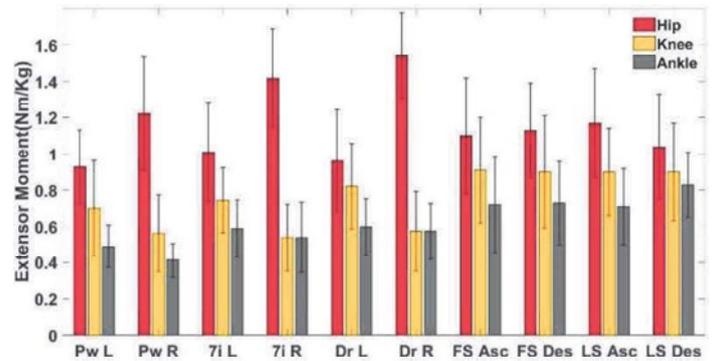

**Methods**

Fourteen of fifteen participants completed a 10-week golf training program with biomechanical, physical, and cognitive testing prior to and after the program. During post-testing, participants were instructed to hit 5 golf shots each with a pitching wedge, 7-iron, and driver while standing on 2 force plates. LE net joint moments were calculated via a marker-based, motion capturing system. PEM and SM of the hip, knee, and ankle during golf swings are reported. Independent-samples t tests were used to examine differences between left and right limbs ( $p \leq 0.05$ ). To assess the relative magnitude of these moments, comparisons were made with common stepping activities using previously reported data, collected with similar methodology, from our laboratory [4]. Results are presented, in Nm normalized to body mass, as mean  $\pm$  standard deviation.

**Results and Discussion**

Participants completed 283/300 (94%) sessions with no program related adverse events. All were right-handed. The right hip PEM was greater than the left hip during the golf swing, regardless of the club ( $p \leq 0.05$ ). At the knee, the left side had greater PEM than the right side for the 7 iron and driver ( $p \leq 0.05$ ), but not the pitching wedge. No differences were found between limbs for ankle PEM. When comparing PEM in the sagittal plane, the golf swing moments appeared larger at the hips and similar at the

knees and ankles compared to common forward and lateral stepping exercise activities in older adults [4] (Figure 1.). In regards to SM, there were no differences between L and R limbs (Table 1.).

**Figure 1.** Average Peak Joint Moments in Golf Swings and Stepping Activities. FS: forward stepping; LS: lateral stepping; Asc: ascending phase; Des: descending phase.

**Table 1.** Golf Swing Support Moments in Three Types of Golf Clubs

	Pitching Wedge		7Iron		Driver	
	L	R	L	R	L	R
SM	1.55	1.34	1.68	1.58	1.64	1.62
(Nm/kg $\pm$ SD)	$\pm 0.33$	$\pm 0.29$	$\pm 0.38$	$\pm 0.48$	$\pm 0.43$	$\pm 0.41$

**Conclusions**

Golf is a multimodal-activity that includes: swings, multi-terrain walking, and bending to mark or tee up the ball. These activities are likely responsible for the reported improvements in physical function (e.g., hip strength) associated with the golf-training program [3, 5]. Our findings suggest that golf swings generate sagittal plane PEM's that are similar or greater than those generated during stepping activities in OAS. Differences between left and right limb PEM's should be considered when prescribing golf as an exercise activity and suggest that other supplemental activities might be necessary to counteract these differences. Understanding the relative biomechanical demands associated with these activities will inform prescription of progressive, safe and effective golf training programs for OAS in the future.

# Racing in the street – Whole-body vibration during road cycling and the effect of different equipment choices to minimise it

Jon Ward<sup>1</sup>, George L Ruell<sup>1</sup>, Timothy P. Holsgrove<sup>1</sup>

<sup>1</sup>Department of Engineering, College of Engineering, Mathematics and Physical Sciences, University of Exeter, UK

Email: [t.holsgrove@exeter.ac.uk](mailto:t.holsgrove@exeter.ac.uk)

## Summary

Whole-body vibration (WBV) exposure can lead to spinal injury and pain, and road cycling can expose participants to substantial WBV. Previous research has shown no difference between a standard seatpost compared to designs that aim to reduce vibration. This study provides further data in this area by focusing on the effect of saddle designs, tyre construction, and tyre pressure on WBV exposure. Our results again highlight the fact that daily WBV exposure limits are rapidly exceeded, and none of the equipment configurations we tested led to a substantial reduction in the WBV exposure. Alternative equipment, such as suspension, or larger volume tyres that can be used at lower pressures may be required to achieve meaningful reductions in WBV during road cycling.

## Introduction

Exposure to whole-body vibration (WBV) substantially increases the risk of low back pain, spinal degeneration, and injury [1, 2]. Standard methods (ISO 2136-1) have been established to evaluate WBV [3], and there are daily WBV exposure action values (EAV) and exposure limit values (ELV) [4]. Cyclists who ride more than 160 km/week are 3.6 times more likely to have back pain compared to those that ride less than 160 km/week [5], and research evaluating seatpost designs during road cycling showed that daily WBV limits were rapidly exceeded with all seatposts [6]. This preliminary assessed the effect of saddle design, tyre construction, and tyre pressure on WBV.

## Methods

Road cyclists completed a predetermined 6.42 km route [6]. The study was approved by the institutional ethics committee (eEMPS00007). One group (n=3) completed the route four times, each time with one of four saddles: Prologo Scratch 2 PAS Nack; San Marco Regal Evo; San Marco Regal; Brooks Cambium C13. Another group (n=3) completed the route six times: three times using Challenge Strada Race nylon vulcanized clincher tyres at pressures of 75, 85, and 95 psi; and three times using Challenge Strada Service Course cotton clincher tyres at pressures of 75, 85, and 95 psi. APDM Opal sensors were positioned at the seat cluster (SC), top of the seatpost (SP), and lumbar region (LB) in the saddle group, and at the rear hub (RH), saddle rails (SD) and lumbar region (LB) in the tyre group. The root-sum-of-squares vibration dose value (VDV<sub>RSS</sub>) was calculated according to ISO 2136-1 [3]. Transmissibility (T) across the saddle was determined from the root mean squared acceleration (a<sub>rms</sub>) at the SP and LB.

## Results and Discussion

The vibration for all participants in all tests comprised both constant low-level vibration, and frequent shocks (Figure 1).

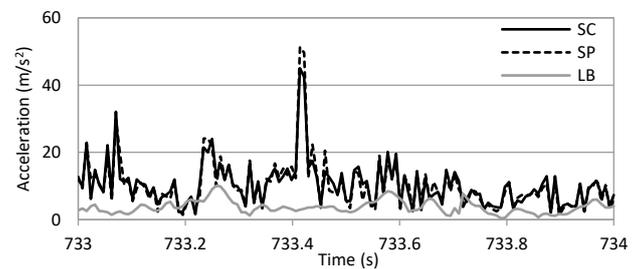

Figure 1: Typical data of the resultant acceleration magnitude.

The VDV<sub>RSS</sub> measured at the RH, SC, SP, and SD exceeded the ELV in all tests, and the mean VDV<sub>RSS</sub> at the LB position exceeded the EAV for all saddles, tyres, and tyre pressures, and the ELV in 40 % of cases (Figure 2). There was a large reduction in the acceleration between the SP and LB in all tests in the saddle group (T range 0.26-0.55), though it is likely that the clothing and soft tissue of the rider contribute to a large part of the observed reduction.

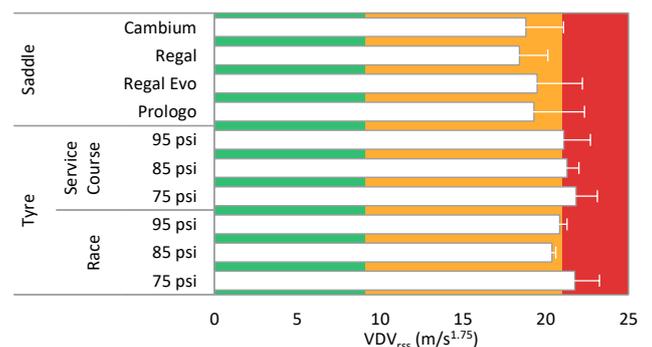

Figure 2: VDV<sub>RSS</sub> at the LB position shown against daily WBV exposures: safe (green); EAV (amber); ELV (red).

## Conclusions

Road cycling results in substantial WBV exposure. None of the test configurations reduced the WBV exposure to within occupational limits. Therefore, alternative equipment choices, are required to meaningfully reduce WBV.

### Summary

The purpose of this study was to investigate the magnitude of relationships between sleep metrics and kicking performance in youth players. Twenty-eight under-17 players completed a kick testing protocol against a goalkeeper. We determined the approach run, foot and ball velocities, mean radial and bivariate variable error, and accuracy during kicking performance. Over 24h before field testing, players were monitored by wrist actigraphy. Self-reported sleep quality and chronotype scores were also collected. Multiple linear regressions indicated that the wake-up time and chronotype scores contributed to 40% of the mean radial error while self-reported sleep quality influenced respectively on 19% and 24% of the accuracy and bivariate variable error variances; taken together self-reported sleep quality and the time of final awakening explained 33% of the accuracy. In short, one-off self-reported or directly determined sleep measures using wrist actigraphy allowed for detecting inter-individual variations of kicking performance in youth-soccer players.

### Introduction

Sleep is fundamental in the day-to-day recovery of physical capacity and motor skills [1]. A night with reduced sleep may disrupt central nervous system functioning, compromising visuospatial perception, decision-making and movements' execution [2]. In senior standards, variations in sleep duration, latency and efficiency produced no effects on match kicking accuracy [3]. However, results from senior players cannot be readily extrapolated to youth [4]. Therefore, the present study aimed to investigate the habitual sleep patterns experienced by youth soccer players and their influence on kicking performance features.

### Methods

Thirty under-17 Brazilian soccer players were monitored using wrist actigraphy in the night immediately before kick testing. The following parameters were identified: sleep-wake phases, time in bed, wake-up time, time of lights out, total sleep duration, wake after sleep onset, latency of lights out and sleep starts, efficiency and number of awakenings [5]. Also, self-reported sleep quality, Karolinska Sleepiness Scale and individual's chronotype score were collected.

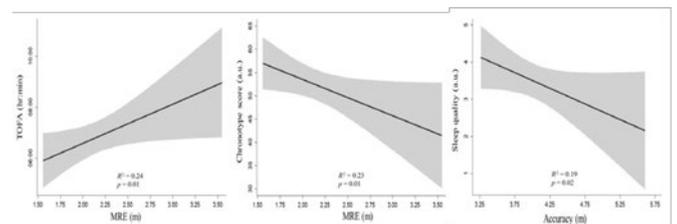

The soccer players performed seven kicks to each goal side and six requested to aim its centre. They kicked stationary balls positioned 18m away from the midpoint goal line, using the instep region of the dominant foot and aiming at the centre of 1x1m targets allocated in the goalpost. Two goalkeepers tried to block the shots. The kicks were recorded, and the

imagens were analyzed in DVIDEOW environment. We calculated the approach run, foot and ball velocities, mean radial (MRE) and bivariate variable error, and accuracy to analyzed kicking performance.

Partial correlations controlling for chronological age and body sizes were computed between sleep parameters and kicking performance indicators. Multiple linear regressions (stepwise method) were used to determine the relative contribution of sleep variables to the variance in kicking performance metrics.

### Results and Discussion

The main findings (Figure 1) were: (1) both subjective and objective measures of sleep were associated with kicking performance ( $r < 0.38, p < 0.05$ ); (2) higher perceived sleep quality was related to better kicking accuracy ( $r^2 = 0.19, p < 0.02$ ) and lower placing variability ( $r^2 = 0.24, p < 0.008$ ). In contrast, athletes with later wake-up time performed poorer kicks as illustrated by fewer kicks on-target ( $r^2 = 0.15, p < 0.04$ ) and higher MRE ( $r^2 = 0.40, p < 0.02$ ); (3) while either sleep quality and duration impacted on ball placement indices, kicking velocity properties were minimally influenced.

**Figure 1:** Associations between kicking performance with the sleep parameters. TOFA wake up time; MRE mean radial error.

### Conclusions

Whilst sleep quality indicators had limited interference on kicking velocity components, good sleep quality and morning behavior may notably produce a better kicking accuracy.

# IN VIVO VALIDATION OF A MUSCULOSKELETAL MODEL OF THE WRIST FEATURING A CONSISTENT ANATOMICAL DATA SET

Oluwalogbon O. Akinnola<sup>1</sup>, Vasiliki Vardakastani<sup>1</sup>, <sup>1</sup>Angela E. Kedgley

<sup>1</sup>Department of Bioengineering, Imperial College London, London, UK

Email: o.akinnola16@imperial.ac.uk

## Summary

Activity of seven forearm muscles during wrist flexion-extension and radial-ulnar deviation was compared to muscle forces predicted from corresponding kinematics. The model predicted agonist muscle activity but perform poorly predicting antagonist activity. Co-contraction is needed for models to accurately predict forearm muscle activity.

## Introduction

Musculoskeletal models of the wrist have been developed with averages of anatomical parameters, which has been shown to significantly affect model predictions [1]. The Imperial College London wrist model was developed from a consistent anatomical data set and previously validated in vitro [1]. However, in vitro validation risks omitting factors present in vivo. To improve the clinical applicability of the model, this study sought to validate the model outputs with electromyographical (EMG) data.

## Methods

23 participants ( $1.71 \pm 0.08$  m,  $68.26 \pm 12.66$  kg,  $28.6 \pm 4.60$  years) took part in this study. Each performed 15 cycles of wrist FE and RUD with their dominant hand. Muscle activity of extensor digitorum communis (EDC), extensor carpi radialis (ECR), extensor carpi ulnaris (ECU), flexor digitorum superficialis (FDS), flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), and pronator teres (PT) were recorded using surface EMG (Delsys, Natick, USA). Joint kinematics recorded using an eight-camera optical motion capture system (Qualisys, Gothenburg, Sweden) were used as inputs for the model. An inversion of the EMG-to-force method was used to generate model-predicted muscle activity [2]. These were qualitatively compared to the recorded EMG data using Statistical Parametric Mapping (SPM) t-testing, Magnitude-Phase-Comprehensive (MPC), and Pearson's Correlation Coefficients (PCC).

## Results and Discussion

The qualitative comparison showed a good match between the model output and the recorded EMG. FCU and FCR were

observed to coactivate during flexion (Figure 1). ECU, ECRL and ECRB were observed to coactivate during extension, but muscles were only activated in the model when acting as agonists. The PCC between the predicted and recorded muscle activity was 0.04 on average. The average MPC values were 0.81 (M), 0.25 (P), and 0.83 (C). Only the ECRL predicted force was different ( $p=0.01$ ) to in vivo estimates.

Both the qualitative comparison and the SPM statistical testing indicate that the model can accurately predict the muscle activation patterns of agonist muscles involved with wrist motion. However, the PCC values indicate that the model is not able to replicate the muscle activation pattern for all the muscles, specifically the antagonist muscles. This is further supported by the MPC values, which showed that the model underestimated muscle activity. The absence of co-contraction means that less activity is needed by the agonist muscles to generate the kinematics. As the model optimizes by minimizing muscle stress, if a muscle is not needed to generate the motion, it is effectively switched off. However, this is not the case in vivo, as antagonist muscles also act as stabilisers. Thus, there is a poor correlation as the model-predicted activity can be zero while the EMG shows activity. In conclusion, the model has been validated for the in vivo muscle activation patterns of agonist muscles during wrist motion. However, the inclusion of co-contraction in the model is needed to accurately capture the complete biomechanical picture.

## Conclusions

In conclusion, the model has been validated for the in vivo muscle activation patterns of agonist muscles during wrist motion. However, the inclusion of co-contraction in the model is needed to accurately capture the complete biomechanical picture.

# Palmar musculature and its role as a dynamic compressor of the carpal tunnel

Trevor Simcox, Lauren Seo, Kevin Dunham, Catherine Petchprapa, Ronit Wollstein

Departments of Radiology and Orthopedic Surgery, NYU Langone Health, New York, NY, USA

Email: ronitwollstein@gmail.com

## Summary

It is possible that the musculature overlying and integrated with the transverse carpal ligament represent a dynamic force that exerts pressure over the median nerve contributing to the development of carpal tunnel syndrome (CTS). The aim of this study was to compare musculature overlying the carpal tunnel between subjects with and without the diagnosis of CTS. There was a very wide range of muscle mass measured. We found that there was a significant correlation between signs of CTS on MRI (median nerve cross-sectional area) and the amount of muscle overlying the carpal tunnel. Further study should refine the measurement method of these muscles to better understand their effect on CTS.

## Introduction

The diagnosis of carpal tunnel syndrome (CTS) remains clinical. While much study has focused on the dimensions and size of the carpal tunnel, there has been little emphasis on possible dynamic factors of increased pressure in this anatomical space. During carpal tunnel release, variable amounts of muscle above the carpal tunnel are commonly observed. It is possible that this musculature may represent a dynamic force that exerts pressure over the median nerve contributing to the development of CTS. We believe these muscles, specifically those found immediately volar to the transverse carpal ligament and cross the carpal tunnel, have a dynamic role in the etiology of CTS especially in manual laborers who use their hands in a forceful and repetitive fashion. [1] This anatomic variant (muscles crossing the area of the carpal tunnel) may also be related to the "square" hand configuration contributing to increased incidence of CTS in these patients. The ability to recognize this "dynamic component" may improve our ability to understand and prevent the development of CTS. We hypothesized that patients with a clinical diagnosis of CTS have more muscle, as quantified by magnetic resonance cross-sectional imaging (MRI), overlying the carpal tunnel than normal controls.

## Methods

**Case control study of a** database of wrist MRI. Cases were patient charts with a diagnosis of CTS. These were matched by age and gender to those without CTS (controls). Exclusion criteria included poor quality imaging, space-occupying mass in the carpal tunnel, concomitant neurological disorders, and previous carpal tunnel surgery. Axial cuts at the level of the hook of the hamate and scaphoid tubercle were used to measure the muscle mass overlying the carpal tunnel. Muscle mass was quantified using: thickness (mm) at 3 points (mid-capitate, capitate-hamate boarder, capitate-trapezoid border) and an average thickness (calculated by dividing the cross sectional area by the carpal tunnel width). Other MRI parameters from axial

cuts were measured: median nerve T2 signal, median nerve shape, and carpal tunnel cross sectional area.[2] Groups were compared with t-tests or Wilcoxon rank-sum tests and statistical significance was defined as  $p < 0.05$ . single-spaced,

## Results and Discussion

A total of 21 cases and controls met the inclusion criteria for the study. There were no significant differences in age, gender, hand dominance, manual laborers, diabetes mellitus, hypothyroidism or nerve shape between case and controls. Average muscle depth in the carpal tunnel group was 2.61mm and control group 2.54mm ( $p=0.83$ ). Muscle depth measurements for carpal tunnel and control groups were 2.36mm and 2.10mm ( $p=0.46$ ) at the mid-capitate, 1.19mm and 0.67mm ( $P=0.23$ ) at the capitate-hamate border, and 3.42mm and 4.30mm ( $p=0.4$ ) and the capitate-trapezoid border respectively. The variability in measurements was significant in all areas measured. We did find a significant correlation between signs of CTS (median nerve cross-sectional area) on MRI and MRI measured muscle mass  $p=0.008$ .

## Conclusions

We found no significant differences in muscle mass overlying the carpal tunnel using our method of evaluation between chart documented CTS and non-CTS wrist MRIs. We did find a correlation with MRI nerve cross sectional area.

It is possible that:

- 1) There truly is no difference.
- 2) Our method of evaluation is flawed:
  - The insertion (footprint) of the muscles may be more important in the mechanics of the carpal tunnel than the amount of muscle and this was not evaluated.
  - Anatomical variation was so great that our measurements were unable to identify true differences.
  - Advanced CTS can cause atrophy affecting the amount of muscle measured on MRI.
- 3) Future research should focus on a refining the measurement method of these muscles and their effect on CTS.

## Fused with Motion: A Biomechanical Comparison of Dart Throw Motions after Partial Wrist Fusions

Frederick W. Werner, Dami O. Oluyede, Garrett Esper, Michael J. Schreck  
 SUNY Upstate Medical University, Syracuse, NY, USA Email: wernerf@upstate.edu

**Summary:** Multiple partial wrist fusions exist for the management of wrist arthritis. The purpose of this study was to measure the motion allowed by different orientations of the dart throwing motion for 7 different partial wrist fusions and proximal row carpectomy.

**Introduction:** Partial wrist fusions may limit wrist motion differently during a dart throw style of wrist motion. The purpose of this study was to measure the retained motion for different orientations of the dart throwing motion for 7 different partial wrist fusions and proximal row carpectomy.

**Methods:** Eight fresh frozen cadaver wrists were tested with the wrist intact and for seven simulated fusions and proximal row carpectomy. In all cases, the wrists were passively moved through a minimum of 4 circumduction motions by 2 testers. Wrist motion was measured by a motion sensor,

attached to the dorsum of the 3<sup>rd</sup> metacarpal. The fusions were scaphocapitate (SC), scapholunate (SL), capitulate (CL), radiolunate (RL), radioscapolunate (RSL), scapho-trapeziotrapezoid (STT), 4 corner fusion (CF) and a proximal row carpectomy (PRC). For each circumduction motion, (figure 1) the area within the circumduction motion was computed, the principal axes of the motion were calculated as the angle it made with the flexion/extension axis, and the range of motion (arc) that a dart throw motion might have until it intersects the boundary of the circumduction motion was determined. The arc of motion was found for a pure flexion/extension motion, a pure radioulnar deviation motion and 11 motions oriented at increasing amounts from the flexion/extension axis. A one-way repeated measures ANOVA with a Bonferroni correction for multiple comparisons was used to compare the different simulated dart motions.

**Results and Discussion:** All fusions except for the SL fusion significantly reduced the area of motion ( $p < 0.01$ ) compared to intact. The SC area was larger than the CL ( $p = 0.04$ ). The SL area was larger than the CL and the RSL ( $p < 0.03$ ). The SC and STT fusions principal axes were more closely aligned with the flexion/extension axis (ave 8 deg) than the intact axis

(19 deg). The SL had a larger angle (20 deg; more aligned toward the radioulnar deviation axis) than the STT (7 deg) or the PRC (8 deg;  $p < 0.04$ ). The arc of motion (table 1) of the intact wrist oriented 20 deg from the flexion/extension axis was greater than any of the other 12 orientations ( $p < 0.03$ ). At the 20 and 25 degree orientations, all fusions had a smaller arc of motion compared to intact ( $p < 0.02$ ). The SC, CL and RSL fusions all had a smaller arc of motion than the intact at all 13 orientations ( $p < 0.04$ ). The SL fusion was the only fusion which did not decrease the area of motion compared to the intact specimen. This finding makes intuitive sense biomechanically, and reinforces the importance of the SL ligament in linking the motion of the scaphoid and lunate bones under normal kinematic conditions of the carpus.

Table 1: Average Arc of Motion at Different Orientations of a Dart Thrower's Motion (angle from flexion/extension axis; mm)

Orientation	Fusion								
	Intact	SC	SL	CL	RL	RSL	STT	CF	PRC
Flex-ext	94	76	81	55	59	41	76	60	73
20 deg	116	73	102	59	83	54	67	65	70
25 deg	108	68	98	59	80	57	61	65	68
30 deg	99	62	92	58	75	57	55	65	63
35 deg	91	57	85	57	69	66	50	65	58
40 deg	83	53	78	55	65	53	46	63	55
45 deg	76	49	72	52	59	50	42	60	51
50 deg	70	46	66	50	55	47	39	57	48
55 deg	65	44	62	47	51	43	37	55	45
60 deg	61	41	58	45	48	40	34	52	43
65 deg	57	40	54	43	45	37	33	50	41
70 deg	54	38	51	42	43	34	32	48	40
Radio- ular	47	35	44	37	36	28	30	42	37

**Conclusions:** This study provides a comprehensive compilation of the range of motion in a functional plane "the dart throw motion" to be expected after various limited wrist fusions and proximal row carpectomy. These data provide the clinician with important information that can be used to educate the patient with regards to expectations after surgery.

**Acknowledgments:** Funded by the Department of Orthopedic Surgery, SUNY Upstate Medical University

## **My current understanding of wrist dynamics**

Marc Garcia-Elias, Barcelona, Spain

The wrist is one of the most complex composite articulations of the human body, comprising 15 bones, 24 joint facets, and 24 ligaments. Furthermore, it incorporates a system of pulleys to control the moment arms of the tendons that cross the joint. The necessity of placing the hand in the best possible position that allows manipulating all sorts of objects with the minimal energy cost, on one side, and the need to ensure that the joint is capable to sustain considerable amount of forces without yielding explains why we are still struggling to understand how needs to be treated when is dysfunctional. In kinetic terms, a joint is meant to be stable when is able to sustain physiologic loads without yielding. To achieve this, when the wrist is loaded, capsular ligaments are the first to react. Some ligaments, however, may have difficulties resisting prolonged tensions, thus the need for muscles to protect the ligaments under the coordination by the sensorimotor system, a specialized group of neural elements that use the proprioceptive information to control stability. This session will cover what is the current understanding of the role of ligaments and muscles in the stabilization of the wrist.

### Summary

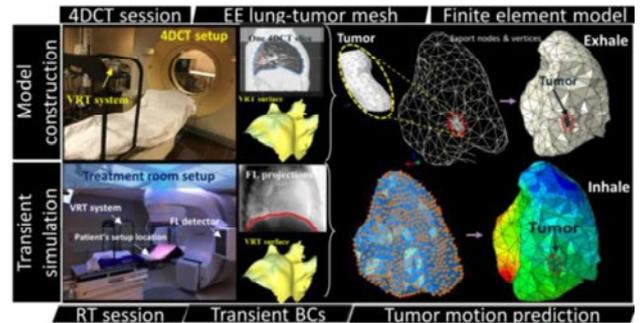

Thoracic radiotherapy (RT) is restricted by breathing-related motion of the target and internal anatomy with limited options available for direct visualization of this motion during treatment. The current standard-of-care for motion mitigation expands the irradiated volume to encompass the entire range of tumor motion as assessed during the planning stages. We present a biomechanical model that predicts tumor motion during RT delivery sessions based on boundary conditions (BCs) derived by monitoring the patient's chest and abdomen surface. Our model can serve as a gold-standard for imaging-based models and can potentially lead to significant reductions in expansion margins, thereby better preserving healthy lung tissue.

### Introduction

Surface images of the chest and abdomen are generally accessible during RT delivery and can be used to monitor patient motion. However, treatment of thoracic cancers require accounting for the motion of the internal anatomy. 4D computed tomography scan (4DCT) done as part of RT planning generates a sequence of volumetric images representing the range of internal anatomy motion over the "average" breathing cycle. To ensure RT delivery to the tumor, the irradiated volume is expanded into the internal target volume (ITV), which encompasses the range of motion observed in the 4D images. Irregularities in the breathing pattern can cause deviations from the average cycle. To account for breathing irregularities and setup uncertainties, the irradiated volume is further expanded into the planning target volume (PTV). These expansions expose healthy lung tissue to undesirable doses of radiation and pose a risk for radiation-induced toxicities. We present a finite element biomechanical model that uses chest and abdomen surface images acquired during RT treatment planning and delivery to predict motion of the internal anatomy including the tumor.

### Methods

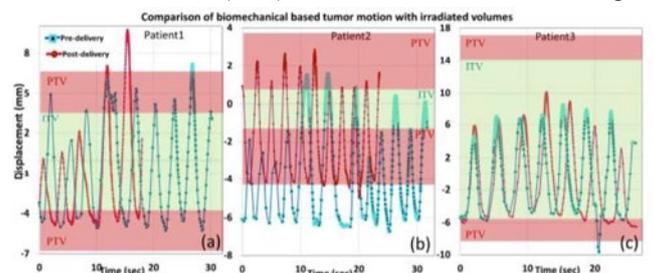

4DCT images, and VisionRT (VRT) surfaces of the chest and abdomen were collected from three lung cancer patients (Figure 1- top row). During RT treatments, two ~30s long datasets of VRT surfaces with concurrent fluoroscopic projections (FLs) were acquired pre- and post-RT delivery (Figure 1- bottom row). To generate BCs for the model, the end of exhale (EE) 4DCT image was mapped to the other images using deformable image registration. A mathematical basis for the observed deformation vector fields (DVs) was derived using principal component analysis. A previously validated surrogate motion model (SMM) that uses VRT surfaces as input was constructed to estimate EE lung surface DVs. [1,2] The SMM applied concurrent VRT surfaces and FL projections to construct and update the internal-external correlation and predict lung surface DVs. [3] An elastic, non-linear finite element model of the EE lung and tumor was generated in the ABAQUS finite element software. Lung and tumor material properties were optimized to minimize the error between model-estimated and 4DCT measured tumor centroid. The SMM-generated lung surface DVs were used as boundary conditions and transient FE simulations were performed to compute tumor motion during the RT delivery session.

**Figure 1 Biomechanical model construction.** Top row: EE Lung and tumor contours were imported into ABAQUS and material properties were optimized. Bottom row: FL projections and VRT surfaces were concurrently acquired and used to construct the SMM that provides lung surface BCs based on input VRT surfaces. These BCs were supplied to the biomechanical model and lung-tumor motion was solved.

### Results and Discussion

Our biomechanical model effectively estimated tumor position during 4D simulation (<3mm centroid error) and RT delivery sessions. For three out of six acquisitions, tumor motion was limited to within the PTV expansion. However, excursions outside of the ITV were observed during three acquisitions (Figure 2 a-b). For one patient (Figure 2 b), a shift in the base line was observed at the end of the fraction with the tumor spending more than 50% of its time outside of the PTV, suggesting the possibility for marginal failure. For another patient (Figure 2 c), the irradiated volume (PTV) overestimated tumor motion range.

**Figure 2:** Tumor centroid motion estimated by the biomechanical model for patients 1-3 (a-c). Shaded green is the internal target volume (ITV) encompassing tumor motion (derived from 4D imaging protocol). Shaded red is the irradiated volume (PTV), generated by further expansion of the ITV.

### Conclusions

Our biomechanical model used lung surface BCs estimated from chest and abdomen surface images to compute tumor motion during RT delivery sessions. Our findings show that the tumor can move outside the irradiated volume. Clinical implementation and application of our model can lead to improvements in RT delivery accuracy and target margin reductions.

## Towards the usage of embedded prosthesis sensors for real-life gait analysis of amputee subjects

Email: sabina.manz@ottobock.de

### Summary

This case study investigated the potential of the sensors embedded into a mechatronic prosthetic knee joint for clinical gait analysis. The results showed a strong correlation ( $\sim 0.99$ ) and small RMSE between the sagittal knee angle ( $\sim 1.5\%$ ) and knee moment ( $\sim 7\%$ ) recorded during over ground level walking using the gold standard (optoelectronic motion capture) and internal device sensor data.

### Introduction

Clinical gait analysis is typically performed in a laboratory environment using optoelectronic motion capture systems and force plates [1]. Due to various limitations of the laboratory assessment (e.g., confined space, constrained pathway), the patient performance is often not representative of real-life gait [1].

To overcome these limitations, researchers have used inertial measurement units (IMUs) to replace optoelectronic motion capture systems and conduct accurate gait analyses in amputee patients outside of a laboratory environment (less than  $1^\circ$  knee angle error) [2]. However, the IMUs are external sensors that have to be placed on the subject and properly aligned to the limb segments. This requires an extra effort and can result in positioning errors that can translate into errors in the recorded movement [3].

Mechatronic lower limb prostheses are equipped with embedded sensors that collect information about orientation, acceleration, angular velocity, joint angles and loads [4]. The validity and potential usage of these sensor data for clinical gait analyses is, however, still unknown. Therefore, there is a need to investigate whether it is possible to accurately measure gait performance using the embedded device sensors, and to compare the performance of these sensors to that of the gold standard of laboratory assessments.

### Methods

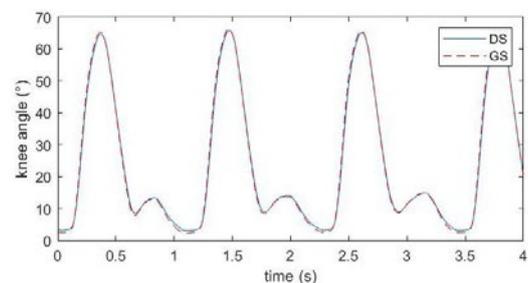

Kinematic and kinetic data were collected from one patient with transfemoral amputation (height: 169 cm, weight: 76 kg, knee joint: GeniumX3) using a gold standard (GS) motion capture system (Vicon, Oxford, UK) and force plates (Kistler, Winterthur, Switzerland). In addition, the device sensors (DS) were used to assess gait performance. The data recorded by the DS included hydraulic loading and knee joint angle. The data were collected during over ground level walking at comfortable walking speed while simultaneously using both systems (DS and GS).

The sagittal knee angle and moment were determined and the obtained profiles were compared between GS and DS using correlation coefficients, root mean square error (RMSE) and maximum error.

### Results and Discussion

The results for a single walking trial are reported in Table 1 and the recorded knee angle profiles are shown in Fig. 1. We found strong correlations between both the knee angle and knee moment acquired by GS and DS ( $\rho \sim 0.99$ ).

Further, the RMSE was below  $1^\circ$  for the knee angle and below 5 Nm for the knee moment (1.5% and 7.2% relative error, respectively). The maximum error was  $3.27^\circ$  and 7.41Nm, respectively. These results demonstrate that the embedded sensors can measure sagittal knee angles with a similar quality as the wearable inertial measurement units [2].

**Figure 1:** The knee angle recorded using device sensors (DS, continuous line) versus gold standard (GS, dashed line).

**Table 1:** Error and correlation between device sensors (DS) and gold standard (GS).

	RMSE	Max. Error	Correlation Coefficient ( $\rho$ )
Knee Angle ( $^\circ$ )	0.95	3.27	0.99
Knee Moment (Nm)	4.26	7.41	0.99

### Conclusions

The preliminary results show the potential of embedded prosthesis sensors to assess knee angle and moments during amputee walking. A limitation is that this analysis only focuses on the affected limb. Additional experiments with other prosthesis sensors and more activities of daily living such as ramp and stair incline and decline, as well as a larger patient sample need to be conducted.

### Summary

The labrum separates the capsular chamber (CC) and the acetabular cavity (AC) of the hip joint. Hip extension and internal rotation bring high intra-capsular pressure within the CC. Therefore, high intra-capsular pressures in the CC are linked with pain. However, no assessment of pressures in the AC has been made and this information might have an impact in clinical assessment. The present study, using cadaveric specimens (n=6), reports variations of intra-capsular pressure in both, the CC and AC during five hip movements. Hip flexion and adduction showed the lowest pressure fluctuations in the CC. Hip extension showed a pressure increased in both compartments. Lastly, hip abduction and internal rotation showed an important depressurization in the AC.

### Introduction

The labrum increases the contact surface of the acetabulum and helps to regulate the fluid exchanges between the AC and the CC [1]. Previous cadaveric studies have reported pressure fluctuations solely in the capsular chamber in different hip positions [2,3]. To date, no information is provided concerning the simultaneous pressure modifications into both, the AC and the CC of the hip joint during hip clinical assessment.

### Methods

The specimens (n=6) were skeletonized from the lumbar spine (L5) to the distal femur and the hip capsular ligaments were carefully preserved. One cluster of reflective markers was placed on each of the following bones: coxal, femoral and tibial bones. CT-scan was performed for each lower limb to link osseous structures and the clusters. Hip kinematics were measured using six Optitrack cameras at 125 Hz. The coxal bones were stabilized in anatomical position on an experimental frame using two external fixators. Two intra-osseous tunnels were drilled to reach both CC and AC avoiding capsular tissue opening. The lateral tunnel was drilled over the greater trochanter with a latero-medial orientation to access the CC, medially to the trochanteric line. The medial tunnel was drilled through the iliac bone to access the AC with a supero-inferior orientation. To measure pressure fluctuations (125Hz), two fibre optic pressure sensors (FISO) were used and inserted in an injection chamber each, which were glued to the entrance of each tunnel. Before pressure measurement, 2.5 ml of mixture (Oil and latex) was injected into each compartment allowing the obstruction small arteries and avoiding leakages. Hip joints were tested in five different positions: 90° of flexion, maximal extension, abduction, adduction and internal rotation in 90° of flexion. Each movement was repeated five times and three trials were performed. Hip kinematics were synchronized with pressure fluctuations. Pressures were measured at the maximal ROM

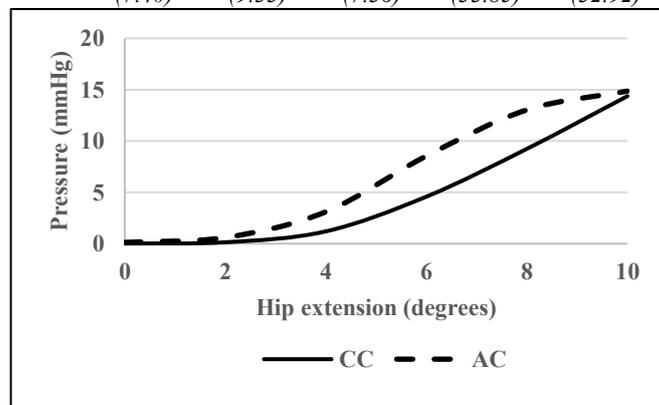

of each movements described previously using Matlab (Version 2019b) (see Table 1).

### Results and discussion

Pressure increased in the CC for all movements. Movements bringing high tension in the capsular ligament seemed to increase pressure in the capsular chamber (EXT, ABD, IR). Movements with lower hip capsular tension show little increase in pressure in the CC (F90, ADD) (p< 0.001). The pressure in the AC increased in two movements and decreased in the others. Flexion, abduction and internal rotation might have a more medio-lateral femoral head motion and create a depressurisation in the AC. The internal rotation showed the greatest difference between both compartments (60.06 mmHg).

**Table 1.** CC and AC mean intra-capsular pressures (SD). F90: 90° flexion, EXT: extension, ADD: adduction, ABD: abduction, IR: internal rotation. All values are in mmHg

	F90	EXT	ADD	ABD	IR
CC	5.93 (10.91)	18.57 (10.96)	3.40 (4.47)	14.71 (10.32)	17.31 (16.66)
AC	-8.58 (7.40)	15.44 (9.33)	7.51 (7.36)	-25.86 (33.85)	-42.75 (32.92)

**Figure 1.** Capsular chamber (CC) and acetabular cavity (AC) pressure fluctuations in hip extension (0-10°).

### Conclusion

This is the first study to provide simultaneous pressures measurements for the CC and AC without altering the capsular tissue. Hip kinematics and optic pressure transducers help to understand the link between hip movements, intra-capsular pressures and compartments. As increased pressure in the CC is linked with pain, these results might have a clinical impact.

## Closing the Kinetic Chain: Weight-bearing versus non-weight bearing maximal force generation and its relation to patient reported outcomes in ACL injured males and females

### Summary

Clinicians often assess knee strength in patients with ACL injuries using open-kinetic chain (OKC) methods in the sagittal plane; yet, knee instability and pain are experienced while weight bearing in closed kinetic conditions (CKC) with multidirectional loading. Furthermore, the relationship or the effect of sex between subjective patient reported outcome measures (PROMs) and functional tasks is unclear. This study sought to determine whether differences exist in OKC vs. CKC force generation tasks, and if peak forces are associated to PROMs in ACL-injured males and females. We identified sex-dependent relationships for both subjective and CKC ground reaction forces (GRFs) measures, but no differences during the OKC task. Using a CKC task during patient assessment may provide additional insight into rehabilitation progression.

### Introduction

Although PROMs are poorly related to postoperative outcomes, they have grown in popularity as they incorporate the patients' perceived function and can be easily administered [1]. It is nevertheless unclear what the relationship is between a patient's perceived and objective functional capacity [2]. Furthermore, despite the sex-bias in ACL injury risk [3], and the fact that over 70% of ACL injuries occur during non-contact CKC events, the influence of sex and ACL injury on knee joint strength during CKC multidirectional loading conditions has yet to be considered. As such, this study sought to i) evaluate differences in PROM scores and objective strength measures during OKC and CKC tasks, and ii) determine if relationships exist between subjective and objective measures of knee function among males and females with and without ACL injuries.

### Methods

Thirty-eight adult patients with ACL injuries (17 females) and 34 (17 females) uninjured controls were recruited for this study and were matched for age and leg-dominance. Participants completed the Knee Injury and Osteoarthritis Outcome Score (KOOS), International Knee Documentation Committee (IKDC), Lysholm, and Tegner questionnaires. While maintaining 50% bodyweight per limb, they then performed a

standing isometric force-generating task [4] while producing maximal anterior, posterior, medial, and lateral GRFs respectively. Participants also completed maximum voluntary isometric knee extension and flexion on an isokinetic dynamometer. The GRFs and torque data were normalised to body mass (N/kg, Nm/kg) and Kruskal-Wallis and post-hoc Mann-Whitney U-tests were used to determine between group differences ( $\alpha = 0.05$ ). Spearman's rho correlation coefficients (rs) were calculated between subjective PROMs and objective outcome measures.

### Results and Discussion

As expected, ACL-injured participants reported lower PROM scores. There were no differences in OKC torque, however, a main ACL injury effect for CKC torque, and subsequent post-hoc analysis identified lower posterior GRF production in ACL-injured females compared to their control counterparts (1.51 N/kg vs. 1.81 N/kg;  $p = 0.048$ ) but not among male participants ( $p = 0.413$ ). Maximum medial CKC GRFs were correlated to both the Lysholm ( $r_s = -0.569$ ;  $p = 0.021$ ) and the Tegner ( $r_s = -0.814$ ,  $p < 0.001$ ) scaling scores for ACL-injured females. No significant differences or correlations were found from the OKC task.

### Conclusions

Our results indicate that (1) males and females with ACL injuries will display different relationships between subjective and objective assessments; (2) CKC measures detected functional deficits in females and (3) CKC evaluations are more closely related to perceived knee joint function in females. We conclude that clinicians should consider how sex affects perceived knee function with their patients and that CKC evaluations provide them additional insight into their functional capacity.

# Biomarkers of Knee Joint Healing Following Anterior Cruciate Ligament Reconstruction: A Systematic Review

Lisa E. Ek Orloff<sup>1</sup>, Michael J. Del Bel<sup>2</sup>, Nicholas J. Romanchuk<sup>3</sup>, Sasha Carsen<sup>4</sup>, Pascal Imbeault<sup>1</sup>, Daniel L. Benoit<sup>1, 2, 3</sup>

Email: [dbenoit@uottawa.ca](mailto:dbenoit@uottawa.ca)

## Summary

Rehabilitation and return to activity (RTA) guidelines following ACL reconstruction (ACLR) is typically guided by post-operative time, patient reported perceived function and functional capacity measures. The purpose of this systematic review was to determine biomarkers which may be used to accurately reflect knee joint healing in patients recovering from ACLR. Using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines, articles that included participants who had undergone ACLR and longitudinally measured biomarkers of knee joint healing were identified. Levels of interleukin-6 (IL-6; reflecting inflammation in the knee) and C-terminal crosslinking telopeptide of type II collagen (CTX-II; reflecting articular cartilage degradation in the knee) were identified as the most prevalent and accurate biomarkers at reflecting knee joint healing. Measuring the levels of these biomarkers during the recovery process in adolescents could lead to rehabilitation and RTA assessment informed by the healing status of the knee.

## Introduction

ACL injuries are increasing in prevalence by 2.3% annually in adolescents [1] and lead to increased risk for early-onset knee osteoarthritis (OA) [2]. Current ACL rehabilitation guidelines do not directly reflect the physiological healing process of the knee joint. Instead, the sole focus is on a patients' perceived function and their ability to meet functional benchmarks in the lower extremities [3]. The physiological healing process could provide prognostic insight for clinicians and physiotherapists when rehabilitating ACL-injured patients. Thus, the purpose of this systematic review was to identify existing literature to determine i) the most prevalent and accurate biomarkers at reflecting knee joint healing in patients after ACLR, and ii) the quantity of these studies which include adolescents.

## Methods

Following PRISMA guidelines, Medline, Embase, SCOPUS and Web of Science databases were searched up until September 2020. Studies were included if they (1) included

participants who had sustained a primary ACL injury and undergone a subsequent ACLR, and (2) measured at least one biomarker of knee joint healing at more than one time point. The NIH quality assessment tool (before-after (pre-post) study with no control group) was used to assess study quality. The following datum were extracted: participant age; biological sample(s); biomarker(s) analyzed.

## Results and Discussion

Seven studies met inclusion criteria for this systematic review (Table 1). IL-6 and CTX-II were the most prevalent biomarkers (3/7 studies). These biomarkers reflected knee joint healing through consistent elevation and/or gradual decrease following ACLR. Six studies evaluated adult populations (age range; Table 1). One study (average age 19.6±4.5) evaluated the effect of age on biomarker levels of knee joint healing and showed a negative correlation between age and CTX-II concentrations ( $r=-.769, p < 0.001$  [6]).

## Conclusions

This systematic review identified (1) only 7 studies which evaluated healing using biomarkers following ACLR, (2) IL-6 and CTX-II were the most commonly used, and (3) there is a significant knowledge gap with respect to evaluating the healing process of the knee in adolescent patients following ACLR. Adolescents are unique from adults due to growth [4] and sex hormone variation [5]. Therefore, biomarker research in adults cannot simply be extrapolated to adolescents. In addition to existing biomechanical rehabilitation tasks (e.g. single-limb hops, limb-strength symmetry indices [3]), we propose that rehabilitation and RTA assessment following ACLR in adolescents could be informed by the healing status of the knee, improving outcomes and reducing their risk of early-onset knee OA.

### Summary

We have developed an open-source workflow to estimate three-dimensional kinematics from inertial measurement unit (IMU) data over long durations (10min). We validated this workflow for common activities, finding minimal drift ( $<1^\circ$ ) and 2-7° (median) RMS difference for all lower extremity joint angles except hip rotation (10-11° median RMS difference).

### Introduction

The ability to track joint kinematics in natural environments over long durations using IMUs has the ability to extend biomechanics and rehabilitation research. An overwhelming number of studies have assessed accuracy over short durations (on the order of one minute) [1]. The majority do not report accuracies over multiple joints or for non-sagittal plane kinematics and lack open-source methods with which to replicate their results [1]. We developed an open-source workflow to estimate three-dimensional joint kinematics from IMUs and validated it for ten-minute trials of both walking and a varied sequence of lower-extremity tasks, including sitting, standing, stair-stepping, side-stepping, walking, and running.

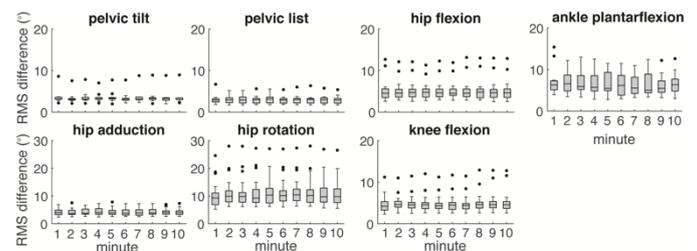

### Methods

We collected both IMU and optical motion capture data for 11 healthy subjects in a laboratory environment, which included significant amounts of electronic equipment and ferro-magnetic materials. Subjects wore eight IMUs (Xsens North America Inc., Culver City, CA) which were affixed to light, plexiglass frames along with a cluster of 4-5 markers, and placed on body segments (sternum, lower back (L5), thighs, shanks, feet). IMU data were streamed at 100 Hz. In addition, 15 reflective markers were placed on anatomical landmarks [2]. Marker positions were measured at 100 Hz using a six-camera motion capture system (Motion Analysis Co., Santa Rosa, CA). Experimental data was collected while each subject completed two trials: (i) ten minutes of walking and turning and (ii) ten minutes of a sequence of lower-extremity movements that included sitting, standing, stair-stepping, side-stepping, walking, and running. We used an open-source complementary filter by Madgwick and colleagues [3] to compute IMU orientations from the IMU sensor data. We used an open-source workflow (OpenSim 4.2 [4]) to compute inverse kinematics from either IMU orientations or optical marker positions, in both cases using a physiological skeletal model [5]. The placement of IMUs on the subject and corresponding skeletal model was determined using an initial pose calibration computed from optical motion capture data, as our main focus was assessing drift. We compared the joint angles computed with IMU orientations to

the joint angles computed from optical motion capture using descriptive statistics including root mean square (RMS) difference. All joint measures were pooled bilaterally.

### Results and Discussion

Our workflow, which used a skeletal model for inverse kinematics and sensor fusion algorithms that incorporated magnetometer data, estimated lower extremity joint kinematics with minimal drift,  $<1^\circ$  over ten minutes. We found RMS differences compared to optical motion capture of 2-7° for sagittal angles and 5-11° for non-sagittal angles over the ten-minute period of walking, which are within the reported variability and uncertainty of motion capture [6]. We saw the same results over the ten-minute sequence of varied lower extremity movements (not shown).

**Figure 1:** Root mean square (RMS) difference between IMU-based and optical-motion-capture-based lower extremity joint kinematics over a 10 minute-period of overground walking.

We discovered that we could monitor drift using the orientation errors from the inverse kinematics solution, which tracked drift when it was present. We also found we could reduce drift by reducing the relative weighting on distal IMUs (most affected by magnetic disturbances) when solving inverse kinematics.

### Conclusions

We share our workflow along with the data, models and software (OpenSense, OpenSim 4.2 [5]) at [simtk.org](http://simtk.org) to allow researchers to reproduce and extend our work. This workflow enables accurate, long-duration measures, bringing the field one step closer to estimating IMU-based kinematics in natural environments.

## Summary

In this study, we evaluated the feasibility of using surface electromyographic (sEMG) recordings of articulatory muscle activity during silent speech for prosodic communication. Surface EMG signals were acquired from the face and neck as 4 speakers with and 4 without vocal impairments silently mouthed a speech corpus of prosodically varying phrases. Resulting signals were processed through a multi-stage architecture to recognize lexical content and categorize differences in phrase-level stress (realized via altered pitch, loudness, and/or duration). Cumulative word recognition and phrasal stress discrimination rates exceeded 90% accuracy across speakers with typical voices and speakers living with vocal impairments. These findings provide a solid foundation for using sEMG signals to recognize lexical and phrase-level prosodic content from silent, mouthed speech.

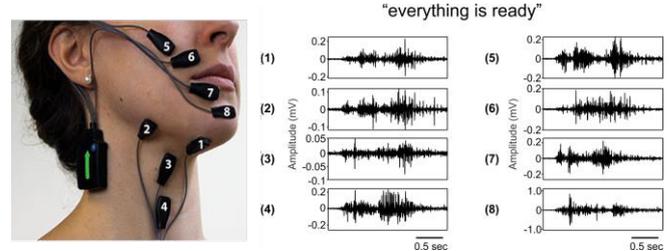

## Introduction

Over 7.5 million people worldwide are unable to vocalize effectively [1]. Among these individuals are cancer survivors who underwent oropharyngeal/laryngeal surgery and must rely on augmentative and alternative communication (AAC) systems such as text-to-speech applications or artificial voice prostheses as substitutes for their natural voices. Yet most of these devices struggle to convey the expressive attributes of prosody, leading to lexical ambiguities and a lack of emotional content [2]. To address this need, we explored the use of sEMG to extract patterns for lexical and prosodic modulation from articulatory musculature during silent, mouthed speech.

## Methods

Our existing algorithms for detecting words from silent speech [3,4] were expanded to recognize lexical content produced with specific prosodic contrasts. The algorithms—which recognize lexical content from articulatory sEMG signals via a hidden Markov model leveraging sEMG-derived Mel-frequency cepstral coefficients (MFCCs)—were augmented to detect prosodic patterns in silent speech by introducing two new processing stages: 1) speaker adaptive training via feature-space maximum likelihood linear regression for phoneme recognition in the presence of prosodic variations, and 2) a multilayer perceptron neural network to classify differences in phrasal stress (first word, last word, no stress) using sEMG features extracted from articulatory muscle patterns captured during silent speech. Our silent speech recognition models were then evaluated on sEMG signals recorded from the face and neck (**Figure 1**) as speakers with (N=4) and without (N=4) laryngectomy silently mouthed a speech corpus comprising 750 phrases

(650 phrases without stress and 100 phrases with first-word or last-word stress).

**Figure 1.** Trigno™ Quattro sensors are shown at 8 locations on the neck and face with examples of corresponding sEMG signals for the phrase “everything is ready.”

## Results and Discussion

Mean word recognition rates ( $96.3 \pm 3.1\%$ ) were comparable between speakers with (95.8%) and without (96.8%) laryngectomy (**Table 1**). Mean accuracy in predicting phrase-level stress ( $91.2 \pm 4.5\%$ ) was also similar between speakers with (89.6%) and without (92.9%) laryngectomy (**Table 1**).

**Table 1.** Word recognition (WR) and phrasal stress discrimination (PSD) rates in speakers with (L) and without (C) laryngectomy.

ID	C1	C2	C3	C4	L1	L2	L3	L4
WR (%)	95.4	96.4	96.3	99.2	96.2	89.5	99.0	98.6
PSD (%)	99.0	86.7	90.0	95.7	86.8	88.0	90.0	93.4

Our results demonstrate a first-of-its-kind wearable system that accurately (>90%) recognizes lexical and prosodic content across speakers with typical voices and speakers living with vocal impairments.

## Conclusions

This work highlights the feasibility of sEMG-based speech recognition to capture prosodic attributes of silent speech in combination with robust lexical content detection. This study is an impactful first step toward the development of a body-worn AAC system for use by individuals with vocal impairments to restore personalized and prosodic speech capabilities for communication.

<sup>1</sup>Department of Rehabilitation and Prevention Engineering, Institute of Applied Medical Engineering – Helmholtz Institute, RWTH Aachen University, Aachen, Germany.

Email: romero@ame.rwth-aachen.de

### Summary

sEMG technologies that enable the monitoring of muscle activation in clinical and out-patient settings are highly relevant for continuous, remote monitoring of patients. These technologies must be easy to use while providing high quality sEMG signals. The aim of this work is to develop an algorithm for the identification of relevant sEMG channels from an autonomously usable 16-channel sEMG sensor system (sEMG SS). The algorithm is based on a hierarchical approach, where channels are identified based on the highest RMS values. Testing of the algorithm was done during flexion and extension of the elbow and wrist to identify the flexor and extensor muscle group of the forearm and the brachioradialis muscle. Results showed the algorithm to be 92.5% effective in identifying these muscle groups. This algorithm in conjunction with the sEMG SS can particularly enhance and promote the autonomous use of rehabilitation devices and systems by patients with motor impairments.

### Introduction

In rehabilitation, the use of wearable devices that record the muscle activation of patients with motor disorders during both therapy and the activities of daily living is extremely important for assessing the efficacy of therapy and patients' progress [1,2]. An autonomously usable sEMG SS has been recently introduced that has proven its effectiveness in obtaining high quality signals while being easy to use and size-adaptive [1]. This armband-shaped system consists of 16 sEMG channels distributed among 8 modules. So far, the device has been used to identify an sEMG channel in which the muscular activation of a specific muscle is recorded. The aim of this work is to develop an algorithm, which will enable the identification of 3 movement specific sEMG channels from the 16 of the sEMG SS.

### Methods

Following a hierarchical approach, an algorithm was developed to identify 3 channels of interest in the sEMG SS, based on the highest RMS values in 80 ms windows [1]. The first relevant channel identified, corresponded to the muscle that could cause crosstalk in the sEMG signals of neighboring muscles. This channel is defined using an initial movement. Once this channel was identified along with adjacent channels in its module, they were removed from the algorithm to ensure a correct recognition of the other two predominantly active muscles, through a second movement.

To demonstrate the validity of the algorithm, two movements were performed: flexion and extension of the elbow and wrist. Thus, a group of forearm muscles (brachioradialis, flexor and extensor) were identified, where the risk of crosstalk was high.

During the measurements, the sEMG SS was autonomously positioned around the forearm, on the line connecting the axis through the wrist and the fossa cubiti, at a location 1/3 from the fossa cubiti. A series of 8 repetitions of elbow flexion (110°) and extension (0°) was then performed, followed by 8 repetitions of wrist flexion (40°) and extension (70°). These repetitions were performed with an external load of 1.5 kg while the subject was seated with the arms hanging at the side of the body. Then, the subject removed the sEMG SS. The procedure was repeated 40 times at a self-selected movement speed. As a result, 40 different positions of the device and 320 movement repetitions (8 repetitions x 40 positions) were achieved.

### Results and Discussion

The algorithm misidentified the brachioradialis muscle in only two of the forty trials. Incorrect identification of either the flexor or extensor muscle groups occurred in only 1 trial. In addition, the algorithm mistook the flexor muscle group for the extensor muscle group in four of the forty trials. This represents 92.5% effectiveness for the algorithm.

Due to the muscle organization in the forearm, identification of these groups is particularly challenging. These results show that the design of the sEMG SS is effective in identifying the 3 selected muscles using 2 simple movements. The algorithm first identified, through the flexion and extension of the elbow, the sEMG channel corresponding to the brachioradialis muscle, as well as its adjacent channels. Thus, the risk of crosstalk was decreased when identifying the flexor and extensor muscle groups of the forearm. Additionally, the performance of an active wrist extension contributed to the differentiation between the two muscle groups.

### Conclusions

The algorithm described has proven to be effective in identifying 3 movement specific sEMG channels from a multichannel sEMG SS through basic movements and without exact positioning around the limb. This bodes particularly well for the future usability of the sEMG SS, for monitoring and assessing patients with motor impairments.

## From Feasible to Practical: Progress in the Development & Validation of Wearables for Accurately Monitoring Tibial Bone Forces in the Real-World

Laura J. Judson, Cameron A. Nurse, Anna E. Wolfe, Emily S. Matijevich, Lauren M. Grohowski, Peter Volgyesi, Karl E. Zelik  
 School of Engineering, Vanderbilt University, Nashville, Tennessee, United States  
 Email: laura.judson@vanderbilt.edu

### Summary

The objective of this study is to characterize how accurately a multi-sensor wearable system can estimate tibial bone force during running. The system is comprised of one inertial measurement unit (IMU) on the foot/shoe, pressure-sensing insoles, and associated machine learning algorithms [1]. We previously showed the feasibility, accuracy, and benefits of this system using lab-based instrumentation and idealized (i.e., simulated) wearable sensor signals. Here, we seek to evaluate the use of real wearable sensors, and benchmark how bone force accuracy compares with estimates from idealized signals. Initial results are encouraging, with real wearable sensors demonstrating only slightly decreased accuracy ( $r = 0.92$ ; correlation with lab-based estimates of tibial force) compared with idealized wearable sensors ( $r = 0.95$ ). This combination of wearable sensors and algorithms continues to look promising as a practical solution for accurately monitoring tibial bone force in the real-world.

### Introduction

Tibial bone stress injuries are amongst the most frequent injuries experienced by runners and are believed to result from the accumulation of microdamage due to repetitive tissue loading [1]. Developing a practical and accurate tool for monitoring tibial bone force outside of a laboratory setting could help us to understand, manage, and reduce overuse injury risks to the tibia. However, existing commercial tools are inadequate for monitoring tibial bone forces because ground reaction force (GRF) metrics (e.g., vertical average loading rate, impact peak) and IMU-based metrics (e.g., tibial shock) are not well correlated with tibial bone force during running and cannot be assumed to indicate loading on this bone or other tissues inside the body [2].

Tibial bone force can be estimated accurately using idealized wearable sensor signals [3], demonstrating the exciting potential of wearables to aid in understanding and mitigating overuse injury risks. However, these idealized signals were derived from lab-based data, and do not reflect the reduced measurement accuracy of real wearable sensors. Here we aimed to evaluate the accuracy of real wearable sensors for estimating tibial bone force when using sensor subsets and algorithms similar to those previously validated with idealized sensor signals [3]. This abstract provides preliminary results from four participants. At the conference, a dataset of approximately ten participants will be presented.

### Methods

Four recreational runners (2 males, 2 females; age 21-26 years, stature  $1.8 \pm 0.05$  m, mass  $71 \pm 11$  kg) completed a series of running trials at different speeds (2.7, 3, 3.3 m/s),

slopes ( $0^\circ$ ,  $3^\circ$ ,  $6^\circ$ ,  $-3^\circ$ ,  $-6^\circ$ ), and stride patterns. Lab-based gold standard measures were collected using a force-instrumented treadmill (Bertec) and motion capture cameras (Vicon). Simultaneously, lower-body kinematics and in-shoe pressure data were collected using real wearable sensors: XSENS IMUs and Novel Pedar insoles. Peak tibial force each step was computed using (i) lab instrumentation (*target metric*), (ii) idealized wearable sensor signals distilled from lab-based kinematic and GRF signals (*idealized wearable estimate*), and (iii) real wearable sensor signals from portable pressure insoles and one IMU on the foot (*real wearable estimate*). Wearable estimates of tibial force were based on machine learning algorithms and training methods similar to [3]. Correlations between each wearable estimate and the target tibial force metric were then computed and compared.

### Results and Discussion

Idealized and real wearable sensor estimates were strongly correlated with lab-based estimates of tibial bone force across running conditions (Table 1). The average correlation coefficient decreased from  $r = 0.95$  with idealized wearable sensors to  $r = 0.92$  with real wearable sensors.

**Table 1:** Correlation coefficients ( $r$ ) between lab-based target tibial bone force and (i) idealized wearable estimates, and (ii) real wearable estimates, for first four participants.

Participant	Idealized Wearable	Real Wearable
1 (M)	0.99	0.93
2 (M)	0.98	0.95
3 (F)	0.97	0.93
4 (F)	0.91	0.77
<b>Mean <math>\pm</math> SD</b>	<b>0.95 <math>\pm</math> 0.03</b>	<b>0.92 <math>\pm</math> 0.08</b>

### Conclusions

Preliminary results show promising potential for combining pressure insoles, a foot/shoe IMU, and machine learning to accurately monitor tibial forces during running, which could unleash various new opportunities to enhance scientific understanding, clinical care, and physical performance.

### Summary

Trunk posture and movement are reported to influence performance in wheelchair sports. However, an ambulatory system to measure on-site changes in trunk inclination is not yet available. Recently, a new inertial measurement unit (IMU)-based approach was proposed to improve the existing Madgwick filter using machine learning, such that body segment orientations can be determined more accurately in IMU challenging sports situations. This approach was applied to measure trunk motion during on-site wheelchair propulsion and the validity of these measures was determined. Twelve participants performed a series of wheelchair sport-specific tests with IMUs attached to their wheelchair and trunk, while simultaneously being measured with an optical motion analysis system to serve as gold standard. Results showed a mean absolute error of less than 5 degrees between IMU-based trunk inclination and a gold standard. With the application of an improved filter approach, IMUs can be validly used to assess instantaneous trunk inclination.

### Introduction

The interaction between athlete and wheelchair is crucial in all wheelchair sports disciplines. More specifically, trunk posture and movement are reported to have an effect on performance in wheelchair sports. However, an ambulatory system to measure changes in trunk inclination in the field is not yet available. IMU-based systems seem to be suitable to measure changes in trunk inclination in daily wheelchair sport practice. To determine orientation from raw IMU signals, the data can be fused together using an Attitude Heading Reference system (AHRS). One commonly used and robust AHRS is the Madgwick filter, which was used in this study.

Although this filter has previously provided accurate orientation estimates, a problem with the use of IMUs to determine body segment orientation in sports, is that the filter assumes that the accelerometer only measures gravity and that the magnetometer only measures the magnetic north. As these assumptions do not hold for sports activities that are characterized by linear accelerations (e.g., every push in speed-skating or wheelchair propulsion) or by the presence of magnetic sources (e.g., because of a bike or a wheelchair), the estimated orientation shows errors that increase over time. For wheelchair sports, this is no different. An approach that improves the existing Madgwick filter, such that more

accurate body segment orientation estimates can be obtained during such sports activities has been proposed.

The aim of this study was to investigate whether this improved approach can be used to accurately measure IMU-based trunk inclination during wheelchair propulsion.

### Methods

Twelve differently skilled participants performed a series of wheelchair sport-specific tests with IMUs attached to their wheelchair (frame) and trunk (sternum), while simultaneously being measured with an optical motion analysis system to serve as gold standard. Using these data, a machine learning model was trained and, accordingly, implemented to improve the existing Madgwick filter. To assess the validity of the 'improved' Madgwick filter approach, trunk inclination was calculated using the gold standard and using the IMU signals which were processed using this approach. In addition, the trunk inclination estimated using the proposed approach was compared with that of the 'regular' approach in which the Madgwick filter is applied.

### Results and Discussion

Results show root-mean-square errors of less than 6 degrees and a mean absolute error of less than 5 degrees when IMU-based trunk inclination was compared with the gold standard. When performance of the regular Madgwick approach was compared with the performance of the improved Madgwick approach as proposed in the current study, a decrease of 2 degrees root-mean-square error was found.

### Conclusions

In conclusion, the improved approach to apply the Madgwick filter provides accurate instantaneous trunk inclination estimates during wheelchair propulsion using IMU data. IMUs can thus be validly used to assess trunk inclination during wheelchair sports activities in the field.

## Summary

Choosing which tests to include when designing a physical testing battery to monitor rehabilitation status following anterior cruciate ligament reconstruction (ACLR) is important for clinicians. The aim of the study was to examine the correspondence between movement strategies when the same task was performed bilaterally and unilaterally, and when two different unilateral tasks were performed. Participants performed a bilateral drop jump, a unilateral drop jump, and a 90° pre-planned cut. For each task, the proportion of work done at the ankle, knee and hip was calculated and compared between tasks. The joint contributing the highest amount of work done was also used to determine the dominant movement strategy for that task (e.g. ankle-, knee-, hip-dominant movement strategy). A significant, strong, positive relationship for proportion of work done was observed between the bilateral and unilateral drop jump, whereas a weak relationship was found for proportion of work done at each joint between the unilateral drop jump and the cut. The similarity between unilateral and bilateral drop jumps suggest that clinicians may only need to test one of the drop jumps and cut in future testing protocols.

## Introduction

A dilemma for clinicians designing a physical testing battery for post-ACLR patients returning to sport is choosing which tests to include. Primarily, bilateral tasks have been used to monitor recovery, but ACL injury mechanisms are more commonly associated with unilateral landing and cutting tasks [1]. Consequently, these movements are becoming increasingly used in clinical testing batteries. The distribution of mechanical work between the ankle, knee and hip can be used to characterise athlete movement strategy for jumping, landing and cutting. Task redundancy can be identified by comparing movement strategies across both bilateral and unilateral tasks, facilitating the design of optimised physical testing batteries. The aim of the study was to examine movement strategies when the same task was performed bilaterally and unilaterally and when two different unilateral tasks were performed.

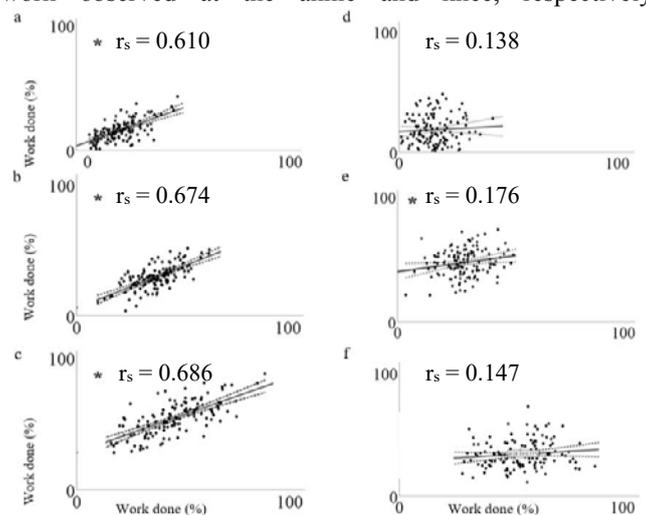

## Methods

127 male, multidirectional field sport athletes aged 18 - 35 years who had undergone ACLR approximately 9 months prior to testing participated in the study (height:  $1.81 \pm 0.06$  m; mass:  $82.7 \pm 9.3$  kg). Participants visited the laboratory once, completing three movement tasks as part of a clinical testing battery: a bilateral drop jump, a unilateral drop jump and a 90° pre-planned cut. Non-invasive reflective markers were placed on the skin and shoes based on the Plug-in-Gait lower limb marker set. Only data collected from the reconstructed leg during the braking phase, defined as the time between initial contact and lowest vertical centre of

mass displacement, was used for analysis. The relative contribution of the ankle, knee and hip work to total lower extremity joint work in the sagittal plane was calculated. Spearman's correlation ( $p \leq 0.05$ ) was used to determine the strength of the relationship between the proportions of work done at the ankle, knee and hip for the bilateral and unilateral drop jump and the unilateral drop jump and the cut.

## Results and Discussion

A significant, strong, positive relationship was observed for proportions of work done at the ankle, knee and hip joints between the bilateral and unilateral drop jump, whereas a very weak relationship was found for proportion of work done at the ankle, knee and hip joints between the unilateral drop jump and the cut (Figure 1). Both drop jumps employed an ankle dominant strategy, whilst the cut utilised a knee dominant strategy, as indexed by the highest proportion of work observed at the ankle and knee, respectively.

**Figure 1.** Correlation of proportion of work done between the unilateral and bilateral drop jump at the (a)hip, (b)knee, and (c)ankle, and between the cut and the unilateral drop jump at the (d)hip, (e)knee, and (f) ankle. \*  $p \leq 0.05$ .

## Conclusions

Movement strategies were similar (transferrable) between the same task performed bilaterally and unilaterally, but not across unilateral tasks. Thus, to assess movement strategies after ACLR, clinicians could consider omitting one of the drop jumps from assessment batteries but should include the 90° pre-planned cut.

## Summary

The effect of 8-weeks of functional resistance training (FRT) on sagittal plane knee biomechanics was tested in individuals with recent anterior cruciate ligament (ACL) reconstruction. The changes in knee flexion moment symmetry were greater in individuals who underwent FRT with resistance bands than those who underwent FRT with a custom-designed brace or a target-match control condition.

## Introduction

Persistent muscle weakness is pervasive after ACL reconstruction [1] and contributes to ongoing gait asymmetries [2] and the possible development of post-traumatic osteoarthritis [3]. FRT, or progressive low-load resistance training performed during walking, may be a safe and effective way early after ACL reconstruction to target gait deficiencies because it allows for task-specific muscle strengthening during gait. The purpose of this project, therefore, was to determine if FRT improves knee mechanics following ACL reconstruction.

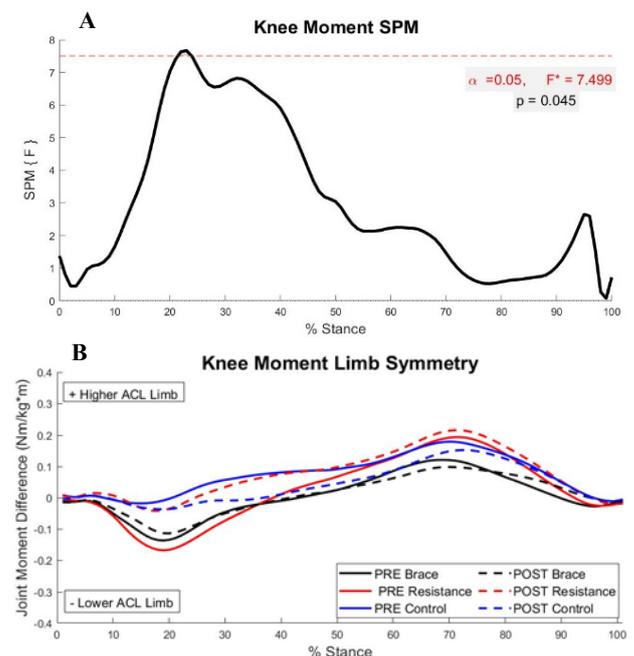

## Methods

Thirty individuals (9.5±2.9 weeks post-surgery) were assigned to one of three groups: 1) FRT with a custom brace designed to provide resistance primarily to the hamstring muscles, 2) FRT with custom resistance band device designed to provide resistance primarily to the quadriceps muscles, or 3) a target-match control group, where they received real-time kinematic feedback with no FRT during walking. All participants completed a 30-minute training session, 2-3 times a week for eight weeks [4]. Three-dimensional motion capture was used to assess knee biomechanics during overground walking at a self-selected speed before and after the first and last training session, respectively. Bilateral sagittal plane knee angles and internal knee moments were calculated. A change score for each variable was calculated as the time difference (post-training–pre-training) of the limb symmetry scores (ACL–uninjured). Statistical Parametric Mapping (SPM) was used to assess group differences in the swing and stance phase independently. Tukey's post-hoc tests were used to identify differences when group main effects were significant. Significance was set a priori at  $p < 0.05$ .

## Results and Discussion

Ten individuals in the brace group (Age=18.7±6.2yrs; Mass=70.1±10.5kgs), eight individuals in the resistance band group (Age=23.1±4.3yrs; Mass=70.3±12.6kgs), and nine individuals in the control group (Age=20.4±5.6yrs; Mass=69.5±14.0kgs) completed this study. The changes in

flexion moment symmetry were different between groups from ~21 to 24% of the stance phase ( $p=0.045$ ). The resistance band group had significantly greater improvements in stance phase flexion moment symmetry than the brace group ( $p=0.043$ ) and the control group ( $p=0.003$ ). No differences were found for stance or swing phase knee flexion angle, or swing phase knee flexion moments.

**Figure 1:** A: SPM Analysis in which the red dashed line indicates the critical threshold, when crossed data in that window is deemed significant. B: Limb symmetry values for before (Pre) and after (Post) intervention for the knee moment.

## Conclusions

FRT targeting the quadriceps muscles may provide benefits to improve knee moment symmetry following ACL reconstruction. An improvement in gait symmetry after ACL reconstruction may help promote long-term knee joint health.

# A Hierarchical Clustering Approach for Examining Potential Risk Factors for Bone Stress Injury in Runners

Jack A. Martin<sup>1</sup>, Mikel R. Stiffler-Joachim<sup>1</sup>, Christa M. Wille<sup>1</sup>, Bryan C. Heiderscheit<sup>1</sup>

<sup>1</sup>Badger Athletic Performance, Dept. of Orthopedics & Rehabilitation, University of Wisconsin-Madison, USA

Email: [jmartin8@wisc.edu](mailto:jmartin8@wisc.edu)

## Summary

A hierarchical clustering approach was used to group runners based on kinematics and kinetics. Bone stress injury incidence was the highest in a group that tended towards a forefoot strike pattern with short stance phase and high peak forces.

## Introduction

Machine learning techniques may be able to provide new insights into risk factors for running-related injury. Hierarchical clustering is an unsupervised learning approach that can group runners based on shared characteristics [1]. Injury incidence can then be studied in these groups to gain insight about potential risk factors for injury. The purpose of this study was to determine whether a hierarchical clustering approach can divide runners into meaningfully distinct groups based on kinematics and kinetics by examining: 1) whether any groups of runners have higher bone stress injury (BSI) incidence, and 2) whether groups of runners show differences in biomechanical metrics potentially relating to BSI risk.

## Methods

Preseason running (4.47 m/s) gait mechanics data from 68 collegiate cross country runners (42F) were analyzed. At the time of testing, athletes were cleared for full participation, had no lower extremity injury in the prior 3 months, and had no history of lower extremity surgery. Standard inverse kinematics and dynamics approaches were applied to marker trajectories and ground reaction forces (GRF).

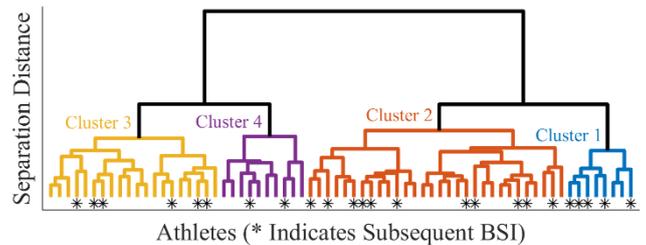

Joint kinematics (hip adduction and flexion, knee flexion, ankle dorsiflexion), kinetics (hip flexion, knee flexion, ankle dorsiflexion moments) and GRF (vertical, anteroposterior, mediolateral), were averaged across strides. Kinetics and GRF were normalized to body mass for each athlete. Data from each variable were normalized to the maximum and minimum value observed across all athletes, and data from all variables were collated into a single vector for each athlete.

Principal component (PC) analysis was used to reduce the dimensionality of the data. Hierarchical clustering was performed to divide athletes into groups exhibiting similar kinematics and kinetics based on their PC coefficients. A hierarchical cluster tree was created based on Euclidean distances between datapoints for each athlete using the Ward

algorithm, and distinct clusters of athletes were identified. Subsequent BSI incidence, confirmed by medical imaging, and biomechanical variables of interest were examined across these clusters.

## Results and Discussion

Clustering identified 4 distinct groups of runners (Figure 1).

**Figure 1:** Hierarchical cluster tree based on running kinematics and kinetics. Endpoints along the x-axis represent individual athletes.

BSI incidence was highest in cluster 1 and decreased through cluster 4 (Table 1). Runners in cluster 1 tended towards shorter stance duration, greater peak vertical GRF and ankle plantarflexion moment, lesser peak knee flexion, and a forefoot strike pattern. Each of these showed a monotonic trend with BSI incidence. Of note, sex was disproportionately divided between clusters; however, similar trends held when only female athletes were included.

## Conclusions

Hierarchical clustering can split runners into meaningfully distinct groups based on kinematics and kinetics. In this case, groups showed differences in BSI incidence and in several biomechanical variables potentially relating to BSI risk. This approach could yield insights into how and why injury risk may differ across different types of runners.

### Summary

In efforts to predict post-traumatic osteoarthritis (PTOA) progression, contemporary mechanobiological models implement cytokine diffusion-mediated inflammation. However, they lack an important biomechanical factor, the advection of cytokines along with the flow of interstitial fluid during physiological loading. Here, we refine the models predicting the PTOA progression by introducing combined diffusion and advection of cytokines in mechanically injured cartilage. Our theoretical model could be used for identifying lesions prone to accelerated inflammation-regulated cartilage degradation involved in PTOA.

### Introduction

Traumatic knee injuries may cause chondral lesions and release of pro-inflammatory cytokines such as interleukin (IL)-1, which infiltrate the articular cartilage via the synovial fluid [1]. The latter occurs through diffusion and advection. Both solute transfer mechanisms have been previously studied in cartilage [2,3], but never in a mechanically injured fibril-reinforced porohyperelastic swelling (FRPHES) material. Here, we implement IL-1 diffusion and advection mechanisms within such material. We aim to estimate the combined effect of both mechanisms on the transport of pro-inflammatory cytokines into the cartilage tissue.

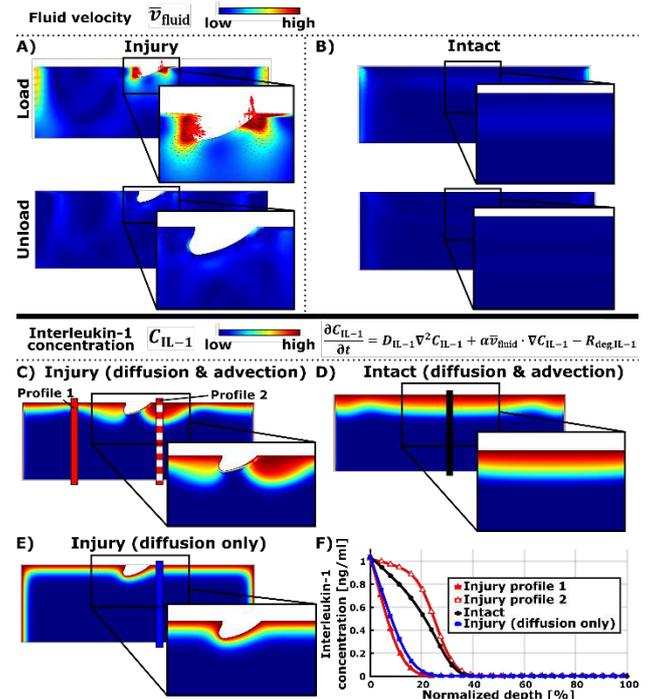

### Methods

Our model is based on a previous experimental study including injurious and dynamic loading and culturing of bovine cartilage in exogenous IL-1 (1 ng/ml) [4]. This dynamical loading mimicking physiological loading was simulated in injured and intact cartilage models using a FRPHES material, incorporating depth-dependent structural and compositional properties [5]. The obtained time-dependent fluid velocity fields were imported into a previous diffusion-driven model [6] and interpolated to each simulation time point. Next, the cytokine diffusion–reaction equations were supplemented with an advection term where the scaling coefficient (Fig. 1,  $\alpha < 1$ ) was inversely proportional to local glycosaminoglycan content and solute molecular weight [2,3]. For comparison, an injury model without advection was created.

### Results and Discussion

Fluid velocities were higher near the lesion than in intact areas (Fig. 1AB). Advection increased IL-1 uptake locally compared to free diffusion (Fig. 1CEF) as suggested previously [2,3]. Our model predicted unevenly concentrated levels of IL-1 near the lesion and those were higher compared to the intact model predictions (Fig. 1CDF). These results

indicate that dynamic loading could locally increase concentrations of inflammatory mediators in injured tissue. If early cytokine infiltration is not mitigated pharmaceutically, elevated shear strains [5] might later degrade cartilage synergistically with inflammation [4].

**Figure 1:** Fluid velocities during a single load/unload depth cycle in A) the injury and B) the intact model. Interleukin-1 infiltration due to diffusion and advection in C) the injury and D) the intact model. E) The cytokine concentrations in the injury model when advection was disabled. F) Depth-wise cytokine concentration profiles show a marked increase of cytokines near the side of the lesion, but not away from it, after simulated dynamic loading.

### Conclusions

Uneven, rapid, and concentrated spread of pro-inflammatory cytokines near lesions could locally disturb the cartilage homeostasis. The adverse effects of advection-regulated cytokine infiltration should be blocked early *e.g.* with interleukin receptor antagonists to decelerate PTOA progression during prolonged dynamic loading.

## A Prospective Study Linking Changes in Dynamic Center of Mass Motion With Lower-Limb Overuse Injuries Using a Single Trunk-Mounted Accelerometer

Gerard Aristizábal Pla<sup>1,2</sup>, Enzo Hollville<sup>2</sup>, Stijn Bogaerts<sup>3</sup>, Kurt H. Schütte<sup>2</sup>, Sam Van Rossom<sup>2</sup>, Benedicte Vanwanseele<sup>2</sup>

<sup>3</sup> Department of Physical and Rehabilitation Medicine, University Hospitals Leuven, Leuven, Belgium

Email: garistizabal@umass.edu

### Summary

The purpose of the current study was to investigate how accelerometry based-features changed in response to fatigue and their possible link with developing lower-leg overuse injuries (LLOIs). Our initial hypotheses were that: (i) fatigue would induce dynamic stability changes mainly occurring in the horizontal plane; and (ii) subjects who sustained an injury during a follow-up period of 6 months exhibited an increase in dynamic loading during a fatiguing protocol compared to subjects who did not sustain a LLOI. The findings of this study support our first hypothesis and partially the second one. With the accumulation of running fatigue, increased impact accelerations in the horizontal plane were detected for participants that would get injured during the 6 months follow-up that are different from the uninjured group.

### Introduction

Fatigue protocols have been used to detect movement compensations [1] or changes in movement dynamics which can possibly be linked with a higher risk of overuse injury [2]. Wearable accelerometers can successfully identify movement deviations caused by running fatigue in indoor [3] and outdoor running conditions [4]. However, no prospective studies have ever attempted to link accelerometry-based measures of dynamic stability and dynamic loading to the development of running related injuries. We therefore investigated how these features changed in response to fatigue and their possible link with developing LLOIs.

### Methods

One hundred and eighty-one participants aged 17-23 years completed the Cooper test. The following accelerometry based-measures of dynamic stability from all acceleration directions (Vertical, VT, Mediolateral, ML and Anteroposterior, AP) were extracted for consecutive ten percent of the Cooper test: the tri-axial ratio of acceleration root mean square normalized with the resultant vector RMS of all acceleration directions, step and stride regularity, and sample entropy. Dynamic loading measures, impact acceleration for all acceleration directions, and spatiotemporal measures, contact time and step frequency, were also extracted for consecutive ten percent of the Cooper test.

Participants then followed the same academic sports program at a common sport facility during 26 weeks per academic year and reported all LLOIs sustained during that period.

### Results and Discussion

With the accumulation of running fatigue, increased impact accelerations in the horizontal plane were detected for

participants that would get injured during the 6 months follow-up that are different from the uninjured group (Figure 1).

The current study demonstrated that including a running fatiguing protocol has the potential to identify runners at risk for sustaining a lower-leg overuse injury. In addition, these findings build on limited available evidence linking an increased dynamic loading with the presence of LLOIs [5][6], as these changes in movement dynamics not only occur after but also prior onset of LLOI.

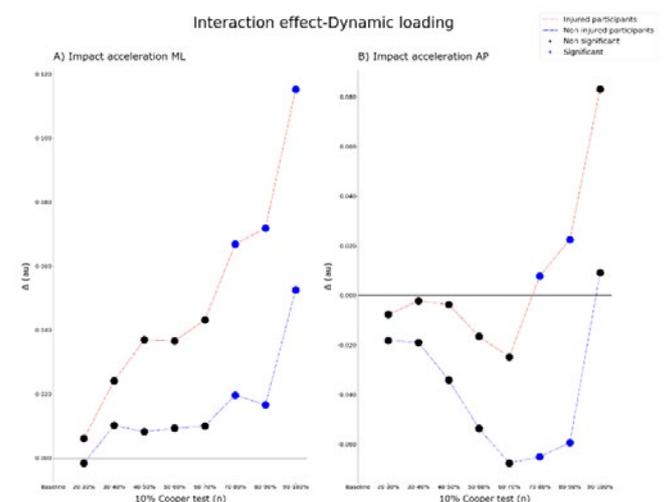

Figure 1: Significant interaction effects.

We also found that the fatigue accumulated with running had a significant effect in several dynamic stability, loading and spatiotemporal measures. Our findings are in line with previous investigations using similar trunk mounted accelerometer and accelerometer-based features [3] [4].

### Conclusions

Our findings indicate that a single trunk-mounted accelerometer can detect changes in CoM motion that are exacerbated by running fatigue and linked to LLOIs.

# Effect of seat configuration on joint power distribution and performance in an elite Paralympic rower: a case study

Jørgen Danielsen<sup>1</sup>, Gertjan Ettema<sup>1</sup>, Anna C. Severin<sup>1</sup>

<sup>1</sup>Center for Elite Sports Research, Department of Neuromedicine and Movement Science, Norwegian University of Science and Technology, Trondheim, Norway

Email: [jorgen.danielsen@ntnu.no](mailto:jorgen.danielsen@ntnu.no)

## Summary

We examined if altered seat configurations affected the contribution of power generated by the elbow, shoulder, and trunk in a world-class Paralympic PR1 rower during submaximal and maximal ergometer rowing. We found that configurations with a reclined back rest increased the total power generated during the maximal effort and increased the relative contribution from the trunk while decreasing relative shoulder contribution.

## Introduction

Paralympic PR1 rowers have no leg function and minimal/no trunk function [1]. Because of the impairments, these rowers may benefit from individualized equipment for optimal technique and performance [2]. We recently reported that employing a seat configuration with a reclined backrest (Figure 1) increased performance and efficiency in a world-class PR1 Paralympic rower [3]. The adjusted seat resulted in higher peak force, longer stroke length, and lower stroke frequency compared to her usual configuration. These effects were mainly attributed to the increased trunk range of motion. In this study, we expanded on the previous analysis [3] and examined if the adjusted seats affected the distribution of power generation about the elbow, shoulder and trunk in the world-class female PR1 rower.

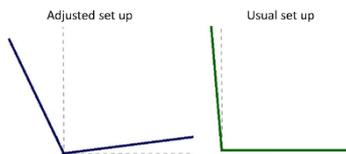

Figure 2 The tested set configurations (backrest/seat): Adjusted (A): 25°/5°, usual (B): 5°/0°.

## Methods

The athlete performed one 4-min submaximal (ergometer power output ( $P_{erg}$ ): 100 W) and one 4-min all-out (maximize average  $P_{erg}$ ) bout of ergometer rowing (modified Concept2) in both configurations (Figure 1). Handle force (200 Hz) and kinematics (100 Hz) were collected, and inverse dynamics were used to compute elbow ( $P_{elb}$ ), shoulder ( $P_{sho}$ ), and trunk ( $P_{trunk}$ ) power output and the relative contribution to  $P_{erg}$ . Work done during drive ( $W_{drive}$ ) was calculated by time integration of instantaneous power.

## Results and Discussion

Employing the adjusted configuration during submaximal rowing doubled  $W_{erg\ drive}$  while stroke rate was halved compared to her usual set up (Table 1). Further, the increased trunk range of motion previously reported [3] coincided with an increase in  $P_{trunk}$  and a decrease in  $P_{sho}$  in the adjusted compared to the usual set up.

During maximal rowing, the athlete was able to increase  $P_{erg}$  by 43% in the adjusted setup compared to the usual setup. As in submaximal rowing, this was mainly due to an increase in  $P_{trunk}$  and  $W_{trunk\ drive}$ . Both during submaximal and maximal rowing, the more work performed during drive was mainly due to higher handle force (and moments) that were generated over a longer time as stroke length was longer (peak angular velocities during drive being quite similar between conditions, Fig. 2). Relative power contributions remained largely unaffected by intensity.

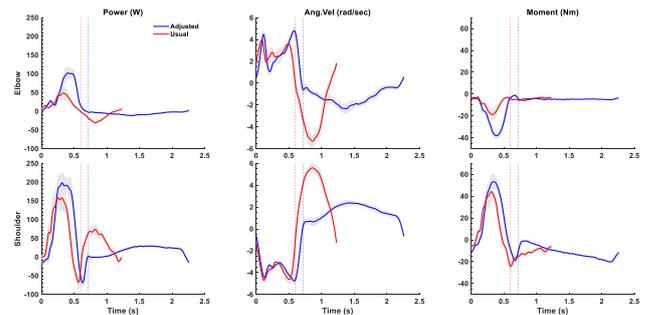

Figure 1. Power, angular velocity and moment about the shoulder and elbow during the submaximal bout of ergometer rowing in the two seat configurations. Vertical lines indicate end of drive phase.

## Conclusions

The increased trunk range of motion permitted by the reclined backrest in the adjusted seat allowed for more work per stroke to be performed, with a considerable increase in trunk power generation, both during submaximal and maximal ergometer rowing in a world-class PR1 Paralympic rower.

Email: johanna.rosen@gih.se

## Summary

In para-kayak, athletes with unilateral above knee amputation (AK) and below knee amputation (BK) compete in the same class which is questionable since the legs are important for paddling performance. The purpose was therefore to examine differences in kinematic and kinetic performance variables between AK and BK para-kayak athletes and between the amputated (A) and non-amputated (NA) sides. No significant differences were observed between the groups in the majority of the examined variables suggesting that these group of athletes may be able to compete in the same class.

## Introduction

Lower limbs may contribute to up to 21% of paddling force, 16% of kayak speed [1], and perhaps ultimately contributing to an increase in kayaking performance by 6% [2]. In para-kayak, athletes with unilateral AK and BK athletes compete in the same class. Since the leg movement during paddling is most likely a result of the flexion and extension of the knee joints, it is questionable whether athletes with these different impairment types should compete in the same class. The purposes of this study were therefore to examine the differences in kinematic and kinetic performance variables between AK and BK athletes and between the A and NA sides during kayak ergometer paddling.

## Methods

11 AK and 6 BK international level competitive para-kayak athletes from 13 different countries participated in this study. The data collection was conducted by the athletes paddling on a kayak ergometer at an intensity level corresponding to the intensity of a 200 m race. Three-dimensional (3D) kinematic data from the body and paddle were recorded during the paddling using a 12-camera optoelectronic system. Force was measured using uniaxial piezoelectric force transducers attached at the paddle shaft, a force plate attached to the kayak seat and 3D piezoelectric force transducers attached to the footrest. Independent *t*-tests and two-way mixed model analysis of variance tests with one between-group factor *group* (AK, BK) and one within group factor *side* (A, NA) were performed. Significant interactions were followed up with Bonferroni post-hoc tests.

## Results and Discussion

There were no significant differences between the groups in the main performance variables such as power output or paddle force which was quite unexpected. Differences

between the groups were only seen in the hip joint in flexion range of motion, flexion and extension velocity and flexion moment where the BK group demonstrated larger values. The NA side demonstrated greater values compared to the A side in posterior force at the seat (Figure 1) and in hip flexion moment. The posterior force at the seat during the drag phase of the A side was smaller compared to the NA side. For the AK athletes an anterior force could be seen for the A side, likely due to the majority of the athletes not wearing a prosthesis leading to an inability to push on the footrest during the drag phase of that side. This results in there only being a pull force on the footrest of the NA side resulting in the athletes gliding anteriorly on the seat, creating an anterior force.

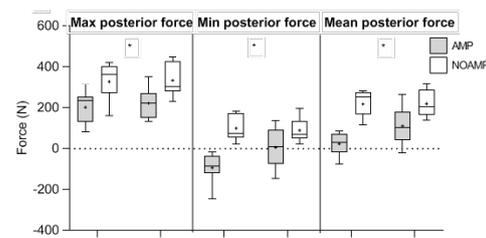

Figure 1: Maximal, minimal and mean posterior force at the seat.

## Conclusions

The study examined differences in kinematic and kinetic performance variables between para-kayak athletes with unilateral AK and BK amputation as well as between the A and NA sides. There were only significant differences between the groups in the hip joint in flexion/extension ROM, flexion and extension velocity and flexion moment. Differences between the sides were seen in posterior force at the seat and in hip flexion moment. The limited number of variables in which differences between the groups were observed indicate that athletes with AK and BK amputation may be able to compete in the same class on similar terms.

## Acknowledgments

We recognize financial contributions from the International Canoe Federation and The Swedish Research Council for Sport Science. Sincere gratitude is expressed to all the athletes who participated in this study.

Email: r.j.f.janssen@umcg.nl

### Summary

Numerous equipment with various protocols to attain the wheelchair-specific anaerobic and aerobic exercise capacity of wheelchair athletes in a standardized lab environment have been used in previous research and practice. These are not necessarily wheelchair or athlete-specific and not very well standardised. This has implications for the comparison and generalizability of the results [1]. This review provides an overview of the assessment of lab-based wheelchair-specific exercise capacity by wheelchair athletes. Different characteristics of protocol designs are used interchangeably and from this review, conclusions cannot be drawn about the influence of the different aspects. Rather than to explore these differences we aim for more standardization and better reporting. Future studies should preferably use equipment that allow anaerobic sprint testing, that can accommodate an athletes own sports wheelchair and has the possibility of measuring power output. The anaerobic and aerobic protocol should be standardized, yet individualized towards their own capacity [2].

### Introduction

This scoping review aims to provide an overview of the assessment of lab-based tests for the anaerobic and aerobic wheelchair-specific exercise capacity in wheelchair athletes. Accurate measurement of those entities provides a basis for individualized training programmes and if athletes are measured over time with the same methods their wheelchair-specific exercise capacity can be monitored. Our second aim is to generate a framework of protocols for standardized, yet individualized lab-based wheelchair-specific exercise capacity testing in wheelchair athletes.

### Methods

A scoping literature search in Pubmed, Web of Science, Embase and CHINAL was conducted with the following search terms: (Wheelchair\*) AND (Ergomet\* OR Dynamomet\* OR Simulator OR Treadmill) AND (Sport OR Athlet\* OR Para-Athlet\*) AND (Exercise test\* OR Laboratory based test\* OR Maximal incremental test\* OR Multistage test\* OR Aerobic test\* OR Sprint test\* OR Wingate OR Anaerobic test\*).

### Results and Discussion

The search resulted in 9 and 37 unique protocols for respectively wheelchair-specific anaerobic and aerobic exercise capacity testing. A variety of participants were included in the studies, numerous treadmills and ergometers were utilized and protocols vary widely. Also, several different outcomes to describe the wheelchair-specific exercise capacity were reported. Besides this, information regarding the participant characteristics or used methods was often missing.

### Conclusions

Different characteristics of protocol designs are used interchangeably and from this review, we cannot draw conclusions about the influence of the different aspects. Rather than to explore these differences we aim for more standardized protocols and better reporting. Future studies should preferably use equipment that allow anaerobic sprint testing, that can accommodate an athletes own sports wheelchair and has the possibility of measuring power output. The anaerobic and aerobic protocol should be standardized, yet individualized. Protocols should be build towards the predicted outcome of the athlete which is based on an earlier performed test [2]. A checklist is provided together with this review, which shows the preferable equipment, protocol and all the relevant information and outcomes that should at least be reported by researchers and practitioners. With these guidelines we hope to work towards more individualization and standardization in future wheelchair-specific exercise testing and more international agreement.

### Acknowledgements

This work was supported by ZonMw (Sport en Beweging 2018) under project number 546003002. This project, named 'WheelPower: wheelchair sports and data science push it to the limit' is a cooperative effort between UMCG, TU Delft, THUAS, VU Amsterdam and is in cooperation with several sports federations collected under the umbrella of NOC\*NSF.

## The impact of leg impairment on strength and race performance in elite para-cyclists

Johanna B. Liljedahl<sup>1</sup>, Anna Bjerkefors<sup>1,2</sup>, Carla F. Nooijen<sup>1</sup>, Anton Arndt<sup>1,2</sup>

<sup>1</sup>The Swedish School of Sport and Health Sciences, Stockholm, Sweden

<sup>2</sup>Karolinska Institute, Stockholm, Sweden

Email: johanna.liljedahl@gih.se

### Summary

Maximal isometric leg strength differs in three groups of para-cyclists with leg impairments while race speed does not, suggesting that the level of impairment in muscles important in cycling can be measured without predicting sport performance.

### Introduction

In the C-class in para-cycling athletes compete on typical race bikes in time trials, mass starts and track cycling. To be eligible for the C-class, athletes must have impaired muscle strength or range of motion, limb deficiency, leg length difference, athetosis, ataxia or hypertonia. Activity limitations caused by impairments are expected to hinder cycling performance and therefore, the C-class covers five sport classes: C1 to C5 (C5 being least impaired).

Research describing the impact of different impairments on race performance is limited. The current classification system needs to be evaluated to assure evidence-based classification procedures, as highlighted by the International Paralympic Committee [1]. The aim of this study was to compare the impact of lower limb impairments on leg strength and cycling performance in the C-class.

### Methods

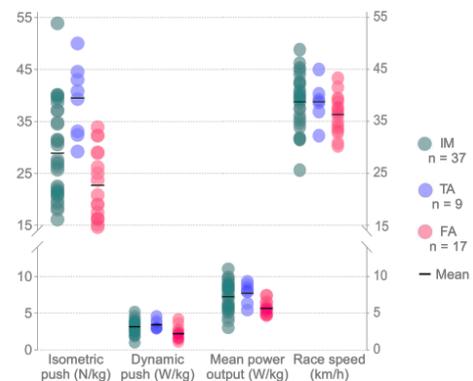

Data from 58 para-cyclists was collected at four para-cycling events (World Cups and World Championships) in 2018-2019, sanctioned by the international cycling federation, UCI. The data collection protocol included isometric and dynamic strength testing and a sprint test.

In the isometric test, the athlete was seated in a custom-built strength setup with one foot on the floor and the tested leg reached horizontally out in front (knee flexion 50°) with the foot against a footrest equipped with force transducers. Maximal force (N) was exerted on the footrest in a leg push. The dynamic test was conducted on a cycling ergometer (Cyclus2, RBM Electronics, Germany) by pushing the pedal from the top (0° of the pedal revolution) to bottom position (180°), measuring peak power (W). A standardized 20-s all-out sprint test was performed to measure mean power output (MPO) (W). The three conducted tests were adjusted for body mass (kg). Time trial results (km/h) from the respective event where the athlete was tested were obtained [2].

Athletes were split into three groups based on impairments: impaired muscle strength (IM), transfemoral amputation (FA; one-legged cycling) and transtibial amputation (TA; two-legged cycling with prosthetics). One-way ANOVA with Tukey's HSD post-hoc test was conducted to compare effect of impairment on strength and performance variables.

### Results and Discussion

The isometric test differed significantly ( $F[2,55] = 12.47, p < .001$ ) between all groups. TA had significantly higher strength than IM ( $p = .003$ ) and FA ( $p < .001$ ), and IM had significantly higher strength than FA ( $p = .037$ ). A significant difference was not evident in race speed ( $F[2,53] = 1.74, p = .185$ ). The dynamic test ( $F[2,55] = 9.20, p < .001$ ) and MPO ( $F[2,54] = 6.79, p < .005$ ) were higher in TA than FA ( $p = .002, p = .009$  for respective test) and in IM than FA ( $p = .001, p = .001$  for respective test). The large variance in particularly the IM group is likely due to a large spread in impairment severity in IM athletes.

**Figure 1:** Effects of impairment on muscle strength tests (isometric and dynamic push) and performance (mean power and race speed).

### Conclusions

To facilitate fair competition in para-cycling, classification methods need to assess activity limitation while not simultaneously impact the outcome of competition. The isometric strength results differ from race outcome results, indicating that the impact of impairment can be determined regardless of cycling performance. Further research is needed to explore confounding variables e.g. training, sex and experience and their role in test and race outcomes.

### Acknowledgments

## Validation of a new sport specific Trunk Test Battery for Paracanoe

Anna Bjerkefors<sup>1,2</sup>, Johanna S. Rosén<sup>1</sup>, Olga Tarassova<sup>1</sup>, Martin Eriksson-Crommert<sup>3</sup>.

<sup>1</sup>The Swedish School of Sport and Health Sciences (GIH), and, <sup>2</sup>Department of Neuroscience, Karolinska Institute, Stockholm, Sweden, and <sup>3</sup>University Health Care Research Center, Faculty of Medicine and Health, Örebro University, Örebro, Sweden.  
Email: anna.bjerkefors@gih.se

### Summary

The Trunk Test Battery (TTB) used in the Paracanoe medical classification is a valid test to measure trunk function in athletes with impaired muscle power, impaired passive range of movement and limb deficiency. A general form of the equation to predict power output from TTB, age and gender is Power output = 197.443 + (2.057\*TTB) + (57.540\*Gender) + (-3.118\*Age).

### Introduction

Para-kayak is one of two disciplines in the sport of Paracanoe and debuted in the Paralympic Games in 2016. In para-sport, athletes need to go through a classification process before they are able to compete. This process allocates athletes to different sport classes based on the impact of impairment on sport performance. In para-kayak, athletes with impaired trunk and/or leg function are allocated to and compete in one of three classes: KL1, KL2, or KL3 based on the results from the medical and technical classification. The medical classification involves tests of trunk and leg function. The Trunk Test Battery (TTB) consists of manual muscle tests (MMT) and functional assessment tests (FA). The outcome is scored on a 0 – 2-point ordinal scale.

The purpose of the study was to validate the TTB used in para-kayak classification. The research question was to examine the effect of age, gender, training intensity, TTB, MMT and FA on sport performance (power output), i.e. kayak ergometer paddling.

### Methods

Fifty international or national level para-kayak athletes (16 females and 34 males) from 11 countries performed the TTB. A subgroup of 26 athletes (8 females and 18 males) completed a sport-specific performance test on a kayak ergometer. The TTB consisted of the MMT (six trunk muscle tasks performed in lying; flexion/extension, rotation left/right, lateral flexion left/right) and the FA (four tasks in unsupported sitting; static, dynamic and perturbation on stable and unstable surface). The kayak ergometer test was performed during high intensity paddling during 20 stroke cycles. Separate multiple linear regression analyses were carried out to investigate whether age, gender and training intensity and either a) TTB, b) MMT, c) FA, d) FA<sub>static</sub>, e) FA<sub>dyn</sub>, f) FA<sub>stable</sub> or g) FA<sub>unstable</sub> could significantly predict athletes' sport performance.

### Results and Discussion

The mean power output during high intensity paddling on the kayak ergometer for males was 226.5 ± 108.6 W and for females 145.3 ± 57.9 W. The results of the regression analyses indicated that Model 3 in all analyses showed the highest R<sup>2</sup> (adjusted in %) in TTB, FA and FA<sub>dyn</sub> (Table 1). In these analyses, the results showed that all independent predictors except training intensity significantly predicted sport performance outcome.

**Table 1.** Multiple linear regression analyses to evaluate if age, gender, training intensity and either a) TTB, b) MMT, and c) FA<sub>dyn</sub>, predict changes in sport performance (power output) in paracanoe athletes (n=26).

	B	SE	P-value
<b>a) TTB</b>	2.057	0.257	<0.001
Gender	57.540	18.602	0.005
Age	-3.118	1.099	0.010
<b>R2 adjusted in %</b>			<b>82.8</b>
ANOVA F(3,22) = 41.189, p <0.001			
<b>b) FA</b>	2.290	0.287	<0.001
Gender	55.396	18.621	0.007
Age	-3.184	1.097	0.008
<b>R2 adjusted in %</b>			<b>82.8</b>
ANOVA F(3,22) = 41.048, p <0.001			
<b>c) FA<sub>dyn</sub></b>	13.047	1.541	<0.001
Gender	57.482	17.184	0.004
Age	-3.337	1.041	0.004
<b>R2 adjusted in %</b>			<b>84.3</b>
ANOVA F(3,22) = 45.577, p <0.001			

Notes: B=unstandardized beta coefficient, SE = standard error of the estimate, R<sup>2</sup>= explained variance adjusted in %. Training intensity was excluded in all three models.

### Conclusions

To facilitate fair competition, the International Paralympic Committee requires all para-sports included in the Paralympic Games to develop and use classification systems based on evidence [1]. The new TTB was shown to be valid to measure sport specific trunk function and it was feasible to perform in Paracanoe classification. Further research on trunk function is needed where athletes with different impairment types are included and the impact of adaptive sport-specific equipment, strapping and positioning is evaluated.

### Acknowledgments

We recognize financial contributions from the International Canoe Federation (ICF) and The Swedish Research Council for Sport Science (CIF). The authors would also like to express their sincere gratitude to all the athletes who participated in this study.

# Biomechanical Evaluation of a Fracture Fixation System for Transverse Fractures of the Metacarpal Neck

Rena Mathew<sup>1</sup>, Nicholas Anastasi<sup>1</sup>, Christopher Jones<sup>2</sup>, Sorin Siegler<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Drexel University, Philadelphia, PA, 19103, USA

<sup>2</sup>Rothman Institute Orthopedics, Old Lancaster Road, Bryn Mawr, PA 19010

Email: [rm3325@drexel.edu](mailto:rm3325@drexel.edu)

## Summary

Metacarpal fractures represent approximately 30% of all hand fractures that are evaluated in the emergency setting due to accidental falls or a direct blow to the fingers [1]. Intramedullary headless compression screw (HCS) fixation is a promising treatment method with the capacity to generate 60 N of compression [1]. Mechanical properties such as displacement with cyclic loading and stiffness were tested with this method to simulate a range of motion hand therapy exercises at 40 N. A test was also conducted to understand the peak load at which the metacarpal strength fails.

## Introduction

Surgical techniques such as K-Wire and external fixation for metacarpal fractures lead to impediments such as infection, tendon injury and malunion [1]. Intermedullary HCS fixation is an alternative method to address high rates of complications post-surgery. The purpose of this study is to evaluate the mechanical properties such as stiffness and strength of HCS fixation of a metacarpal neck fracture.

## Methods

A metacarpal neck fracture model was created in 13 fourth generation composite Sawbones by removing a volar-based bone wedge using a custom cutting jig to simulate a typical apex dorsal fracture, unstable in flexion (Figure 2). The bones were then fixed by 3.0 mm retrograde HCS fixation. A 3-D printed fixation jig was used to assure all hardware was identically placed. Models were potted at the base and mounted vertically in a material testing machine (Mark10:ESM1500), employing a cable tensioned over the metacarpal head to simulate forceful grip loading. Cyclic loading to 40N (simulating finger active range of motion exercises) and failure testing were performed. Load, displacement, and failure mode were recorded [2].

## Results and Discussion

During cyclic loading to 40 N, the HCS models (n=4, 7.1±0.4 mm) exhibited significantly higher displacement with cyclic loading than a healthy metacarpal (5.4±1.2 mm). In addition, average displacement to failure of the HCS models (3.3±0.7 mm) were non—significantly lower and their corresponding loads to failure (137.4±30.17 N) were significantly higher than a healthy specimen (63.8±24.9 N) (Figure 1a). Lastly, even though average final stiffness was higher than average initial stiffness, the average of the difference between them (5.1±3.8 N/m) was non-significantly higher than that of healthy specimen (4.7±1.3 N/m).

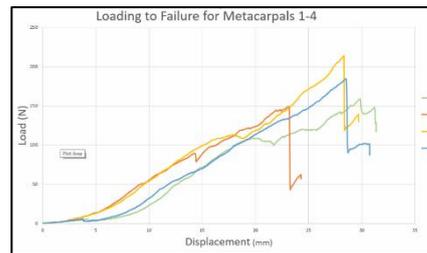

Figure 1: Plot of Total Force to mechanical failure

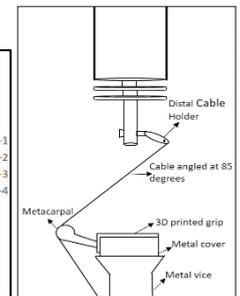

Figure 2: Experimental set-up

## Conclusions

The HCS model provided comparable evidence of its mechanical properties which are similar to a simulated grip model (Table 1) [1]. The construct is also internally buried inside the bone and avoids the restrictive nature of pins that limit early motion exercises.

## Model of the Midcarpal Joint Accounting for Structural Difference

Ronit Wollstein<sup>1</sup>, Martin Pendola<sup>1</sup>

<sup>1</sup> NYU Grossman School of Medicine, Department of Orthopaedic Surgery, NY, USA

Email: ronitwollstein@gmail.com

### Summary

There are multiple challenges to the study of in-vivo wrist mechanics. We present a preliminary model of the midcarpal joint based on computed tomography (CT) scans of normal wrists. By applying forces acquired in-vivo to the model we can study in-vivo biomechanics without invasive procedures. Our model predicted that the angle between the lunate and the capitate is significantly different between lunates type 1 and 2 in the midcarpal joint  $p < 0.0001$ . Significant differences in force transfer are predicted by the model, dependent on midcarpal joint type. Further study will delineate disparate measurements calculated from the model and may improve the model's ability to predict force transfer and kinematics.

### Introduction

It is difficult to obtain in-vivo data to study structure of the wrist and its effect on wrist function[1,2]. We present a preliminary model of the midcarpal joint based on computed tomography (CT) scans of normal wrists. By applying forces acquired in-vivo to the model we can study in-vivo biomechanics without invasive procedures thus providing a platform for the study of wrist mechanics.

Previous models have not succeeded in accounting for variable patterns of bony shape and configuration likely due to the complexity of wrist structure.

Our purpose was to:

- 1) Generate an initial model of the midcarpal joint of the wrist based on normal wrist CT scans.
- 2) Generate separate models for the midcarpal joint based on 2 distinct wrist types (type 1 and type 2).

### Methods

Thirty-five CT scans, (dicom files, anonymized, 2mm/slice resolution) were selected from a normal patient database and converted into 3-dimensional .stl files using OsiriX software (version 9, 2016, GNU LGPL), for classification. Solid Mechanics study in stationary conditions was used through the COMSOL library. Material properties for these models were generated from COMSOL materials library. The models were divided into 2 categories based on lunate type. Simulated loads were applied to the most distal articular

surface of the model. A load of 200N was applied in a distal to proximal direction, consistent with other studies. The predicted forces and movement were compared between the 2 wrist types.

### Results and Discussion

Thirty-three percent of individuals displayed a Type 1 joint, and 67% of individuals in the sample presented with a Type 2 joint. The movements or displacement of the components in the midcarpal joint differed between wrist types 1 and 2. The angle between the lunate and the capitate was significantly different between lunates type 1 and 2  $p < 0.0001$ . On force application, the surface stress and volume stress on the carpometacarpal (CMC) joints did not differ significantly between the 2 wrist types  $p = 0.38$ . However, the forces were predicted to travel more ulnarly in a type 1 wrist, and more radially-towards the scaphoid and scapholunate ligament- in type 2 wrists.

### Conclusions

- The model can be used to predict movement after loading through the midcarpal joint.
- Significant differences in force transfer are predicted by the model, dependent on midcarpal joint type.
- Further study will delineate disparate measurements calculated from the model. And improve the model's ability to predict force transfer and kinematics

# Three-Dimensional Carpal Tunnel Reconstruction and Analysis Using Multimodal Co-Registration of Ultrasonography and Computed Tomography

Rakshit Shah, **Hui Zhang**, and Zong-Ming Li

Hand Research Laboratory, Departments of Orthopaedic Surgery & Biomedical Engineering

University of Arizona, Tucson, Arizona, United States

Email: lizongming@arizona.edu

## Summary

A 3D carpal tunnel model was created by co-registering computed tomography scanning of carpal bones and robot-assisted ultrasound imaging of the transverse carpal ligament. The model allowed morphological analyses of bone and ligament arches at various tunnel locations and provided previously unknown information of carpal tunnel morphological properties. The developed multimodal imaging technique and the morphological analyses can be applied to examine pathomorphological changes of the wrist.

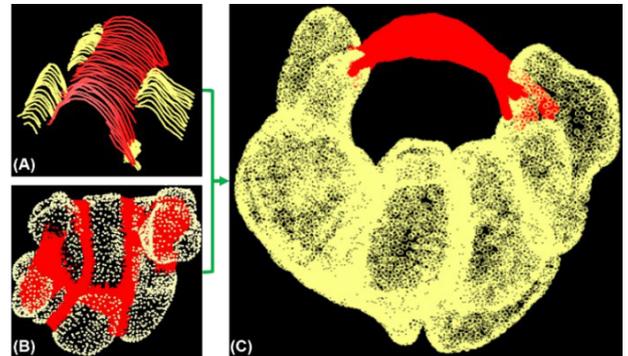

## Introduction

The carpal tunnel is bounded by the transverse carpal ligament and carpal bones, which can be divided into the ligament and bone arches. The ideal imaging modality for morphology investigation of the carpal tunnel as an osseoligamentous structure is ultrasonography for ligament arch and computed tomography for bone arch. Therefore, the purposes of the study were to 1) establish methodology for reconstructing three-dimensional carpal tunnel by computed tomography scanning of carpal bones and ultrasound imaging of the ligament, and 2) investigate the morphology of the bone and ligament arches across carpal tunnel. We hypothesized that the ligament arch would occupy lesser carpal tunnel space as compared to the bone arch, and the bone and ligament arch spaces would be dependent on the location of the carpal tunnel.

## Methods

Nine freshly frozen male cadaveric hand specimens were used. To reconstruct the ligament arch, multiple cross-sectional images of the ligament and the ligament-osseous attachments were collected using robot-assisted ultrasonography. Then the 2D image coordinates of anatomical features were spatially assembled to 3D point cloud of ligament arch using the positional information from the robot (Figure 1A). To reconstruct the bone arch, 3D surface of individual carpal bones was obtained by performing image segmentation on computed tomography scans. A 3D bone arch point cloud was reconstructed by filling the space between two adjacent bones with surrogate tissues of up to 3 mm thickness (Figure 1B).

The bone and ligament arches were co-registered into a common coordinate system to model a 3D carpal tunnel point cloud (Figure 1C) using the iterative closest points algorithm. The algorithm provided a rigid transformation matrix by performing a geometric match between the partial bone information from 3D ultrasonography and entire bone geometry from computed tomography scans.

**Figure 1:** Sample reconstruction of ligament arch using ultrasonography (A), bone arch using computed tomography (B), and carpal tunnel using multimodal co-registration of both arches (C).

## Results and Discussion

Total tunnel volume was  $6820.8 \pm 1278.7 \text{ mm}^3$ , agreed with a previous study [1]. The bone arch volume ( $5719.6 \pm 1049.2 \text{ mm}^3$ ) was significantly greater than the ligament arch volume ( $1101.2 \pm 230.5 \text{ mm}^3$ ,  $p < 0.05$ ), consistent with previous findings [2]. The bone arch areas were significantly larger than the ligament areas at all tunnel levels (proximal, middle, distal, all  $p < 0.05$ ). Additionally, both arches varied significantly with tunnel locations ( $p < 0.05$ ). The ligament arch area progressively increased from distal to proximal locations, whereas the bone arch area was greatest at the middle location but tapered down towards the tunnel edges.

The robot-ultrasound incorporation allows for 3D ligament reconstruction from 2D ultrasound images, advancing the imaging of the carpal tunnel. The developed multimodal imaging technique and the calculated outcome parameters can be applied to examine the pathomorphological changes associated with the carpal tunnel.

## Conclusions

A multimodal imaging technique was developed to reconstruct 3D carpal tunnel for advanced morphological analyses of bone and ligament arches, which advances our understanding of the carpal tunnel morphological properties.

### Summary

Dynamic computed tomography (CT) can be used to quantify joint motion. Joint angles are often calculated using manually placed anatomical landmarks (AL). This can be a highly subjective process and a better understanding of the associated errors resulting from manually placed AL on joint angles from dynamic CT scans is needed. Further, processing dynamic CT data can be prohibitively long. A semi-automated post-processing pipeline is proposed to improve processing times for joint angle quantification. Inter- and intra-rater analysis was performed on segment coordinate system (SCS) orientation and joint angles between three raters. Results show excellent reliability between raters for SCS orientation.

### Introduction

Osteoarthritis (OA) is a degenerative joint disease that commonly affects the joints of the hand, including the trapeziometacarpal (TMC) joint [1]. OA is considered a complex and multifactorial disease in which biomechanics play a role [1]. While dynamic CT can provide real time visualization of bone and joint motion, structural joint changes caused by OA can impact the reproducibility of calculated joint angles from manually placed ALs. It is not clear how much variation in SCS orientation and resulting joint angles can be expected from this subjective task. A joint angle reproducibility study of the TMC joint using a joint coordinate system (JCS) is presented for dynamic CT data sets. Further, a semi-automated post-processing pipeline has been developed to quantify joint angles from dynamic CT scans of the TMC joint and improve upon the extensive processing times presented in literature [2].

### Methods

Ten cadaveric hand specimens (5 female, age: 83.4±15.0 yrs) were scanned. Dynamic CT was acquired with 120kVp, 100mA, 4cm longitudinal coverage, 4vol/s gantry rotation, and 15s scan time. A custom passive motion device was used to move the thumb through radial abduction-adduction. Due to limitations in dynamic CT image quality and longitudinal coverage, high resolution peripheral quantitative CT (HR-pQCT) scans with 61µm isotropic voxels (XtremeCTII, Scanco Medical) were acquired to generate masks and for SCS definition (Figure 1). Static CT images were binarized using global thresholds, binary morphological operations, and connected component labelling. Dynamic CT images were binarized using intensity-based sequential registration of CT

bone masks. Joint angles were measured using a JCS representation [3]. SCS for each bone in the TMC joint were generated using ALs [4] selected by three raters. SCS orientation between raters was assessed by comparing angles between SCS axes and the principal axes of each segment. Inter- and intra-rater reliability was assessed using a two-way intraclass correlation coefficient (ICC) for SCS orientation and joint angle results between all three raters.

### Results and Discussion

A semi-automated post-processing pipeline was developed that only required minor manual adjustments to the binary masks of each bone, due to narrow joint space and landmark placement. SCS orientation between raters showed excellent intra- and inter-rater reliability (Table 1). This study provides the groundwork for future studies that will assess the relationship between joint structure and function in osteoarthritic TMC joints using dynamic CT.

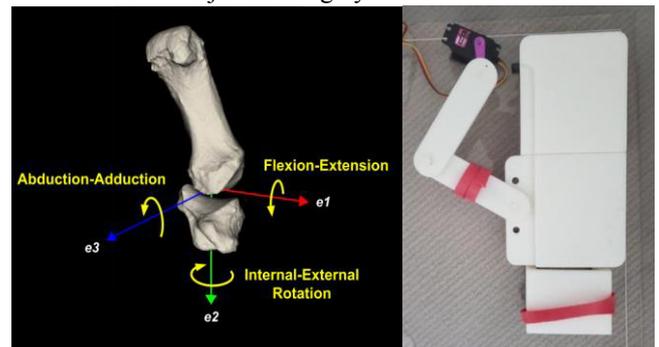

Figure 1: JCS defined on the TMC joint (left) and the passive motion device used during dynamic CT scanning (right).

### Conclusions

Both inter- and intra-rater reliability was excellent when comparing orientation of both SCSs. This suggests that careful placement of AL on 3D bone models using detailed instructions and high-resolution bone models can provide reliable SCSs for the trapeziometacarpal joint.

Email: surajcha@usc.edu

### Summary

We developed a passive device implanted between the *flexor digitorum profundus* (FDP) tendons of insertion to construct a passive “differential mechanism” between the *extensor carpi radialis longus* (ECRL) muscle and the finger tendons (US Patents 9,925,035 and 10,595,984). This differential mechanism enables some finger(s) to continue to flex and make contact with the object even if other finger(s) are locked (checkreined) by already having made contact.

### Introduction

High median-ulnar nerve injury paralyzes part of the FDP muscle and the entire *flexor digitorum superficialis* (FDS) muscle, resulting in limited grasp function by the patient. One of the current surgical solutions to restore flexion of the four fingers is a tendon transfer procedure that re-routes and directly sutures all four FDP tendons of insertion to the single tendon of insertion of the ECRL muscle, a wrist extensor innervated by the radial nerve.[e.g., 1] However, this procedure has a fundamental drawback: the surgery couples the previously independent movement of all four fingers because the excursion of the ECRL determines the excursion of all four FDP tendons of insertion. With this coupled finger flexion, all fingers cease to flex as soon as one finger makes contact with the object. This prevents all fingers from making contact when grasping irregularly shaped objects. Simple tasks such as holding an apple or using a knife with a contoured handle become challenging. This results in reduced function affecting quality of life.

### Methods

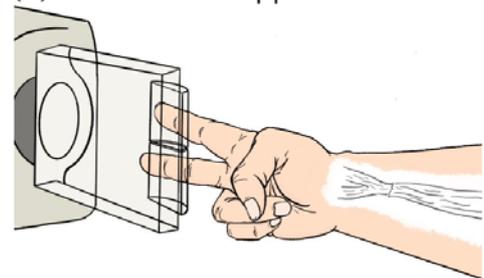

We tested the implant's ability to create differential flexion between the index and middle fingers during grasp when actuated by a single muscle in two human cadaver hands using a closed-loop computer-controlled actuation and measurement paradigm. In the cadaveric models, the implants enabled significantly more differential flexion between the index and middle fingers for a wide range of donor tendon tensions. The implants also redistributed fingertip forces between fingers.

### Results and Discussion

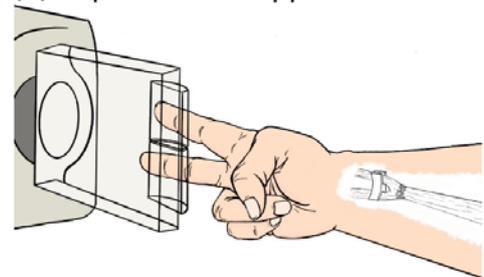

When grasping uneven objects, the difference in contact forces between the index and middle fingers was reduced by 23% when compared with the current suture-based surgery. This means that force distribution is more even with the

implant in spite of the difference in flexion angle of the fingers. These results suggest that self-adaptive grasp is possible in tendon transfers that drive multiple distal flexor tendons with one donor muscle.

#### (A) Suture-based approach

#### (B) Implant-based approach

**Figure 1:** Experimental set up with cadaveric hands. For the traditional (A) and implant conditions (B), we measured the fingertip forces on the sensing paddle for a given tension in the donor tendon for different rotation angles of the sensing paddle.

### Conclusions

The addition of an implant in the transfer of the ECRL to the FDP of the index and middle finger enhanced the cadaveric model's ability to flex each finger different amounts and apply variable pressure. Translating this biomechanical advantage to patients would likely enhance hand functional recovery after high median nerve palsy surgical reconstruction.

## Biceps femoris long head fascicle length increases after 3 weeks of eccentric exercise training are due to sarcomere lengthening rather than serial sarcomere addition

### Summary

Nordic hamstring exercise (NHE) is an eccentric exercise that elicits substantial changes in hamstring fascicle length, which potentially protects the muscle from subsequent injury. Yet, the macroscopic and microscopic changes that contribute to the mechanical load-induced hamstrings lengthening response remain poorly understood. In this study, we measured in vivo fascicle and sarcomere length changes in the biceps femoris long head (BFlh) in ten individuals after a three-week NHE training program. We found an increase in fascicle and sarcomere lengths in the distal but not the central portion of the BFlh. Our results suggest that fascicle lengthening is due to sarcomere lengthening rather than serial sarcomere addition at the outset of the adaptive process.

### Introduction

Eccentric training helps enhance muscle strength, power, speed, and protection from subsequent exercise-induced muscle damage [1,2]. NHE is one such eccentric exercise that elicits changes in fascicle length; however, the mechanisms underlying these fascicle length changes and the role of muscle architectural adaptations in preventing injuries are still largely unknown. Therefore, this study aimed to measure multi-scale BFlh adaptations by in vivo measurement of fascicle and sarcomere lengths before and after NHE training.

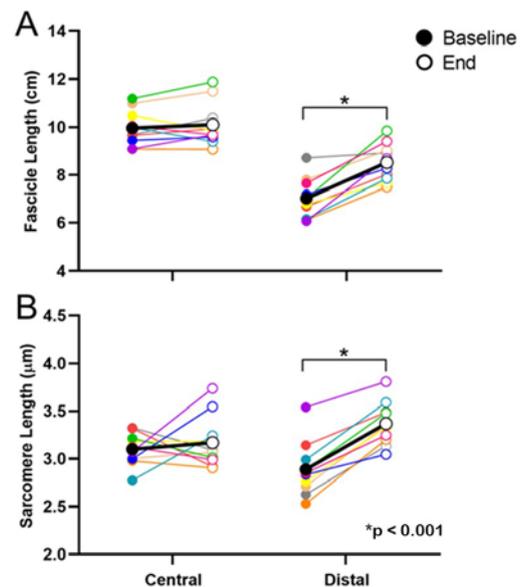

### Methods

Ten recreationally active participants (age:  $27 \pm 3$  years, mass:  $70 \pm 14$  kg, height:  $174 \pm 9$  cm) completed three weeks (nine sessions) of NHE training. Participants performed NHE using a custom padded board with uniaxial load cells attached to ankle braces. We estimated eccentric knee flexion strength as the average of the load cells' highest measurements during three maximal NHE repetitions. We measured in vivo sarcomere and fascicle lengths in the central and distal regions of the BFlh using second harmonic generation microendoscopy [3] and freehand 3D ultrasonography, respectively. During imaging, participants laid prone with their hips and knees fully extended and their feet in a neutral position off the end of the bed.

### Results and Discussion

Eccentric knee flexion strength increased after the training (15%,  $P < 0.001$ ,  $\eta_p^2 = 0.75$ ). Fascicle lengths significantly increased (21%,  $P < 0.001$ ,  $\eta_p^2 = 0.81$ ), as well as sarcomere

(17%,  $P < 0.001$ ,  $\eta_p^2 = 0.9$ ) lengths, in the distal but not the central portion of the BFlh.

**Figure 1:** Fascicle lengths (A) and sarcomere lengths (B) in the central and distal portions of the BFlh at baseline (filled circles) and after NHE training (End, open circles). Each color is an individual participant, with the average across participant averages in black.

### Conclusions

Fascicle length adaptations appear to be heterogeneous in the BFlh in response to three weeks of NHE training. An increase in sarcomere length, rather than the addition of sarcomeres in series, appeared to be underlying the initial BFlh adaptations we studied. The mechanism driving regional increases in fascicle and sarcomere length remains unknown, but we speculate it may be driven by regional changes in the passive tension of muscle or connective tissue adaptations.

## Summary

Foot-strike and toe-off detection is often critical in the assessment of running biomechanics. The onset and offset of the vertical ground reaction force is regarded as the “gold standard” method for step event detection, but several kinematics-based algorithms have been proposed to detect foot-strike and toe-off in the absence of force plates. However, the accuracy and generalisability of kinematics-based methods are often limited. Therefore, we developed FootNet, an algorithm using kinematic input and deep learning, to improve the detection of foot-strike and toe-off events during treadmill running in a variety of speed, foot-strike angle and incline conditions.

## Introduction

The accurate detection of foot-strike and toe-off events based on kinematics has historically proved a challenging problem within locomotion biomechanics. Although several marker trajectory-based and segment/joint kinematics-based algorithms exist, these methods typically require markers to be affixed to highly deformable areas of the shoe which can be problematic. The accuracy of these methods can also be affected by running speed and a runner’s preferred foot-strike pattern (foot landing angle). Further, algorithm development and validation has typically been conducted in a single laboratory, potentially limiting their generalisability [1].

The purpose of this study was to develop and evaluate FootNet, a new kinematics and deep learning-based algorithm to detect foot-strike and toe-off in treadmill running.

## Methods

Five treadmill-running datasets from three independent laboratories with different motion capture systems and instrumented treadmills were gathered from previous studies. These datasets included kinematics and kinetics of athletes of different abilities and foot-strike patterns running at multiple speeds and on different inclines. Marker trajectories were processed to calculate leg, foot and ankle kinematics. Running trials were divided in cycles and the non-contact and contact phases within each cycle were detected using the raw vertical ground reaction force (non-contact: vGRF < 50 N; contact: vGRF ≥ 50 N).

FootNet is based on a recurrent neural network with long, short-term memory (LSTM) units [2]. The network takes the distal tibia anteroposterior velocity, ankle dorsi/plantar flexion angle, and the anteroposterior and vertical velocity of the foot centre of mass as input features (entire time-series of a cycle) and predicts whether each time point belongs to the

contact or non-contact phases. Foot-strike and toe-off can then be simply identified by finding the first and last timepoints identified as contact. We used the five datasets for model development (70% participants from each set) and testing (30% participants of each set). The model underwent 5-fold cross-validation and the best set of weights was selected for final model testing.

Non-parametric Bland-Altman analyses (median bias and 2.5<sup>th</sup> and 97.5<sup>th</sup> percentile as 95% limits of agreement, 95LA) [3] and root mean squared error (RMSE) were used to assess the performance of FootNet against the onset and offset of the vertical ground reaction force method for the detection of foot-strike, toe-off and contact times. The linear association between detection errors and running speed, foot-strike angle and incline respectively were also investigated.

## Results and Discussion

FootNet achieved close agreement with the force plate method (Figure 1), with a median bias of 0 ms for foot-strike (95LA = [-10, 7] ms, RMSE = 5 ms), toe-off (95LA = [-10, 10] ms, RMSE = 6 ms) and contact time (95LA = [-15, 15] ms, RMSE = 8 ms). These errors were two to four times smaller than those previously reported in the literature [1]. Linear associations between detection errors and running speed, foot strike angle and incline were small and practically negligible. Thus, FootNet seems robust to different running speeds, foot strike patterns and treadmill gradients, one of the main limitations highlighted in previous research.

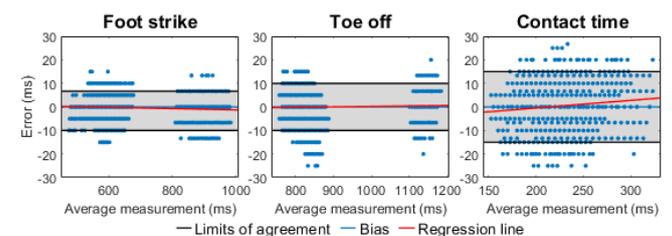

Figure 1: Bland-Altman plots.

## Conclusions

FootNet improves the detection of foot-strike and toe-off events in treadmill running, and is robust to different speeds, foot-strike patterns and inclines. FootNet and its source code is publicly available for the biomechanics community.

<sup>3</sup> Department of Clinical Sciences Lund, Orthopaedics, Clinical Epidemiology Unit, Lund University, Lund, Sweden

Email: [mohammadhossein.ebrahimi@uef.fi](mailto:mohammadhossein.ebrahimi@uef.fi)

## Summary

The fibril-reinforced poroelastic (FRPE) material properties of human femoral condyle cartilage and how these properties compare to other cartilage sites in knee are largely unknown. We combined multi-step stress-relaxation measurements with FRPE modeling to characterize these properties in the femoral condyle cartilage at different stages of osteoarthritis (OA) and compared them with other cartilage sites in knee. Our findings suggest that the strain-dependent fibril network modulus of femoral cartilage was smaller compared to that of tibial cartilage in normal and moderate OA, indicating less progressive fibril recruitment as a function of strain.

## Introduction

Osteoarthritis affects the main constituents of articular cartilage (i.e., collagen network, PGs and interstitial fluid) [1,2]; thus, weakening the tissue function. FRPE modeling of cartilage tissue can quantify constituent-specific material properties and reveal their contributions to tissue mechanical response [1]. However, these properties are not known for human femoral cartilage. Thus, we aimed to quantify these properties and characterize how they compare to other cartilage sites in the knee joint at different stages of OA.

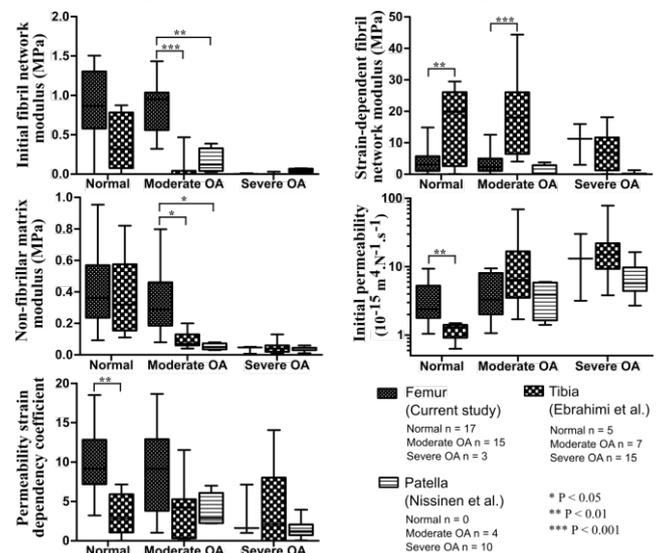

## Methods

Osteochondral samples ( $n = 35$ ) were extracted from medial and lateral femoral condyles of 14 total knee replacement patients and 10 donors without known clinical knee OA. A 3-step stress-relaxation protocol in indentation consisting of 5% strain and 15 minutes of relaxation at each step was applied. Sample-specific axisymmetric finite element models were created in Abaqus and cartilage tissue was modeled using the FRPE material model. The material parameters were obtained by minimizing the difference between the simulation results and experiments in the 2nd and 3rd stress relaxation steps (Matlab). Samples were histopathologically graded by OARSI score and grouped to *normal* (grade = 0-1,  $n = 17$ ), *moderate OA* (grade = 2-3,  $n = 15$ ) and *severe OA* (grade = 4,  $n = 3$ ). An age-adjusted linear mixed model was used to compare the femoral cartilage material parameters **1**) between normal and moderate OA at medial and lateral condyle, **2**) with those of tibial [1] and patellar cartilages [2].

## Results and Discussion

We did not observe essential differences between normal and moderate OA femoral condyle cartilage samples. However, in normal and moderate OA femoral cartilage, the strain-dependent fibril network modulus was smaller by 11.64 and

15.72 MPa compared to tibial cartilage (Figure 1), indicating that the superficial femoral cartilage has a more homogenous structure (homogenous structure leads to less progressive recruitment of fibers, represented in the model as a smaller strain-dependent fibril network modulus). In moderate OA, the initial fibril network and non-fibrillar matrix moduli of the femoral cartilage were greater than those of the tibial (0.77 and 0.18 MPa) and patellar cartilages (0.69 and 0.21 MPa); suggesting that the OA-related changes in PG and collagen matrices of femoral cartilage may occur later compared with other sites. In the severe OA, statistical tests could not be performed due to the small sample size ( $n = 3$ ).

**Figure 1:** The fibril-reinforced poroelastic properties of human femoral cartilage compared to those of tibial and patellar cartilages.

## Conclusions

The initial fibril network and non-fibrillar matrix moduli of femoral cartilage were greater compared to those of tibial and patellar cartilages, in the moderate OA, while the strain-dependent fibril network modulus of femoral cartilage was smaller compared to that of tibial cartilage in normal and moderate OA, suggesting less progressive fibril recruitment.

Email: [arnault.caillet17@imperial.ac.uk](mailto:arnault.caillet17@imperial.ac.uk)

### Summary

We developed a computational model of a muscle actuator composed of in-parallel Hill-type models of motor units (MUs) using as inputs the motor unit discharge times obtained from decomposed high-density surface EMG (HDEMG) signals. We then used the model to simulate isometric muscle contractions. This work extends the traditional Hill-type muscle models and enables further modelling possibilities such as HDEMG-based simulations and controllers.

### Introduction

In computational muscle modelling, whole muscle dynamics are mostly described as a single functional MU modelled with a Hill-type model. This assumption requires lumping the MU neural contributions to a single control [1], that is dissociated from the physiological control of muscle forces, which limits the range of uses of these models. Recent advances in the acquisition and decomposition of HDEMG signals [2] open new possibilities for the definition and use of Hill-type models at the MU scale. In this work, we propose a multi-MU Hill-type muscle model driven by experimental motoneuron discharge times obtained from HDEMG recordings [2].

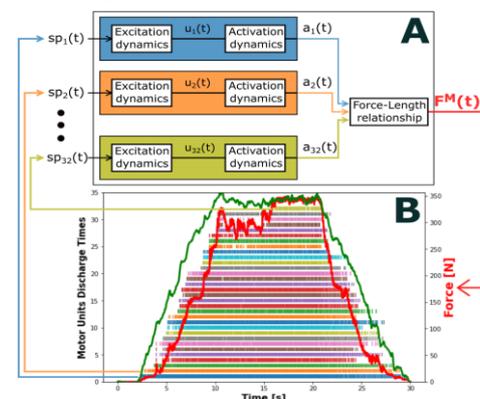

### Methods

The time-histories of the discharge times  $sp_i(t)$  of 32 identified MUs were obtained from blind source separation of HDEMG signals acquired during an isometric trapezoidal contraction up to 35% of the maximum force of the tibialis anterior (TA) muscle of a healthy subject (male, 27 years old, 189 cm, 77 kg) [2]. The whole muscle (Figure 1A) is modelled as 32 in-parallel Hill-type MU actuators. The excitation and activation dynamics of each MU are modelled using an updated Hatze's model [3] with parameters recalibrated using mammalian data. In this model, each neural discharge time  $sp_i(t)$  fires a model of neural action potential which drives two cascading second-order differential equations of the dynamics of the muscle action potential (MAP) (excitation dynamics) and of the length-dependent calcium concentration transients in the sarcolemma (activation dynamics). The active state obtained from an adapted calcium-dependent 8-state model of cross-bridge attachment dynamics [4] scales a normalized isometric force-length relationship yielding the  $i^{\text{th}}$  MU normalized force. The following simplifying assumptions were made. The 32 identified MUs are representative of the population of recruited MUs at 35% maximum force and an exponential frequency distribution of the MU-specific maximum forces was considered. Accounting for the variation of optimal fibre lengths ( $l_0^M$ ) with recruitment threshold, all MU dynamics are sub- $l_0^M$  and passive parallel forces can be

neglected. The contribution of the short tendon of the TA is for now neglected. Finally, the 32 output MU forces are linearly summed to yield a whole muscle force profile  $F^M(t)$ .

### Results and Discussion

The time profiles of the MAPs  $u_i(t)$  and active state  $a_i(t)$  of each  $i^{\text{th}}$  MU (Figure 1A) could be simulated from the HDEMG discharge times  $sp_i(t)$ , yielding a simulated whole muscle force  $F^M(t)$  (red trace, Figure 1B) resembling experimental results (green trace, Figure 1B). Delays in force onset will be corrected by identifying or simulating the dynamics of supplementary representative MUs.

**Figure 1:** (A) Cascading dynamics of the 32-MU muscle model. (B) Discharge times of the 32 identified MUs. Experimental transducer force (green). Simulated whole muscle force (red).

### Conclusions

This new muscle modelling approach enables the use of decomposed HDEMG signals with Hill-type muscle simulations. Defining a multi-MU muscle actuator with MU-specific properties clearly separates excitation and activation dynamics. Ongoing work will consolidate the current model by mapping the sample of identified MUs to an estimate of the entire population of active MUs, reducing the number of simplifications and using ad hoc experimental data for neural inputs and model calibration and validation.

Email: arthur.jourdan@univ-eiffel.fr

### Summary

A genuine semi-automatic post-processing method has been designed for a fast and reliable quantification of abdominal wall muscles deformations during breathing and muscular contraction from real-time dynamic MR images.

### Introduction

Kinetic imaging of the abdominal wall is largely underused in clinical practice. However, the quantification of abdominal muscles motion could bring valuable information in medical diagnosis of any situation involving abdominal muscle deficiency such as hernia, muscle dystrophy or obesity. It could also facilitate *in-vivo* patient-specific biomechanical characterization of muscle tissue.

A semi-automatic post-processing method dedicated to real-time dynamic MRI aiming at a fast and reliable quantification of abdominal wall muscles deformations during controlled exercises is reported.

### Methods

Twenty healthy subjects ( $30.6 \pm 8.7$  y.o., 8 females) were scanned during a controlled breathing session, coughing and Valsalva maneuvering at the L3-L4 disc level using real-time dynamic MRI at 3T with a time resolution of 182ms.

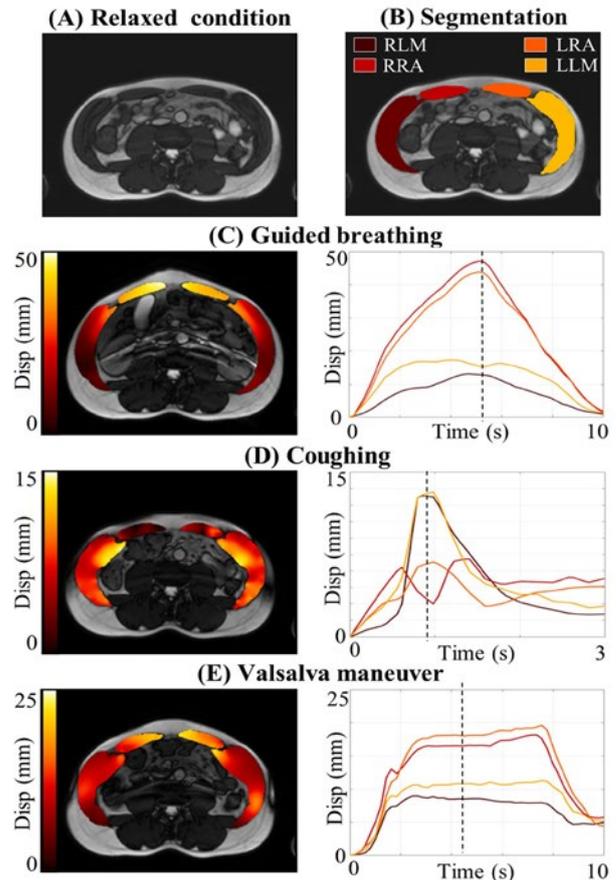

In the corresponding image series, four regions of interest (ROIs) were segmented using a supervised 2D+ segmentation procedure [1]: right and left lateral muscles (RLM – LLM) and rectus abdominis muscles (RRA – LRA).

The evolution over time of the displacement magnitude of the muscles with respect to relaxed condition was computed from registration of the segmented masks [2].

### Results and Discussion

As illustrated in Figure 1 for a typical subject, this evolution differs according to the type of exercise. During breathing and Valsalva maneuvering, maximum displacements (respectively 50mm and 25mm) are observed in the rectus abdominis muscles. The variation of RLM and LLM shape and thickness during Valsalva maneuver suggests greater muscle activation. During coughing the higher displacements (15mm) occurred in the deep zone of the lateral muscles, suggesting the activation of the transversus abdominis.

Our results support the specificity of muscle involvement during exercises and provide some quantitative metrics. The distribution of muscular displacements reported here supports the basic physiological knowledge regarding abdominal muscles activation [3] and is in agreement with previous studies reporting external measurements [4].

**Figure 1:** MR slice in relaxed condition (A); Segmentation ROIs (B); MR slice with 2D displacement field during: maximum inhalation (C), cough (D) and Valsalva maneuver (E); for each exercise the curves represent the evolution during time of the average displacement value in each ROI.

### Conclusions

The present genuine post-processing method provides a quantitative analytical frame that could be used in further studies for the assessment of dysfunctions of the abdominal wall mobility and for a better understanding of abdominal wall biomechanics in physiological and pathological situations.

### Summary

Accurate predictive simulations of human gait rely on optimization criteria to solve the system's redundancy. This study evaluated how well healthy gait could be predicted with a generic planar musculoskeletal model with 18 Hill-type muscles that were activated using a reflex-based, parameterized controller based on the weighted combination of different physiological-based cost function criteria (i.e., foot-ground impact, head stability, cost of transport, knee ligament use, and muscle activity). Criteria were first optimized individually, and then combined and weighted in a stepwise approach. The gait predicted with the combined, weighted cost function had better agreement with experimental data than when optimizing each criterion separately. Despite having a weak  $R^2$  when minimized alone, cost of transport contributed most to the combined, weighted cost function.

### Introduction

Predictive simulations of human gait rely on the optimization of criteria to handle system redundancy, yet these criteria are non-obvious. This study used different physiologically motivated criteria, and combined and weighted them in a stepwise manner to predict healthy gait and validate the predictions against experimental data.

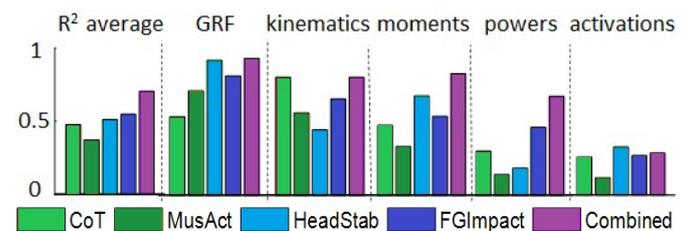

### Methods

A generic planar OpenSim [1] model with 18 Hill-type musculotendon actuators and nine degrees of freedom was controlled based on the model by Geyer and Herr [2]. Muscle excitations were generated using a combination of constant motor signals and reflexes based on muscle length and force, and active phases of gait. The parameterized controller was optimized using SCONE [3]. Each walk's simulation took 10 seconds and walking speed was free to vary. The initial pose and reflex gains were optimized for five cost function criteria: (1) cost of transport (CoT) using a muscle metabolic model [4], (2) muscle fatigue represented as activation squared, (3) head stability quantified by head acceleration per meter (HeadStab), (4) foot-ground impact quantified as the derivative of the ground reaction force per meter (FGImpact), and (5) extreme ranges of knee motion that minimized the use of knee ligaments (KneeInj). Coefficients of determination ( $R^2$ ) quantified the agreements between simulated and experimental biomechanical variables, i.e., ground reaction forces (GRF); joint kinematics, moments and powers; and muscle activations. The average  $R^2$  was calculated for each and across the variable categories.

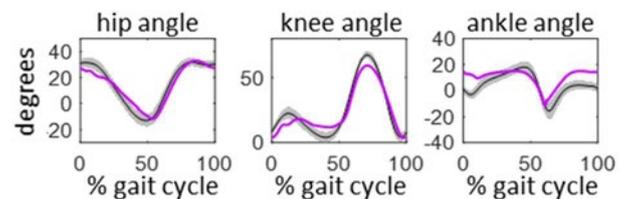

The combined cost function was built in two stages. First, each criterion was optimized independently, except for KneeInj since it became zero when optimized alone. Second, the criteria were ranked by average  $R^2$  and then added stepwise, in rank order, to create a combined cost function. At each step, criterion's cost-function weighting was systematically chosen to produce the best average  $R^2$ , yielding the final combined, weighted cost function.

### Results and Discussion

When optimizing for each criterion alone, the average  $R^2$  was highest for FGImpact, followed by HeadStab, CoT, and MusAct (Figure 1). Average  $R^2$  increased each step when combining the weighted criteria, yielding a combined cost function with an average  $R^2=0.70$  (Figure 1 & 2). CoT had the highest normalized weighting in the combined cost function.

**Figure 1:** The agreement with experimental data ( $R^2$ ) for each of the criteria separately and for the combined cost function.

**Figure 2:** Kinematics predicted by the combined cost function (purple) compared to experimental data (black=mean; grey area=sd)

### Conclusions

Tuning of the weightings in a cost function combining different criteria, in a stepwise approach, provided overall improved and acceptable agreement of the forward simulations of gait with experimental data. A next step is to validate the framework for pathological gait to be able to answer clinical what-if questions.

## Summary

We simulated walking with an ankle-foot exoskeleton to evaluate the predictive capability of a musculoskeletal model. Simulations were performed without prior knowledge of the experimental data. Predicted changes in muscle activity and metabolic rate were consistent with the direction, but not the shape or magnitude, of experimentally observed changes, while the simulation predicted some substantial changes in kinematics that were not observed experimentally.

## Introduction

Forward simulations of human walking are currently being developed with the aim to predict the effect of interventions, such as a wearable robotic device, on human locomotion [1]. Even though these simulations capture important features of human walking [1], the predictive capability is unclear. In many studies, experimental data used for validation are also incorporated within the simulation (i.e. as a tracking term [2] or to tune high-level parameters), which limits the conclusions that can be drawn about predictive validity.

Here, we used physics-based simulations to predict the effect of an ankle-foot exoskeleton on human walking and evaluated model predictions against experimental observations that were shared after predictions were made.

## Methods

We predicted walking with an ankle-foot exoskeleton using a framework for simulations of human movement [1]. A model (gait2392) was scaled to the subject [4]. The exoskeleton was modeled as rigidly connected to the foot and shank segments. Exoskeleton torque was a function of stride and was modeled as equal and opposite torques applied to the calcaneus and tibia. We predicted walking without the exoskeleton and with the exoskeleton in zero-torque mode and in active mode. Motions were predicted by minimizing a weighted multi-objective cost function consisting of (1) joint accelerations, (2) muscle activations, (3) metabolic energy [3], (4) passive forces and (5) actuators driving the arms while imposing average speed and periodicity of the movement [1].

We used integrated motion capture, electromyography and respirometry of one subject walking with and without bilateral ankle-foot exoskeletons, in zero-torque and assistance modes, to evaluate the simulations.

## Results and Discussion

Simulation predictions of muscle activity were consistent with experimentally observed reductions in average activity, though not the timing of these reductions (figure 1). Soleus and gastrocnemius groups exhibited the largest changes.

The simulation predicted changes in kinematics that were not observed experimentally. The increase in ankle ROM in the active condition was overpredicted (figure 1). The simulation underpredicted step width by about 10 cm in all simulations.

The predicted decrease in cost of transport in the active mode was close to the experimental value, but the increase in cost of transport due to wearing the exoskeleton in zero-torque mode was underpredicted (figure 1).

Differences between the simulated and observed effects of wearing an exoskeleton on kinematics and cost of transport could only partly be explained by modelling the step width imposed by the split-belt experiment and adapting the baseline muscle activity in the simulation. In the next iteration, we will use a novel assistance profile to evaluate whether these adaptations improve the predictions.

## Conclusions

Predictive simulations of human walking can anticipate some changes in muscle activity and energy consumption in response to ankle-foot exoskeleton assistance. Further development is needed for more accurate predictions, especially of metabolic energy and joint kinematics.

D) The simulation predicted changes in ankle angle in the active mode were not observed experimentally.

## Three-dimensional Knee Reduces Metabolic Cost and Joint Loading in Simulated Running

Ross H. Miller<sup>1</sup>, Matthieu B. Trudeau<sup>2</sup>

<sup>1</sup>Department of Kinesiology, University of Maryland, College Park, MD, USA

<sup>2</sup>Brooks Sports Inc., Seattle, WA, USA

Email: rosshm@umd.edu

### Summary

Optimal control simulations of running with various cost functions were performed with knee models allowing one or three degrees of freedom. The results suggest non-sagittal knee motions can reduce metabolic cost and joint loading.

### Introduction

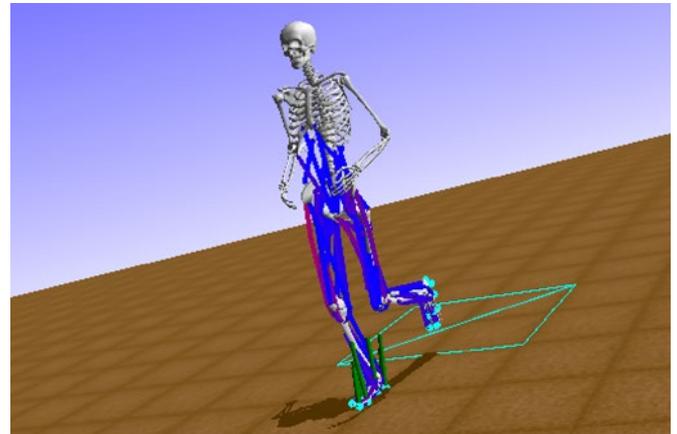

“Overuse” running injuries at the tissue level can be viewed as biomechanical events that exhaust the fatigue-life of the injured tissue [1]. The Habitual Motion Path (HMP) theory suggests that knee injuries may be averted by running in footwear that affords movement along a trajectory in 3-D joint space that resembles its path in other activities of daily living [2]. HMP may also relate to running performance, e.g. perhaps economy is worsened by deviations from the HMP. HMP is conceptually similar to the “cartilage conditioning” theory which argues osteoarthritis results from joint loads that are “too unusual” compared to loads the joint typically sustains [3]. However, HMP remains untested as a causal factor to running injury or performance.

Computer simulations are useful for estimating internal loads that relate more directly to tissue damage than variables like ground reaction forces and joint motions. Most previous simulations of running have used knee models with one degree of freedom, making it difficult to test theories like HMP on the knee specifically. Our purpose was to compare running performance- and injury-related outcome variables from optimal control simulations between models allowing one vs. three degrees of freedom at the knee. As the study was exploratory, no hypotheses were posted, but we examined as outcome variables the metabolic cost and knee contact force.

### Methods

Optimal control simulations of running were performed using a 3-D OpenSim model [4] (Fig. 1). Optimizations were performed in Moco software using direct collocation [5] to determine the muscle excitations and associated model states that minimized the cost function  $J = J_{track} + w \cdot J_{effort}$ , where  $J_{track}$  was the mean squared deviation from average human kinematic and ground reaction force data from instrumented gait analysis at an average speed of 3.2 m/s [6].  $J_{effort}$  was defined with several different forms, the sum of muscle excitations raised to various integer powers, with or without muscle-specific weighting by muscle mass. The coefficient  $w$  had the same value for all simulations and was set so that the metabolic costs were realistic ( $\sim 4$  J/m/kg).

For the 3-D knee, torque-angle functions softly limiting frontal and transverse ranges of motion were defined using

**Figure 1:** Modified Rajagopal model [4] in mid-stance from simulation of running at 3.2 m/s generated with Moco software [5].

cadaver data [7] and deviations of the frontal and transverse knee angles from zero were included in  $J_{track}$ .

### Results and Discussion

Regardless of the cost function or knee degrees of freedom, the model tracked the experimental data with average errors less than 0.6 standard deviations away from the target means.

Regardless of the cost function, both metabolic cost (0.9-6.8% lower) and peak knee contact force (0.5-1.2 bodyweights lower) were reduced with a 3-D vs. 1-D knee, primarily due to less quadriceps force: peak force was up to 12% lower with the 3-D knee. Compared to joint angles from a simulation of squatting with minimum effort, the non-sagittal knee angles in running deviated from the squatting joint angles by up to 7° with the 1-D knee, compared to 3° with the 3-D knee.

### Conclusions

A 3-D vs. 1-D knee reduced metabolic cost and knee contact forces even though the 1-D knee required no direct muscular effort to control non-sagittal motions. The theory that non-sagittal knee motions similar to habitual motions are beneficial for running performance and joint health warrants further attention. Suppressed or abnormal non-sagittal knee motions may cause unusual motions at other joints.

## Simulating Human Movements for Assistive Robotics

C. Karen Liu, Associate Professor of Computer Science, Stanford University

Unlike conventional robots, robots that physically assist humans need to embrace physical contacts and learn to utilize them for enabling human's activities of daily living. An immediate concern in developing such an autonomous and powered robotic device is the safety of human users during the early development phase when the control policies are still largely suboptimal. Learning from physically simulated humans and environments presents a promising alternative which enables robots to safely make and learn from mistakes without putting real people at risk. However, deploying such policies to interact with people in the real world adds additional complexity to the already challenging sim-to-real transfer problem. In this talk, I will present our current progress on solving the problem of sim-to-real transfer with humans in the environment, actively interacting with the robots through physical contacts. We tackle the problem from two fronts: developing more relevant human models to facilitate robot learning and developing human-aware robot perception and control policies. To contextualize our research effort, we develop a mobile manipulator to put clothes on people with physical impairments, enabling them to carry out day-to-day tasks and maintain independence.

## Micro-structured Hollow Fiber Membranes – Reducing the Main Transport Resistance in Membrane Oxygenators

<sup>2</sup>Institute of Engineering Design and Product Development, TU Wien, Vienna, Austria

Email: paul.ecker@tuwien.ac.at

### Summary

Micro-structured hollow fiber membranes allow an increase of the available gas exchange surface area and offer a great potential for oxygenator optimization. In this study, experimental and numerical methods were used to investigate the flow within fiber packings with various fiber geometries. By calculating the local Sherwood number, we demonstrate that there is a tradeoff between increased surface area and flow stagnation zones and propose an optimized geometry.

### Introduction

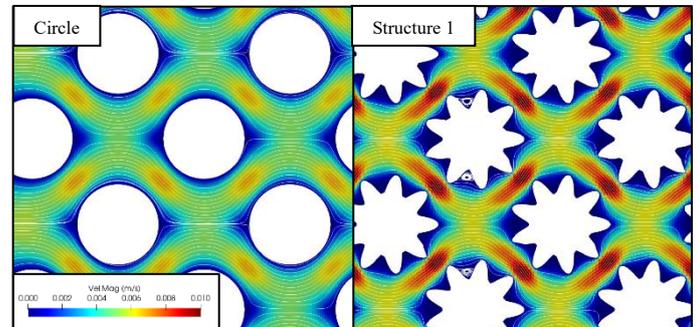

Enhancing mass transfer in membrane oxygenators is a key point in designing more efficient products. One way to achieve this is the use of micro-structured fiber geometries that offer an increased surface area [1]. Experimentally validated, numerical simulations offer the possibility to estimate mass transfer capabilities of different fiber geometries and arrangements [2].

### Methods

Several fiber geometries with varying surface area, yet equal average diameter, were created and set in a staggered arrangement, mimicking the flow inside a membrane oxygenator. In order to quantify the mass transfer capability of each fiber geometry, the local Sherwood number ( $Sh = k_c d/D$ ) was calculated on the membrane surface using computational fluid dynamics (CFD). Steady state simulations were carried out using the open source CFD code OpenFOAM®. Experimental validation of the numerical results was done by micro particle image velocimetry ( $\mu$ PIV) measurements. For this purpose, an acrylic test channel resembling the investigated fiber structure was built and experiments with various Reynolds numbers were performed. Velocity profiles at the center plane of the channel were extracted and compared to the numerical results. Based on the obtained Sherwood numbers, the CO<sub>2</sub> removal performance was predicted using the specific area of the different geometries.

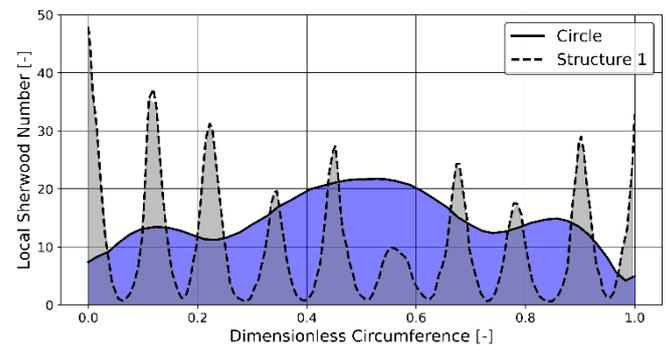

### Results and Discussion

The calculated flow field for two different fiber geometries is given in Figure 1. In comparison to the circular geometry, Structure 1 has an increased specific area of about 80 %, however also a less uniform velocity distribution with areas of high velocity between the tips of the fiber and areas of low velocity inside the cavities. Areas of low velocity are of importance in membrane separation processes as they lead to concentration polarization, i.e., regions that obstruct mass transfer due to the lack of convective transport.

**Figure 1:** CFD result of the flow field for two different structures. Fluid flow is from left to right.

This is again reflected by the local Sherwood number along the circumference of the structures (Figure 2). Due to the low velocities, convective mass transfer is close to zero inside the cavities of Structure 1. Benefits of increased surface area are diminished by adverse flow structures if membrane module geometries are small.

**Figure 2:** Local Sherwood number along the circumference of two structures.

### Conclusions

Improving mass transfer by increasing membrane surface area is a feasible way to optimize oxygenators. Validated CFD simulations aid in the search for the best possible fiber geometry and arrangement.

Email: [dbj893@student.bham.ac.uk](mailto:dbj893@student.bham.ac.uk)

### Summary

This paper uniquely investigates how multi-muscle coordination in the neck is modified in people with chronic neck pain (CNP) through intermuscular coherence analysis.

### Introduction

Neuromuscular impairments are frequent clinical features in patients with CNP; studies using electromyography (EMG) have revealed altered behavior of the neck muscles (e.g., increase co-activation, reduced specificity of activity, delayed onset) in patients with CNP compared to asymptomatic individuals [1]. We hypothesized that the connectivity between neck muscles will be modified in people with CNP. Verification of this hypothesis would provide further evidence of a common neuromuscular adaptation in people with CNP.

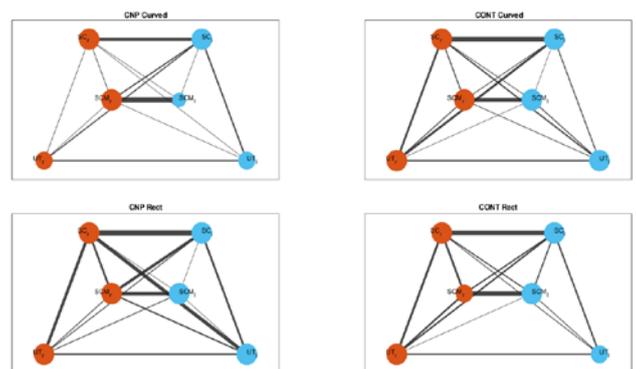

### Methods

Twenty asymptomatic individuals and 20 people with CNP were recruited for this study. Participants were asked to walk barefoot at a self-selected speed along a curvilinear path (radius 1 meter) and along a rectilinear path (6 meters). EMG was recorded from the upper trapezius (UT), splenius capitis (SC), and sternocleidomastoid (SCM) muscles bilaterally.

Intermuscular coherence was used to map functional interactions between multiple muscles by the calculation of magnitude squared coherence (MSC). MSC generates a value of connectivity strength for each pair of filtered EMG signals at a specified frequency band, resulting in a weighted adjacency matrix per subject. This matrix is then thresholded in order to emphasize only significant connections and remove those that can obscure them. A proportional threshold was used to maintain the same connection density across participants. Once the average coherence matrix was obtained for each group, the connectivity between muscles can be represented graphically. Five frequency bands were considered in the calculation of the connectivity matrices to encompass the whole spectrum:  $\delta$  (1–4 Hz),  $\theta$  (4–8 Hz),  $\alpha$  (8–12 Hz),  $\beta$  (12–25 Hz), and high  $\beta$  (25–30 Hz). To compare functional networks, we focused on strength and betweenness centrality (BC) features. BC identifies hot points of high information traffic and it is calculated as the proportion of shortest paths between all node pairs in the network that passes through a given index node. Strength is the sum of weights of links connected to the node that provides information about how strong the connections are between muscles [2].

### Results and Discussion

The topology of complex networks was analyzed to compare functional interactions between neck muscles across different conditions and frequencies for both groups. The BC showed significance during curvilinear walking in the  $\delta$  band between those with and without CNP ( $p=0.021$ ). For rectilinear walking, BC was not significantly different between groups at the same frequency range ( $p=0.068$ ). In contrast, the strength was not significant between groups. No significant differences were found in other frequency bands. Figure 1 shows neck muscle networks in the  $\delta$  band for curvilinear and rectilinear walking where statistical differences were found. This band is the most relevant for the generation and control of force [3]. As can be seen in this figure, the muscle network in those with CNP presents thinner edges and a smaller number of connections, which suggests a weaker connectivity network between muscles during curvilinear walking [4].

**Figure 1:** Functional networks of CNP and control groups during curvilinear and rectilinear task at  $\delta$  band. Node's size represents the degree, which is the number of edges connected to other nodes (muscles). Connection strength is reflected by the width of the edge. Orange nodes represents left side muscles and blue nodes the right-side ones.

### Conclusions

This study suggests different muscle synergies in people with CNP and the presence of task-specific muscle synergies that appear only when walking along a curved path.

### Summary

Parkinson's disease (PD) patients frequently experience an impaired facial expression with respect to healthy control (HC) subjects. In order to quantify the degree of hypomimia, we propose a preliminary assessment of facial expressivity using a face tracking methodology based on the Facial Action Coding System (FACS) [1]. A face mobility index is defined and compared between healthy and PD subjects in the six basic emotions.

### Introduction

PD is a neurodegenerative disorder characterized by motor and non-motor symptoms. Among other features, hypomimia is considered one of the clinical hallmarks of this disorder [2]. However, quantitative measures of hypomimia are not currently available. FACS encodes changes in facial appearance by means of action units (AUs): AUs are associated with the contraction of specific facial muscles and completely describe the human basic emotions (anger, disgust, fear, happiness, sadness, surprise and neutral) [3]. Nowadays, FACS-based face tracking algorithms are mainly used for emotion recognition and classification, but they are not investigated in the medical research field. The aim of our study is to conduct a preliminary assessment to compare face mobility of HC and PD subjects exploiting a face tracking approach. Therefore, we propose a quantitative and easy-to-interpret index that can express the effects of the disease on the movement of face muscles involved in basic emotion expressions.

### Methods

Data from 17 HC subjects (10 women and 7 men; mean( $\pm$ SD) age: 66.53( $\pm$ 7.16) years) and 29 PD individuals (13 women and 16 men; mean( $\pm$ SD) age: 68.48( $\pm$ 7.80) years) were analyzed. Frontal face videos of the subjects were recorded while they were instructed by a clinician to randomly perform the following facial expressions: anger, disgust, fear, happiness, sadness, and surprise. The neutral face expression was also acquired. Subjects were comfortably seated with a white background behind them at a distance of 1.36 m from a commercial camera placed at eye level. From the acquired videos, four frames were extracted per each expression. Based on the FACS encoding system, a set of 56 facial landmarks was defined and tracked in the 2D image space per each expression and frame, using a self-developed software (*TrackOnField*, *BBSof S.r.l.*) [4]. These coordinates were used to compute 35 Euclidean distances. Per each emotion, the ratio between the obtained distance and the one of the

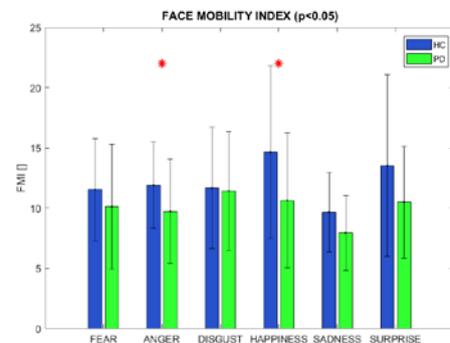

neutral expression was derived (*ratio*). Values outside the interquartile range were excluded from the analysis. Moreover, a face mobility index (FMI) was defined and calculated per each subject as follows:

$$FMI_j = \frac{\sum_{i=1}^{n\_dist} |1 - ratio_j| \cdot 100\%}{n\_dist} \quad j = 1 \dots 6$$

Per each emotion ( $j=1 \dots 6$ ) the FMI was determined as the summation of the percentage deviation from the neutral expression ( $1-ratio$ ) of all the distances; the FMI was then normalized to the number of available distances ( $n\_dist$ ). The non-parametric Kruskal Wallis test ( $p < 0.05$ ) was performed in order to compare the FMI in the two cohorts of subjects.

### Results and Discussion

As expected, results showed a greater face mobility in HC subjects with respect to PD patients. Furthermore, statistically significant differences were highlighted in two expressions: anger and happiness (Figure 1).

**Figure 1:** Comparison of FMI between HC and PD for the 6 emotions. The zero value corresponds to the neutral expression.

### Conclusions

Besides some limitations (numerosity of the sample, subjectivity in the interpretation and expression of the emotion), promising results were achieved. The proposed face mobility index could be used as a quantitative measure for the degree of hypomimia in PD patients.

### Summary

A biosensor can detect as well as quantify the concentration of the biomarker in the body fluid, making it easy to monitor and or track the progression, making it effective to treat and change the course of treatment. Therefore, a microfluidic integrated electrochemical biosensor was fabricated to detect on-set and monitor the progression of the disease.

### Introduction

Osteoarthritis (OA) is a common bone and joint disease and a leading cause of disability worldwide [1,2]. Biochemical markers of OA such as cartilage oligomeric matrix protein (COMP), C-terminal telopeptide, have been identified in bodily fluids, such as blood, and synovial fluid that are equally reliable be equally reliable for diagnostic and prognostic purposes as imaging technique [3]. The concentration of these markers classifies individuals as diseased or not, and its severity. Traditional ELISA-based analytical techniques detect biomarkers from the body fluids but cannot monitor the change in the biochemical signals. Conventional ELISAs-based analytical techniques can detect biomarkers from the body fluids but cannot monitor the change in the biochemical signals. Therefore, a more versatile detection system must be developed that can overcome the shortcoming of ELISAs and fulfill the clinical needs of OA. Sensors are compatible with different bodily fluids and detects up to picogram/mL analytes' concentrations. Microfluidics minimizes the use of synovial fluids and similar samples to a few microliters. Therefore, a microfluidic-integrated electrochemical biosensor must be developed for OA to detect and diagnose early-onset and monitor disease progression.

### Methods

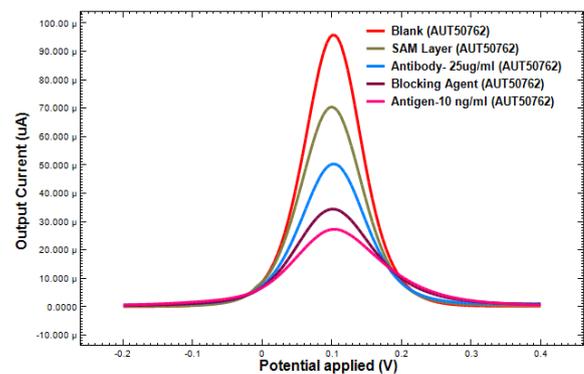

The microfluidic chip was fabricated using Polymethylmethacrylate (PMMA) sheet. The channels were designed in AutoCAD (student version), cut and engraved using LASER cutter. The active detection region was designed with the aim of working with 25 ul of sample.

The Biosensor was fabricated using a commercially available 3 electrode system with gold as active region Thiol-based self-assembled monolayer (SAM) surface modification was used to modify the surface of active region to facilitate immobilization of COMP specific antibody. Later, to block non-specific binding 0.01% bovine serum albumin was used as a blocking agent followed by 10 ng/ml COMP protein prepared in PBS that binds with the antibody. After incubating it for 30 min, the surface was cleaned with PBS and ready for

differential pulse voltammetry (DPV) measurements in the presence of redox probes.

### Results and Discussion

Atomic force microscopy (AFM), and Scanning electron microscope (SEM), and Fourier transform infrared spectroscopy (FTIR) confirmed the successful surface modification of the biosensor. Electrochemical characterization using the DPV provides currents recorded for each step of the biosensor creation (Figure 1). The decreasing trend in the current peaks is indicates the active region's modification to a COMP-biosensor.

**Figure 1:** Characterization of the COMP biosensor by recording the DPV response in the presence of redox probes. Au bare (Red), Surface modification (green), COMP antibody (blue), and BSA blocking (brown), 10ng/ml COMP antigen.

The difference in the current peaks for the blocking step and 10 ng/mL COMP protein indicates the biosensor's ability to detect the quantify the target within the microfluidic chip.

### Conclusions

The microfluidic biosensor fabricated is capable of selectively detecting the biomarker of OA by using just 25microlitre of sample. This can be used as a tool to monitor the progression of the disease by small sample volume.

### Summary

Percutaneous cement discoplasty is a spinal surgical technique that has rarely been evaluated outside the clinical setting. This study aimed at developing an ovine model framework to allow testing and optimization of discoplasty in a controlled laboratory environment.

### Introduction

Percutaneous cement discoplasty (PCD) is a minimally invasive surgical method developed for treating advanced degeneration in elderly patients whom, due to co-morbidities, cannot undergo major open surgery, in this case spinal fusion [1,2]. The procedure consists of the injection of poly(methyl methacrylate) (PMMA) into a disc via a Jamshidi needle entering either through the Kambin's triangle [1], or the vertebral endplate [2]. Insertion from the endplate avoids circumferential perforation of the disc.

To the best of the authors' knowledge, only one study has reported on the biomechanics of discoplasty [3]. In that study, the method of injury did not entail an overall annulus degeneration or an accurate representation of the vacuum phenomena. Therefore, the present study aims to develop a more clinically representative framework to explore PCD in a controlled laboratory setting. Papain-induced disc degeneration was used to this end. The obtained model could allow for optimization of the surgical procedure, materials used, and investigate the effect on the biomechanics of the spinal segments regardless of the needle's entry method.

### Methods

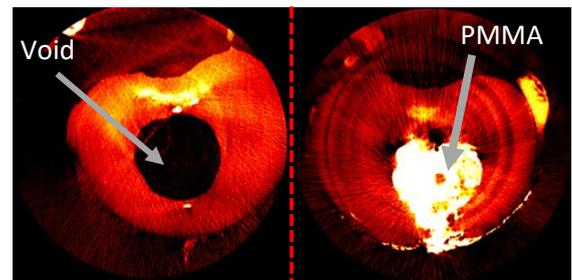

Female sheep spines were cleaned, dissected and segmented to functional spinal units (FSU). They were submerged in phosphate buffer solution (PBS) and 1%vol penicillin-streptomycin for 24 h before testing. FSUs were scanned in a tabletop Skyscan 1172 CT and subsequently mechanically tested in dry conditions at a rate of 5mm/min on an MTS 858 Mini Bionix T/II.

A papain solution of 60 U/ml was prepared using a previously reported protocol [4]. Approximately 100  $\mu$ L was injected into the disc. The volume injected depended on the intradiscal pressure and size. The FSU was incubated at 60°C for 16 h. The FSUs were then rehydrated, scanned, and mechanically tested.

An orthopaedic surgeon (K.P) proceeded to perform the PCD procedure on the FSUs. A Jamshidi needle was guided using fluoroscopy into the intradiscal void. Vertebroplastic V-Steady™ PMMA bone cement (G21 srl, San Possidonio, Italy) was prepared and injected through the needle. The cement was left to harden for 24 h in PBS. The FSU was scanned and mechanically tested one final time.

### Results and Discussion

Ten FSUs were used to optimize papain injection volume, as determined by comparison to the vacuum phenomena found in advanced degeneration in PCD candidate patients [5]. Figure 1 shows an L1-L2 FSU with a void created after degeneration with papain (left) and after treatment with cement (right). Three FSUs were successfully injected and scanned.

**Figure 1:** Shows CT images of a L1-L2 segment after degeneration with papain (left) and after treatment with cement (right).

The treated disc demonstrated increased mechanical stability, i.e. a significant increase in stiffness as opposed to the injured disc, confirming a positive biomechanical effect of the procedure in this aspect.

Future work includes increasing the sample size for statistical relevance, and further biomechanical investigation of treatment effects, e.g. after using different types of bone cements.

### Conclusions

A methodology for the mechanical assessment of percutaneous cement discoplasty was developed. Early results show clinical relevance of the voids created in the intravertebral discs, and a biomechanically promising treatment demonstrated by an increased stiffness of the spinal segments.

### Summary

Some terrestrial beetles are able to walk underwater, presumably by trapping an air bubble around their feet. The bubble is thought to help in adhesion via surface tension forces, however its significance remained unclear. To investigate the exact role of the bubble, we performed *in-vivo* underwater adhesion measurements of a ladybug beetle's leg, as well as made theoretical estimates based on a simple model. Our experiments revealed that on a hydrophobic substrate, even without a bubble, the beetle exhibited similar adhesion underwater to that in air. On a hydrophilic substrate, underwater adhesion was significantly reduced, with or without a trapped bubble. Our results demonstrates that the wetting properties of the fluid secreted by the leg determines the insect's adhesion in both air and underwater conditions.

### Introduction

Many small animals are able to adhere to smooth and slippery surfaces by using specialized adhesive pads on their feet, often consisting of a dense array of hair-like structures. The tip of each hair secretes an oily fluid, which promotes adhesion via surface tension, otherwise known as capillary forces. Typically, reversible and reliable underwater adhesion is complicated to achieve. However, a previous study [1] has revealed that terrestrial leaf beetles can attach quite well to surfaces underwater by trapping an air bubble around their pads. It has been hypothesized that a combination of capillary forces due the air bubble and hair contact within the de-wetted area results in its adhesion underwater. In this study, we aim to provide clarity on the source of insect adhesion underwater and the exact role played by the trapped bubble by a combination of experiments and theory.

### Methods

Normal adhesion force measurements on a restrained leg of a live ladybug beetle (*Coccinella septempunctata*) were performed against smooth glass (hydrophilic) and fluorinated (PFOTS; hydrophobic) surfaces. Underwater measurements were also done in the absence of a trapped bubble by using degassed water.

The adhesive pad was then modeled as an array of cylindrical hairs with a certain amount of oil at the hair tips. Net adhesion was estimated as the sum of the capillary force contributions due to the oil bridges in contact with the substrate. Here, individual capillary forces due to the oil and the trapped bubble were calculated from Surface Evolver simulations. All model parameters were fixed corresponding to the ladybug beetle.

### Results and Discussion

Experimental measurements (Figure 1) show that underwater adhesion on PFOTS surface is significantly larger than on glass. Here, the presence of a bubble does not appear to influence adhesion. But on glass, underwater adhesion is significantly lower than in air. The bubble's presence only slightly improves the adhesion underwater in this case.

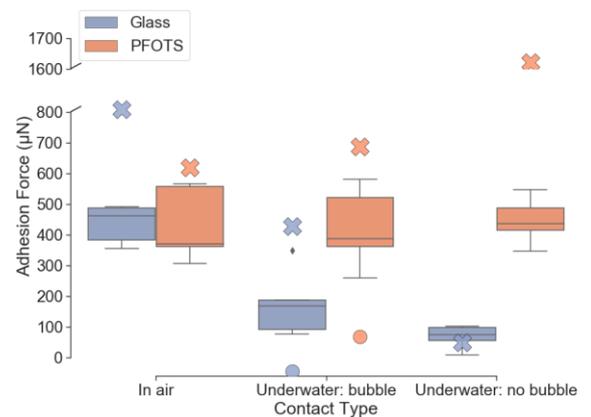

Figure 1: Single leg pull-off force of a ladybug beetle.

Theoretical predictions of the ladybug's adhesion from the model follow our experimental results ('x'). The model further shows that the bubble by itself has a negligible capillary contribution to the adhesion ('o'). The observed trend can be explained by the different oil interfacial tension and contact angles with each substrate in air and underwater, which determines the capillary adhesive force in each case. A similar reasoning also well predicts previously reported underwater measurements in geckos [2], which highlights the possibility of capillary contributions to gecko adhesion.

### Conclusions

Animals can use its oily fluid secretions to adhere to surfaces even in underwater conditions. Due to the small contact angles of the oil to hydrophobic surfaces underwater, the animals achieve good adhesion even without a trapped bubble. Future studies should characterize the fluid secretion's interfacial properties with a substrate to better quantify the animal's adhesion, which may inspire reversible underwater adhesives.

## Relatively Shorter Muscle Lengths Increase the Metabolic Rate of Cyclic Force Production

### Summary

During locomotion, force-producing leg muscles are almost exclusively responsible for the entire body's metabolic rate. Animals can change the operating lengths of their leg muscles by altering body posture, kinetics, or the structural properties of their biological tissues via chronic exercise. Currently, it is uncertain whether muscle operating length has a measurable metabolic effect during cyclic locomotion-like contractions. Thus, we quantified the metabolic rate of human participants as they cyclically produce two distinct ankle moments at three separate ankle angles (90°, 105°, 120°) on a fixed-position dynamometer using their soleus. We found that increasing ankle angle decreased minimum soleus operating length by 17% ( $p < 0.001$ ) and increased metabolic power by 208% ( $p < 0.001$ ). Because we found an association between participant muscle fascicle operating length and metabolic power ( $p < 0.001$ ), increasing the length of muscles that operate on the ascending-limb of their force-length relationship can likely reduce whole-body metabolic rate during locomotion.

### Introduction

During locomotion, force-producing leg muscles are almost exclusively responsible for the whole-body's metabolic rate. One parameter that is not often considered to have a *measurable* effect on whole-body metabolism is relative muscle length. Perhaps, that is because muscle length is typically studied during isometric contractions [1], and it is difficult to isolate the metabolic effect of muscle length from other parameters during locomotor-like contractions (e.g., mechanical work). To help link locomotion biomechanics to metabolic rate, our goal was to determine the metabolic influence of cyclically producing force at different muscle fascicle lengths (Fig. 1). We hypothesized that cyclically producing the same average force at relatively shorter fascicle lengths would increase metabolic rate.

**Figure 1.** Three ankle angles (90°, 105°, and 120°) with the corresponding hypothetical soleus fascicle operating length and its region on a force-length curve.

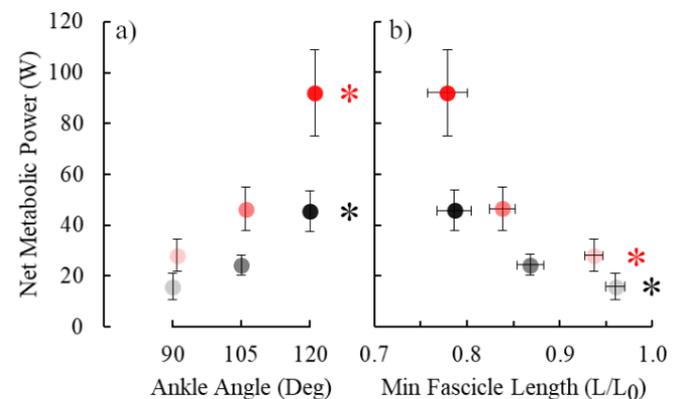

### Methods

Nine human participants cyclically produced ankle moments for five-minutes at two-distinct magnitudes and at three separate ankle angles (90°, 105°, 120°) on a fixed dynamometer using their soleus. During these trials, we collected rates of oxygen

uptake and carbon dioxide production, dynamometer torque data, motion capture data, soleus fascicle length via ultrasonography, and surface electromyography. We used linear mixed models and regressions to test the associations between independent and depend variables.

### Results

Participants produced two distinct cycle average ankle moment levels: 4.85 Nm and 6.58 Nm ( $p < 0.001$ ) (black & red symbols, respectively; Fig. 2). In each level, the duration of active force production ( $p \geq 0.158$ ), force production cycle frequency ( $p \geq 0.375$ ), and cycle average ankle moment ( $p \geq 0.678$ ) were indistinguishable across ankle angles. Increasing participant ankle angle reduced their minimum soleus fascicle length by 17% ( $p < 0.001$ ) and increased metabolic power by 208% ( $p < 0.001$ ) (Fig. 2). Across moment levels, metabolic power was not driven by fascicle mechanical work ( $p = 0.591$ ), fascicle force rate ( $p \geq 0.235$ ), or active muscle volume ( $p \geq 0.122$ ). Supporting our hypothesis, net metabolic power was correlated with participant average soleus fascicle operating length ( $r = -0.72$   $p < 0.001$ ).

**Figure 2:** Average  $\pm$  SE net metabolic power versus a) ankle angle & b) minimum soleus fascicle length. Black and red symbols indicate lower and higher ankle moment levels, respectively. Asterisks (\*) indicate statistical significance ( $p < 0.05$ ).

### Conclusions

Enabling active muscles to operate further up the ascending limb of the force-length curve may decrease metabolic rate during locomotion. These findings may help resolve why metabolic rate differs across and within animal species, in addition to informing biomechanical interventions aimed at augmenting locomotor performance.

## Summary

To better understand musculoskeletal soft tissue (MST) strains in dynamic conditions *in vivo*, we have developed an implantable strain sensor capable of transmitting high-frequency data wirelessly across the skin. In this study, we surgically implanted one sensor on the quadriceps muscle of a sheep cadaver. Wireless measurements from the sensor indicated peak strains of 7.8% in the muscle during passive flexion of the stifle joint.

## Introduction

Measurement of *in vivo* MST is critical for investigating muscle-tendon mechanics and informing data-driven treatment [1]. We developed a novel implantable strain sensor that innovates on existing designs through wireless data transmission and minimal impingement with neighboring tissues [2]. To prepare for *in vivo* applications, we performed a surgical implantation and demonstrated its efficacy in cadaveric sheep measurements.

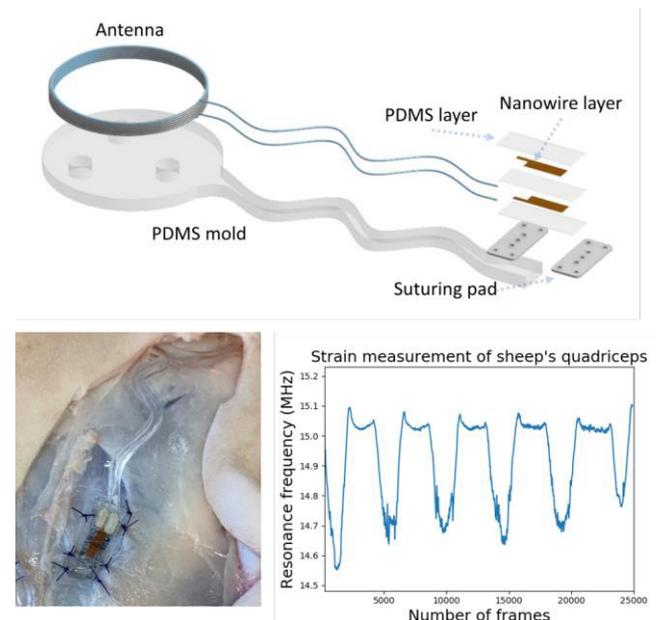

## Methods

A stretchable capacitive sensor was fabricated by embedding two nanowire layers within polydimethylsiloxane (PDMS). The capacitive sensor was connected to a coil antenna to form a passive inductor-capacitor-resistor resonator, and bonded to laser-cut PMMA suturing pads (Fig. 1, top). A custom pre-strain device facilitated suturing the sensor to muscle fascia and tendons. A readout system was developed to wirelessly excite the sensor and measure its resonance frequency (RF) across 1-2 cm of tissue with a rate up to 1024 Hz. Stretching the sensor resulted in a linear change in its RF over a 0-30% strain range, enabling wireless assessment of *in vivo* tissue strains. The sensor was calibrated using a custom stretching device. A 6 cm skin incision allowed the sensor to be implanted on the quadriceps muscle of a sheep cadaver (Fig. 1, bottom left), where the strain sensor was sutured onto the fascia of quadriceps muscle in a slack position. Subcutaneous pockets were formed to position the sensor coil, and the incision was closed. The lower limb was then manually manipulated through its full range of motion while the sensor RF was wirelessly measured across the skin.

## Results and Discussion

The sensor design and surgical procedure enabled robust fixation to the MST. The wireless readout successfully

recorded the signal across the skin without disruption throughout the test. Post-experiment sensor calibration determined the sensor's sensitivity of 0.046MHz/mm. The peak strain in the quadriceps fascia during passive movement was 7.8%, which was measured at peak flexion of the stifle joint (Fig. 1, bottom right).

**Figure 1:** Top, Sensor structure; Bottom left, *In vitro* sensor implantation; Bottom right, Changes of sensor RF during test.

## Conclusions

The successful surgical procedure and excellent sensor performance demonstrates that the stretchable sensor is ready for upcoming *in vivo* sheep measurements to investigate biocompatibility and muscle-tendon kinetic interactions during locomotion.

## Acknowledgments

This study was funded by the Swiss National Science Foundation Project 182241.

## Morphological determinants of glenohumeral mobility in primates

Erin C.S. Lee<sup>1</sup>, Nathan M. Young<sup>2</sup>, Michael J. Rainbow<sup>1</sup>

<sup>1</sup>Mechanical and Materials Engineering, Queen's University, Kingston, Canada

<sup>2</sup>Orthopaedic Surgery, University of California, San Francisco, USA

Email: erin.lee@queensu.ca

### Summary

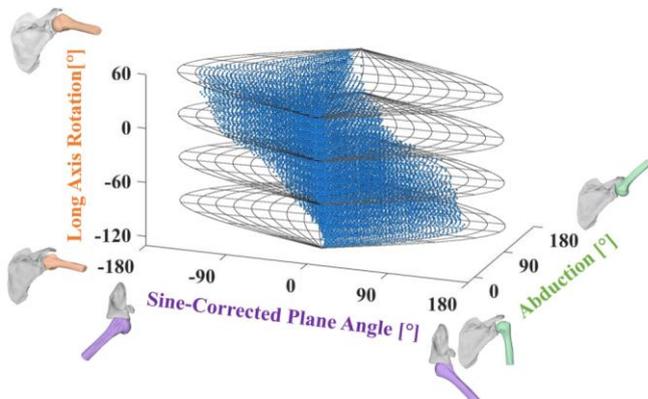

Glenohumeral features are frequently used to infer functional demands in primates. The interactions among specific shape features and range-of-motion have been inferred but not quantified. Here, we use a congruence-based model to predict glenohumeral mobility across primate species and test its association with specific morphological features. Only glenoid orientation and glenoid surface area were correlated with mobility, indicating that the morphological pathways enabling mobility are more complex than previously assumed.

### Introduction

Primate glenohumeral features are frequently used to infer functional demands in living and extinct taxa. For example, traits such as a relatively large humeral head, an oval-shaped glenoid, and a cranially-oriented scapula are found in suspensory apes and are thus assumed to enable enhanced range-of-motion (ROM) [1]. However, experimental ROM data opposes these assumptions [2], and the biomechanical pathways through which these features alter mobility remain largely untested. Computational models capturing the interaction between morphology and mobility can provide insight into glenohumeral mechanics and augment the current framework for mapping form-to-function.

### Methods

Here, we use a 6dof model to estimate glenohumeral ROM, and test if specific morphological features are correlated with enhanced mobility. We acquired scapula and humerus meshes of sixteen subjects sampling living and extinct primate taxa (including lorines, suspensory monkeys, and apes) and used a novel congruence algorithm to simulate rotational positions spanning abduction, abduction plane angle, and long-axis rotation. The ROM was defined as positions where the humeral head and glenoid maintain congruence. We visualized these positions in Euler space and quantified *mobility* - a function of the size of the ROM (Figure 1) [3].

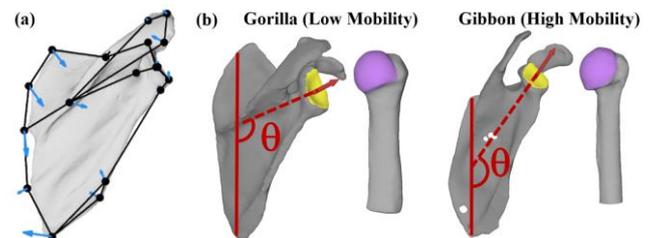

**Figure 1:** ROM positions of fossil hominin *Australopithecus sediba*. Plane angle is sine-corrected to account for distortion [3].

To determine morphological features important for mobility, we identified 22 and 20 landmarks on the scapula and proximal humerus, respectively. Following Procrustes superimposition, we regressed the landmark coordinates on mobility to visualize overall shape changes associated with enhanced ROM. Informed by the landmark visualization and long-held assumptions, we measured eight morphological parameters on scaled bone meshes and performed linear regression on mobility as a function of each parameter.

### Results and Discussion

Predicted mobility was consistent with *a priori* expectations regarding locomotor repertoire, as mobility increased with suspensory behaviour. Contrary to previous assumptions, only two of the eight measured parameters – high cranial angle ( $p=0.01$ ,  $R^2=0.38$ ) and low glenoid surface area ( $p<0.03$ ,  $R^2=0.30$ ) – were associated with mobility (Figure 2). The landmark regression revealed potential factors for mobility requiring further investigation including acromion projection, humerus tubercle size, and glenoid curvature.

**Figure 2:** (a) Scapula landmarks and wireframe of mean shape, with blue arrows indicating landmark trajectories as mobility increases. (b) Comparison of least and most mobile subjects. The eight measured parameters were cranial angle (red) defined as the angle between the medial border and glenoid normal, glenoid surface area (yellow), humeral articular surface area (purple), critical shoulder angle, glenoid width, glenoid height, glenoid aspect ratio, humerus-to-glenoid surface area ratio, and humeral head radius.

### Conclusions

Our congruence-based ROM predictions indicate that the morphological pathways enabling glenohumeral mobility are complex. Cranial angle and glenoid surface area are associated with mobility, but other features previously used to infer range-of-motion are not. Identifying shape features that best explain mobility in primates is necessary for reconstructing upper limb function in fossil taxa and may provide insight into why scapula shape is associated with shoulder injury in modern humans [4].

## Lateral stability and the frontal shape of land animals

Neelima Sharma<sup>1,\*</sup>, Madhusudhan Venkadesan<sup>1,§</sup>

<sup>1</sup>Department of Mechanical Engineering and Materials Science, Yale University, New Haven, CT, USA

Email: \*[neelima.sharma@yale.edu](mailto:neelima.sharma@yale.edu), §[m.venkadesan@yale.edu](mailto:m.venkadesan@yale.edu)

### Summary

Among land animals, insects sprawl, small mammals crouch, and large mammals are upright, suggesting a scaling of frontal shape with size. We propose a scaling law for the frontal shape based on lateral stability considerations, governed by statistics of unevenness of natural terrain. Natural terrain is more uneven at the scale of small insects than larger animals. Therefore, to remain stable, we hypothesize that smaller land animals must have a landscape frontal profile, whereas larger animals can be portrait-shaped for stability. Using known terrain statistics across a range of sizes, we quantify frontal shape using the aspect ratio ( $a$ ), the ratio of the base width to the center of mass height, and find that it scales with mass ( $m$ ) such that  $a \propto m^{-n}$ , where  $n=0.17$  for  $a \ll 1$  and  $n = 0.36$  for  $a \gg 1$ . Data from 369 species varying over  $10^8$ -fold in mass follow the predicted scaling and support the stability hypothesis.

### Introduction

Control of balance during terrestrial locomotion is crucial to prevent falls, catch prey, and avoid predators. Lateral stability relies on the modulation of stance-width, so that wider is more stable [1]. A ubiquitous source of perturbations to lateral stability is the earth's uneven terrain. We hypothesize that animals have evolved their frontal shape to remain passively stable against the random height variations of natural terrain.

### Methods

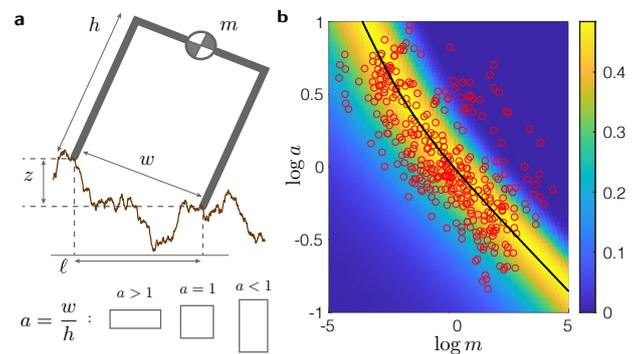

Natural terrain are well-approximated by a fractional Brownian process, namely a random process with fractional Gaussian increments [2]. The variance of the height difference  $z$  between two points that are horizontally separated by a distance  $l$  is given by  $E[z^2] \propto l^{2H}$ , where  $0 < H < 1$  is the fractional exponent. Past measurements of natural terrain have characterized the unevenness using such a stochastic model and estimated values for  $H$ .

We consider an animal whose center of mass is at a height  $h$  above the ground, has width  $w$  for its base of support, and fore-aft length  $d$ . Its mass  $m \propto dwh$ , and the fore-aft length is known to scale according to  $d \propto m^{1/3}$  [3]. These yield a relationship between mass and frontal plane dimensions. In order to remain barely stable, the critical angle of lateral tipping depends on the frontal aspect ratio  $a = w/h$ . When the tilt induced by the terrain  $z/l$  equals this critical angle, the animals is at the edge of becoming unstable (Figure 1a). We derive the scaling law for a critically stable animal and find  $a \propto m^{-n}$ , where  $n=0.17$  for  $a \ll 1$  and  $n = 0.36$  for  $a \gg 1$ . In addition to a scaling for a typical animal, we derive a probability landscape for marginally stable animals as a function of their  $m$  and aspect ratio  $a$  (Figure 1b).

We collected data for the aspect ratio of the front profile and mass for 369 animals. Photographs of front profiles were analyzed to calculate the aspect ratio using Fiji (Version 1.0).

### Results and Discussion

Data show systematic scaling of the aspect ratio with animal mass across over eight orders of magnitude such that small animals sprawl and larger animals are upright. The predicted scaling law and the probability densities agree with the trend in the data (Figure 1b).

**Figure 1:** a. Terrain height perturbations inform the critical aspect ratio of the animal under the stability hypothesis. b. Data from 369 animals (red dots) follow the predicted scaling (black curve) and probability densities (heatmap) of aspect ratio and mass.

### Conclusions

The frontal profile of diverse taxa, spanning a large range of body masses and habitats show systematic variation with mass in agreement with the scaling law derived using terrain unevenness statistics alone. The mean profile and the spread are consistent with the model. Underlying the model is assumption that marginal stability, and not maximal stability, is the driving factor. Although wider is generally more stable, being wide incurs other costs such as increased muscle stresses and metabolic energy for locomotion [4].

# Endoprosthesis size optimizes impaction force and circumferential stress in transtibial intramedullary prostheses

Carolyn E. Taylor<sup>2,3</sup>, Heath B. Henninger<sup>2,3</sup>, Kent N. Bachus<sup>1,2,3</sup>

<sup>1</sup>Department of Veterans Affairs, Salt Lake City, Utah, United States of America

<sup>3</sup>Department of Biomedical Engineering, University of Utah, Salt Lake City, Utah, United States of America

Email: [carolyn.taylor@utah.edu](mailto:carolyn.taylor@utah.edu)

## Summary

Finite element analysis was used to estimate the force required for impaction and the circumferential stress around a conical endoprosthesis similar to those used for percutaneous osseointegration (OI) attachment of prosthetic limbs. This analysis revealed that there is an optimal size in each bone where force is maximized and stress minimized to improve initial fixation and decrease chances of fracture.

## Introduction

Percutaneous osseointegration (OI) as a means of prosthetic limb attachment has experienced growing popularity with six systems in use worldwide. All of these devices were initially developed for transfemoral amputations, but many have been used in the tibia [1, 2] without translational research to indicate either similar, or better clinical results. While there has been some success, continued reports of aseptic loosening [3] indicate that tibia-specific endoprosthesis design may be needed for transtibial amputation patients.

This research examines the observations of cortical bone fracture during implantation of the endoprosthetic stem, occurring from excessive circumferential cortical stresses resulting from excessive impaction force.

## Methods

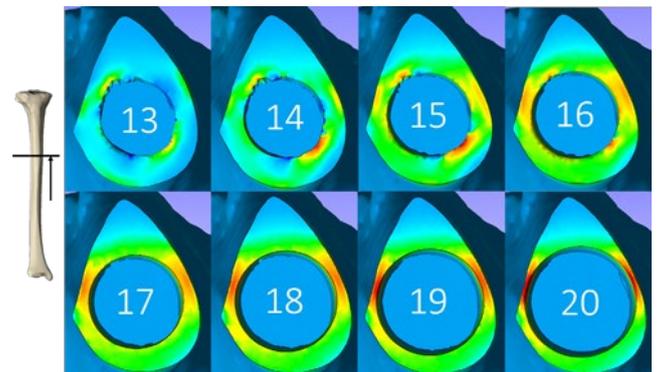

Axial CT scans were collected with a calibration phantom (Mindways Software Inc., Austin, Texas) on three cadaver tibias (18, 34, and 46yr Caucasian males, 173, 188, and 183 cm tall, 86, 75 and 91 kg, respectively). 3D reconstructions were virtually amputated at 40% residual length and underwent a virtual surgical protocol to place an implant [4].

Bones were meshed with a coarse mesh proximally (1.2 mm edge length) tapering to a very fine mesh around the distal thin-walled region (0.2 mm). The endoprosthesis mesh had a uniform edge length of 0.7 mm. All meshes were constructed in 3-Matic (v13.0, Materialise, Plymouth, MI) and imported into FEBio Studio (v1.2, FEBio Software Suite, febio.org). Bones were assigned a neo-Hookean material, where density and Young's modulus values were derived from equations relating image intensity of the calibration phantom to bone in CT scans. A Poisson's ratio of 0.3 was assigned for the entire bone [5]. The endoprosthesis was assigned rigid body titanium material properties [5, 6].

The endoprosthesis was virtually implanted by positioning it into the bone according to a displacement ramp function. A sliding elastic contact interface was assigned between the bone and endoprosthesis [6]. A range of endoprosthesis sizes were simulated with the smallest barely in contact with the endosteal surface and largest just before penetration through the outer cortex. The impaction force and circumferential stress around the bone (first principal stress) were recorded. Results of each endoprosthesis size were normalized to the average diameter of the intact distal osteotomy.

## Results and Discussion

The maximum impaction force of all bones modeled followed a bell curve with peak force occurring in the case where the endoprosthesis used was the same as the average diameter of the medullary canal at the distal osteotomy. Circumferential stress was lowest at or within one endoprosthesis size of this same endoprosthesis model (Figure 1). Larger endoprosthesis sizes caused an exponential increase in the circumferential stress.

**Figure 1:** Circumferential stress distribution. Inset numbers indicate diameter (mm) of endoprosthesis used.

These data show that there is an optimal size endoprosthesis in each tibia where stress around the bone is minimized and force to impaction is maximized.

## Conclusion

Size selection is determined by the operating surgeon when placing percutaneous OI implants. This research shows that the correct size selection determines initial fixation and fracture risk. Careful preoperative evaluation should be implemented to determine the implant size that minimizes stress while maximizing impaction force to encourage successful outcomes.

## Effects of cyclic loading on the mechanical properties and failure of human patellar tendon

### Summary

Nineteen human patellar tendons underwent cyclic loading until failure while anterior surface strain distributions were captured using digital image correlation (DIC). Creep rate and damage rate displayed high correlations ( $r^2 \geq 0.86$ ) with the number of cycles to failure ( $N_f$ ). Non-invasively tracking these measures – through ultrasound or other means – may provide meaningful predictions of patellar tendon failure *in vivo*.

### Introduction

Patellar tendinopathy is a common overuse injury in basketball and volleyball athletes, owing to the repetitive loads their patellar tendons experience during jumping. Repetitive loading causes microdamage accumulation within the collagenous extracellular matrix, leading to a weakened tissue that is susceptible to injury [1]. This degeneration of stiffness and strength after submaximal repetitive loading resembles that of mechanical fatigue. Therefore, quantifying the fatigue behaviour of the patellar tendon may allow for the prediction of patellar tendon injury.

### Methods

Nineteen whole patellar tendons, clamped at the patella and tibia bone, were cyclically loaded until failure. The cyclic loading protocol was segmented by four ramped loading tests to capture images for DIC analysis. Cyclic testing was performed in load control using a 2 Hz sinusoidal waveform. The minimum stress was set to 2 MPa and the maximum stress was randomly assigned to each tendon, ranging between 11% and 60% of the estimated ultimate tensile strength. Ramped loading tests were performed just prior to cyclic loading, and at timepoints corresponding to 10%, 20%, and 30% of maximum cyclic stiffness loss. Anterior surface strain distributions from the initial ramped test were used to calculate initial median strain. Creep rate (i.e., the rate of increase in peak cyclic strain) and damage rate (i.e., the rate of Young's modulus degradation) were calculated between 30-70% of  $N_f$ .  $N_f$  was correlated with the aforementioned variables, and anterior surface strains were visualized to examine the effect of cyclic loading on strain distributions.

### Results and Discussion

Peak stress and initial median strain explained 65% and 60% of the variance in  $N_f$ , respectively. Creep rate had the strongest relationship with  $N_f$  ( $r^2=96\%$ , Figure 1), followed by damage rate ( $r^2=86\%$ ). Anterior surface strain distributions illustrated strain concentrations within the tendon midsubstance that tended to grow in size and magnitude as the tendon fatigued (Figure 2).

Tendon failure at several length scales has been shown to be strain controlled [2]. Tendons with higher creep rates reached this limiting strain sooner and failed after fewer cycles, explaining the high correlation between this measure and  $N_f$ . Using DIC analysis, we observed the existence of localized strain concentrations that tended to increase in size and magnitude over the course of the cyclic loading protocol. This behaviour supports the hypothesis of load transfer between discontinuous fibrils via shear, which in turn begin to fail as peak strain increases with continued cyclic loading [3].

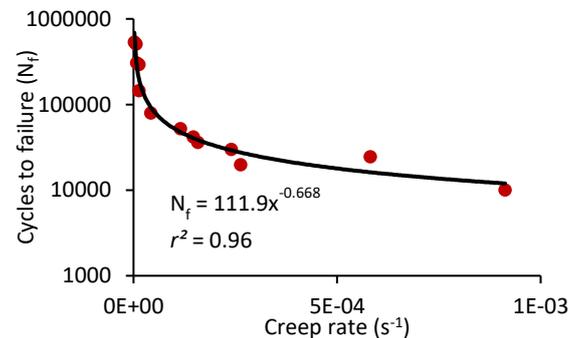

Figure 2: Creep rate versus cycles to failure.

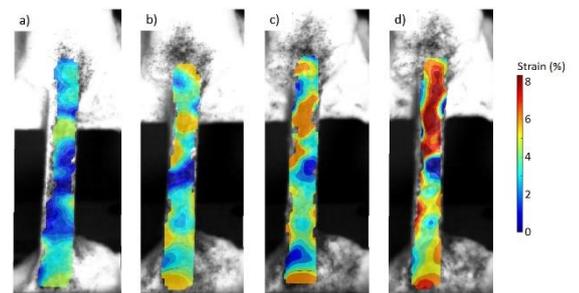

Figure 1: Axial surface strains of a representative sample at: a) 0%, b) 10%, c) 20%, and d) 30% of maximum stiffness loss.

### Conclusions

Both creep rate and damage rate were highly predictive of patellar tendon fatigue failure. Thus, quantifying these rate-dependent measures with technologies such as ultrasound or shear wave elastography may be useful for the prediction and prevention of patellar tendon injury.

# Mechanical Fatigue In Spinal Joints: Viscoelastic Responses To Altered Rate And Frequency of Compression Loading

Jackie D. Zehr, Jessa Buchman-Pearle, Jack P. Callaghan

Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada

Email: [jackie.zehr@uwaterloo.ca](mailto:jackie.zehr@uwaterloo.ca)

## Summary

This study examined a widespread experimental challenge associated with fatigue-failure analyses – the (potential) confounding effects of loading rate and frequency on the lifespan of spinal units. An *in vitro* paradigm was used to compare custom waveforms with equal compression rates and frequencies. Dose discrepancies were equalized between groups and revealed that the effect of loading rate on cyclic lifespan depends on loading frequency. Together, these findings have implications on the future examination of overuse injury pathways.

## Introduction

Compression loads associated with habitual motor tasks can cause fatigue-failure in lumbar spine tissues [1]. Modulators of the demonstrated fatigue response in spinal joints [2] and isolated tissues [3] include load magnitude and frequency. Given that manipulation of these loading factors alters the applied loading rate, it is conceivable that the pattern of interaction may be influenced by viscoelastic tissue responses. As such, this study investigated the effects of loading rate and frequency on the fatigue response in isolated porcine functional spinal units (FSUs).

## Methods

Thirty-two porcine FSUs (16 C3C4; 16 C5C6) were assigned to one of four experimental groups. Each group differed by average compression rate (4.2 kN/s  $\pm$  0.25, 8.3 kN/s  $\pm$  0.46) and frequency (0.5 Hz, 1 Hz). Custom haversine functions were developed (Figure 1).

Loading rates were controlled by normalizing the maximum compression to 20%, 40%, or 80% of the predicted ultimate tolerance and the minimum compression to 8% of the determined maximum. The discrepancies in compression dose – force-time integral – were normalized *post hoc* using dose correction factors computed from linear and nonlinear [4] risk-exposure relationships (Table 1).

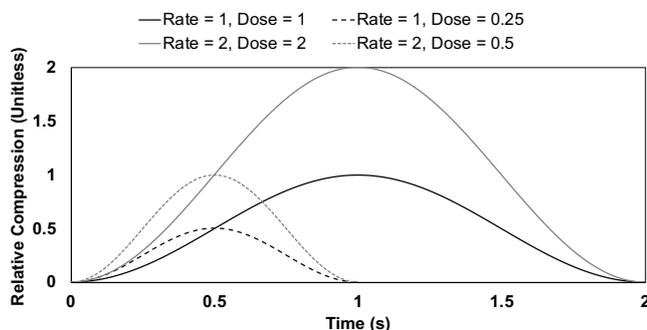

Figure 1. The relative compression signals.

Table 1. Dose correction factors for each condition.

	Linear		Nonlinear	
	4.2 kN/s	8.3 kN/s	4.2 kN/s	8.3 kN/s
0.5 Hz	1.00	2.00	1.0027	5.5
1 Hz	0.25	0.50	0.25	0.5013

Following a 0.3 kN preload and flexion-extension range-of-motion test, FSUs were positioned in the determined neutral posture. Cyclic testing was performed with a materials testing system until failure occurred or 10,800 cycles were tolerated. Force and displacement data were sampled at 100 Hz. Measurements of non-normalized and normalized (linear and nonlinear) cyclic lifespan were evaluated. A standard general linear model ( $\alpha = 0.05$ ) was used to examine the effects of loading rate and frequency.

## Results and Discussion

Significant main effects for loading rate and frequency were detected for the non-normalized cyclic lifespan ( $p < 0.001$ ). FSUs tolerated 71% and 49% fewer cycles when loaded at 8.3 kN/s and 0.5 Hz, respectively.

A significant loading rate  $\times$  frequency interaction was observed following linear and nonlinear normalization ( $p < 0.001$ ). The lifespan did not significantly differ (4%) between loading rates for a 1 Hz loading frequency ( $p > 0.988$ ). At 0.5 Hz, the 8.3 kN/s loading rate reduced the lifespan by 97-99% ( $p < 0.001$ ).

## Conclusions

The effects of compression rate and frequency on fatigue-failure in isolated spinal joints were dependent on the normalization of differences in applied loading dose. Although the non-normalized lifespan findings align with the outcomes of previous fatigue studies [2,3], the emergent interaction between compression rate and frequency highlights the importance of dose-normalization for the examination of fatigue-failure at slower loading frequencies (i.e. 0.5 Hz).

## A one-dimensional viscoelastic model of collagenous tissues with damage

Jeff M. Barrett<sup>1</sup>, Jack P. Callaghan<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Waterloo, Waterloo, Canada

Email: jeffery.barrett@uwaterloo.ca

### Summary

We present the addition of viscoelastic effects into an existing collagen distribution-based elastic model. The resulting model predicts a variety of established hyper-viscoelastic phenomena ubiquitous to biological tissues: hysteresis, stress-relaxation, creep, and, most notably, progressive failure.

### Introduction

Macroscopic biomechanical models aiming to predict injury require biofidelic tissue models. The goal of this investigation was to present a biofidelic representation of biological tissues. We previously derived a partial differential equation (PDE) model which describes the rate of fibre-recruitment in a purely collagenous tissue [1], based on the Huxley muscle model:

$$\frac{\partial \rho}{\partial t} + v(t) \frac{\partial \rho}{\partial x} = -B(x, t) \rho(x, t) \quad (1)$$

Where  $\rho(x, t)$  is the distribution of fibre strain ( $x$ ) at the instant  $t$ ;  $v(t)$  is the strain-rate; and  $B(x, t)$  is the function describing the rate of failure of collagen fibres strained by  $x$  at an instant  $t$ .

### Methods

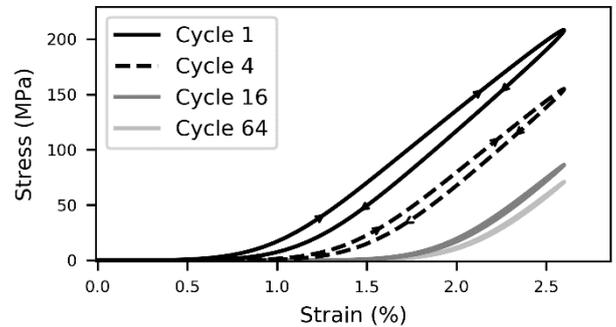

We approximated  $\rho(x, t)$  with a Gaussian distribution, and used the method of moments to reduce this PDE to a series of three ordinary differential equations (ODEs):

$$\begin{aligned} \dot{Q}_0 &= M_0 \\ \dot{Q}_1 &= M_1 + vQ_0 \\ \dot{Q}_2 &= M_2 + 2vQ_1 \end{aligned} \quad (2)$$

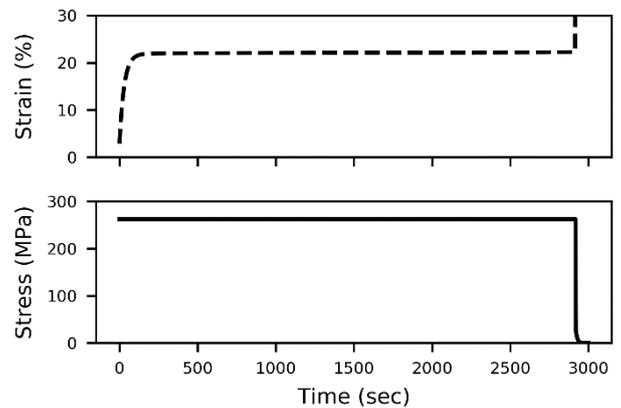

Where  $Q_0$ ,  $Q_1$  and  $Q_2$  are the estimated raw-moments of  $\rho(x, t)$ ;  $M_0$ ,  $M_1$  and  $M_2$  are the approximations to the weighted product of  $\rho(x, t)$  and  $B(x, t)$ , expressed as functions of  $Q_0$ ,  $Q_1$  and  $Q_2$ . Similar expressions have been derived for the DM approximation to the Huxley model [2]. A Voigt-element in series with this non-linear spring was used to represent the viscoelastic non-collagenous elements, which have been shown to play a critical role in viscoelasticity. Separate systems of differential algebraic equations (DAEs) were derived for strain-control and stress-control simulations.

### Results and Discussion

The resulting model possessed several characteristics reminiscent of true biological tissues. These included stress-relaxation, hysteresis (Figure 1), failure, and, most notably, a three-phased creep curve. This curve begins with an initial deformation of the model, a prolonged quasi-static period, and an abrupt failure portion (Figure 2).

**Figure 1:** Cyclic loading demonstrating both the hysteresis (area between loading and unloading) and stress-relaxation predicted by the model.

**Figure 2:** Model predictions during a prolonged creep protocol with strain (top) and stress (bottom).

### Conclusions

The model agrees with several experimentally observed phenomena of biological tissues, including, most notably, fatigue. It may be used with macroscopic biomechanical models to aid in the understanding of these cumulative loading injuries and time dependent responses.

### Summary

The mechanical properties of the human skull are influenced by its diploë morphometry. Trabecular thickness was positively correlated with bending modulus, whereas porosity and non-plate-like trabeculae were associated with a reduction of failure stress in bending. By identifying which morphometric properties are significantly associated with mechanical properties, surrogate designers and computational modelers can identify the morphometry to prioritize when designing a skull fracture model.

### Introduction

Limited studies have examined the relationship between diploë morphometry and the mechanical response of cranial bone [1,2]. Adanty et al employed regression techniques to predict fracture strain from morphometry, however, the correlative relationship between morphometry and mechanical properties has not been examined [1]. Quantifying this relationship could increase our knowledge on the role of morphometry in mechanical response and provide morphometric data to design skull fracture models. The purpose of this work was to determine the correlation between diploë morphometry and mechanical properties of human skull specimens in quasi-static 4-pt bending. The null hypothesis was the correlation coefficient between morphometry and mechanical properties is equal to zero.

### Methods

The methods were approved by the University of Alberta Research Ethics Board (ID: Pro00089218). All bodies were obtained through donation via the University of Alberta Anatomical Gift Program. From 10 embalmed cadavers (Male: 5, Female: 5), one parietal specimen was extracted from each skull (N=10). Each specimen was then scanned using micro-computed tomography (CT) (Bruker-Skyscan 1176) at a resolution of 18  $\mu\text{m}$  to determine diploë morphometry: trabecular number (Tb.N), trabecular thickness (Tb.Th), porosity (%), and un-plate index (uPi). The specimens were then tested in quasi-static 4-pt bending using an Instron E3000 (Figure 1). The mechanical properties of interest were strain at failure measured using fiber Bragg gratings (FBGs), estimated failure stress, and an estimated effective bending modulus. Spearman's correlation tests were performed to determine the correlation coefficient ( $r_s$ ) between morphometric and mechanical properties.

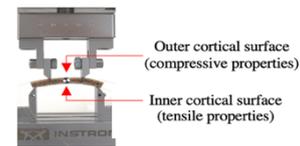

Figure 1: Specimen in 4-pt bending. Displacement rate: 2 mm/min

### Results and Discussion

Table 1 presents significant  $r_s$  between morphometric and mechanical properties ( $p < 0.05$ ). Porosity was negatively correlated with stress at failure. Non-plate-like trabeculae (uPi) was negatively correlated with stress and strain at failure. Tb.Th was strongly correlated ( $r_s$  close to 1) with compressive bending modulus. No significant correlations were found with Tb.N.

Table 1: Significant  $r_s$  between morphometric and mechanical properties ( $p < 0.05$ ).

	Tb.Th	Porosity	uPi
Outer cortical failure stress	-	-0.78	-0.67
Inner cortical failure stress	-	-0.67	-0.70
Inner cortical failure strain	-	-	-0.68
Compressive modulus	0.89	-	-

### Conclusions

Porosity, uPi, and Tb.Th had a significant association with the mechanical response of cranial bone during bending, thus rejecting the null hypothesis. These findings will support our next stage of work that will include the fabrication of a surrogate model of the skull for fracture simulation.

## Summary

We examined the mechanical fatigue behavior of whole rabbit tibiae under uniaxial compression and biaxial compression + torsion. In uniaxial loading, bones exhibited a logarithmic relationship between load and fatigue life ( $r^2=0.68$ ). Similarly, fatigue life under biaxial loading decreased with greater superimposed torsion. Specimen-specific finite element (FE) modelling illustrated that spatial peak stress/strain poorly explained fatigue life variation under biaxial loads; variation was better explained by measures of stressed/strained volume. Strained volume based on pressure-modified von Mises strain explained 73% and 59% of the variation under uniaxial and biaxial loading, respectively. This highlights the importance of stress/strain distributions, not peak values, in the prediction of fatigue-life of whole-bone.

## Introduction

Stress fractures are mechanical fatigue phenomena associated with progressive microdamage accumulation, material property degradation, and eventual structural failure with repetitive loading. Nonlinear relationships between load magnitude and fatigue life are well characterized in small material samples, but it is unclear if similar relationships can be extrapolated to more complex whole-bone structures. Material studies also identified that biaxial loading (compression + torsion), which occurs during running, may be particularly detrimental to fatigue life; again, this has not been demonstrated at the whole bone level. Finally, it is unclear how the complex distribution of stress/strain in whole bone structures relates to fatigue life. Thus, the purpose of this study was to quantify the fatigue life of whole-bones under uniaxial and biaxial loading, and to identify the relationship between fatigue life and FE predictions of stress/strain.

## Methods

12 rabbit tibiae were cyclically loaded in uniaxial compression (peak load: 925-2450 N), until failure. Another 22 tibiae were loaded in biaxial compression + torsion. These bones were loaded to 50% compressive strength, and either 0% (n=10), 25% (n=6), or 50% (n=6) of torsional strength. Specimen-specific FE models were generated from computed tomography imaging prior to testing (220 mA, 120 kVP, 0.39 mm and 0.625 mm in-plane and between-plane resolution). Based on strain gauge testing, bone was modelled as a heterogeneous isotropic material, with modulus computed from CT intensity at each element. We examined principal, von Mises and pressure modified von Mises [1] equivalent

stress and strain, reporting the peak values and stressed/strained volume (volume above a threshold).

## Results and Discussion

Under uniaxial compression, number of cycles to failure was well described by a logarithmic relationship ( $r^2=0.68$ ;  $p<0.001$ ). Similarly, fatigue-life in biaxial loading significantly decreased with the magnitude of superimposed torsion (Kruskal-Wallis test,  $p=0.034$ ). From FE models, peak stress/strain demonstrated a poor correlation with fatigue life in biaxial loading conditions, explaining <38% of the variation; stressed/strained volume better explained variation in this loading mode (Fig 1). In particular, pressure modified von Mises explained 73% and 59% of variation under uniaxial and biaxial loading, respectively.

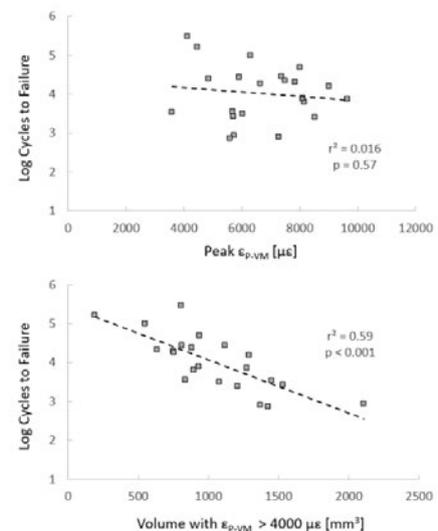

Fig 1 Log cycles to failure vs. pressure-modified von Mises Strain ( $\epsilon_{p-VM}$ ) under biaxial loading. Variation was better explained by strained volume (BOT;  $r^2=0.59$ ) vs. peak strain (TOP;  $r^2=0.016$ )

## Conclusion

Increased load was associated with nonlinear reductions in whole bone fatigue life under uniaxial and biaxial modes. Fatigue life variation was best explained by strained volume calculated from pressure modified von Mises strain. These results highlight the importance of stress/strain distributions, not peak values, in fatigue-life of whole bone. These findings have important implications for FE-based predictions of stress fracture risk.

### Summary

Glenohumeral osteoarthritis (OA) can result in symmetric or asymmetric (eccentric OA) glenoid bone loss and causes pain and weakness. Unresolved strength imbalances are thought to contribute to inferior post-surgical outcomes in patients with eccentric OA, yet pre-operative strength has not been quantified. Further, current knowledge of strength in OA is confounded by pain. We sought to evaluate strength balance, accounting for pain, in patients with eccentric OA. As the shoulder functions in multiple degrees of freedom, we assessed 3-dimensional strength. Preliminary data suggest a pain-independent strength imbalance with relative weakness of extension and internal rotation in patients with eccentric OA compared to healthy adults. Our findings may provide insight to further enhance rehabilitation and surgical outcomes in patients with eccentric OA.

### Introduction

Glenohumeral osteoarthritis (OA) results in shoulder weakness and pain. Post-surgical outcomes are inferior in patients with asymmetric glenoid wear (eccentric OA) [1], but it is not fully understood why. Imbalanced strength between agonist/antagonist rotator cuff muscles is theorized to play a role [2]; yet, strength balance has not been quantified in patients with eccentric OA. Further, pain likely impacts strength measures, but has not been accounted for previously [3]. We sought to determine if strength imbalances, when accounting for pain, exist in patients with eccentric OA, which may direct rehabilitation and improve surgical outcomes. The shoulder works in multiple degrees of freedom, so we measured strength in many directions to assess 3-dimensional (3D) strength.

### Methods

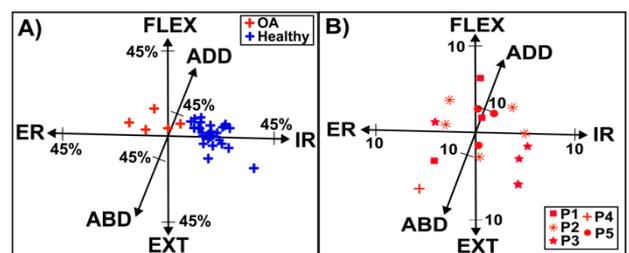

Five patients with end-stage eccentric OA (2F; mean±SD: 58±17 yrs) and 26 healthy adults (14F; 59±13 yrs) participated. Participants performed maximal isometric contractions in 26 equally spaced directions spanning shoulder flex/extension, ab/adduction, and internal/external rotation. The affected (OA) or dominant (healthy) arm was casted, attached to a six degree-of-freedom load cell, and positioned in 90° abduction (healthy) or 50° scapular plane elevation (OA) to measure shoulder torque. Patients with OA rated pain (0-10) with each trial. Trials rated above the patient's average pain were plotted along the corresponding torque direction. Maximum torque in each direction was calculated. Strength magnitude was computed and normalized by bodyweight (Nm/kg). To quantify relative strength in opposing directions (strength balance), 3D torque data were averaged across all directions [4]. Mann-Whitney

U tests ( $\alpha=0.05$ ) were used to test for differences in strength magnitude and strength balance between groups.

### Results and Discussion

Preliminary results suggest strength magnitude is reduced in patients with OA compared to healthy adults (diff in mean rank, [95% CI]: -13.6, [-22.3,-4.9],  $p=0.002$ ). We observed an unexpected shift in strength balance towards external rotation (-15.5, [-24.2,-6.8],  $p=0.0005$ , Fig. 1A) and flexion (+9.1, [+0.4,+17.8],  $p=0.04$ ) in patients with OA compared to healthy adults. Among patients with OA, above-average pain was experienced in 13 unique directions. Only 3/13 directions were repeated in 2/5 patients.

The observed reduction in strength magnitude is expected with OA. Despite a consistent directional shift in strength balance, this was not observed in above-average pain (Fig. 1B). Our preliminary findings suggest patients with eccentric OA have pain-independent strength imbalances with relative weakness in extension and internal rotation.

**Fig. 1:** **A)** 3D strength balance (% strength magnitude). **B)** Above-average pain in OA patients (P1-5). Flex/extension= FLEX/EXT. Ad/abduction= ADD/ABD. Internal/external Rotation= IR/ER.

### Conclusions

Preliminary results suggest pain-independent strength imbalances with relative weakness of internal rotation and extension in patients with eccentric OA compared to healthy adults. These results highlight the utility of accounting for pain when measuring strength in this population. Our findings may guide rehabilitation to target strength deficits, potentially improving surgical outcomes. Future comparison to patients with symmetric glenoid bone loss is warranted.

## Anterolateral Versus Medial Plating for Varus Type Pilon Fractures

Marisa Kohut<sup>1</sup>, Ali Ammar<sup>1</sup>, Bashar Alolabi<sup>2</sup>, Cheryl Quenneville<sup>1,3</sup>

Email: [ammara@mcmaster.ca](mailto:ammara@mcmaster.ca)

### Summary

Pilon fractures occur mainly from high-energy impacts. Orthopaedic surgeons can repair these injuries using either anterolateral or medial fracture plates, but with little biomechanical basis for which provides superior stability. Paired cadaveric tibia-fibula specimens were ‘fractured’ and repaired with both types of plates (R/L randomized). Under axial loading, stiffness and strength were measured to determine which plating method provided the greatest stability. No benefits were found in choosing one plating technique over the other. These findings can be used to allow other factors such as soft tissues and surgeon preference to guide decision making.

### Introduction

Pilon fractures are caused by high energy impacts, such as falls and automotive collisions, and typically result in a high level of comminution with articular surface involvement [1]. The most common treatment for pilon fractures is open reduction and internal fixation (ORIF) using medial or anterolateral plates. The current dogma is to put the plate across the opening side of the wedge, but there is no biomechanical data to support this. Patients after surgery report negative outcomes affecting their quality of life, regardless of the type of treatment [2]. The purpose of the present study was to evaluate different plating techniques on a varus fracture based on cadaveric specimen stiffness and strength.

### Methods

**A. Specimen Preparation:** Six pairs of lower leg cadaveric specimens (tibia, fibula, and inter-osseous membrane) were used in this study. One specimen from each pair was randomly allocated to each plating type with the right and left assignment randomized. Specimens were potted proximally using dental cement in square metal tubing in an inverted position, vertically aligned using a bull’s eye level.

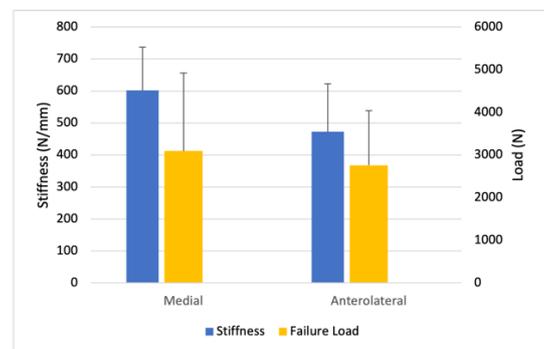

**B. Fracture and Plating:** Plates were pre-drilled and tapped into the specimen before the fractures were created. This allowed for planned positioning of the screws to ensure alignment post-repair. A typical Y-type intra-articular fracture was made on the articular surface using an oscillating saw. A varus wedge fracture was similarly created 4 cm from the medial gutter. A transverse fibular fracture was also created, aligned with the vertex of the wedge. Finally, plates were attached, lining the screws up to the pre-drilled holes.

**C. Mechanical Testing:** An artificial talus was made using bone cement (Simplex P, Stryker) to reduce unnatural stress

concentrations yet be able to transmit high loads to the tibial plafond. Cyclic loads were applied quasi-statically from 75-400N at a rate of 0.1 mm/s for 10 cycles using a material testing machine (Instron 5967, Canton MA, USA). The stiffness was calculated, then a ramp load was applied to failure, which was defined as a load drop greater than 100 N.

### Results and Discussion

The medial plated specimens tended to be stiffer than the anterolateral plated specimens, but this was not significantly different (M:  $601.7 \pm 135.2$  N/mm; AL:  $472.6 \pm 150.3$  N/mm;  $p=0.28$ ). The failure load for the medial plated specimens was not different from that of the anterolateral plated ones (M:  $3096 \pm 1826$  N; AL:  $2760 \pm 1279$  N;  $p=0.73$ ) (Figure 1).

**Figure 1:** Repaired Stiffness and Load to Failure Results

Although there was no significant difference between the two plating methods (potentially attributable to the low number of specimens used), this study allowed for direct comparison by using paired specimens to assess both plating methods. As the biomechanical performance was similar, this allows other factors such as soft tissue access and surgeon preference to guide the decision making.

### Conclusions

Based on stiffness and strength, both techniques appear to be valid for repairing varus pilon fractures.

### Acknowledgments

Surgical materials (plates and screws) were provided by DePuy Synthes through an Investigator Initiated Study. Other funding is through NSERC Discovery program.

## Summary

Varus malalignment and increased knee adduction moment (KAM) in knee osteoarthritis (OA) and subsequent post-total knee arthroplasty (TKA) patients are associated with worsening symptoms and poor outcomes. These gait patterns were present in OA patients compared to controls in the current study, with the greatest KAM, KAM impulse and knee adduction angle in obese OA patients.

## Introduction

While higher KAM and knee adduction angles have been linked to progression of OA and poor post-TKA outcomes [1], the deleterious effects may be even more pronounced in obese patients [2, 3]. Based on the lack of previous research comparing pre- and post-TKA patients to controls and with the increasing prevalence of both obesity and knee OA, the current study compared walking frontal plane gait in healthy controls and TKA patients pre- and 12-months post-surgery.

## Methods

Pre- and 12-month post-TKA walking gait of 29 knee OA patients (40 knees) under 85 years old and able to walk without an aid was compared to 146 control participants (146 knees). Kinematics (240 Hz) of three walking gait trials were collected from 29 retroreflective markers and synchronized to kinetic data which was measured via a force plate. Repeated measures analyses of variance was performed to compare main effects over time, with Fisher's

least significant difference test to compare group means. Significance level was set at  $p < 0.05$ .

## Results and Discussion

Pre-operatively, obese patients had significantly higher KAM, KAM impulse and knee adduction angle than healthy weight OA patients and all weight categories of controls. Post-TKA, no differences were noted between weight categories for TKA or control patients and only overweight TKA KAM and knee adduction angle were significantly lower than controls. The results indicate significant changes over time in KAM impulse and peak KAM for the overweight and obese TKA group. Significant changes over time were observed for peak knee adduction angle in the healthy, overweight, and obese TKA group.

## Conclusions

Obese OA patients exhibit significantly greater deleterious gait patterns compared to less obese patients and controls. However, these differences were not noted following TKA.

## The use of a wireless passive electronic strain sensor to measure hysteresis of sheep hindlimb tendons:

### A first step towards directly comparing *in vitro* and *in vivo* tendon properties

Bossuyt FM<sup>1</sup>, Han S<sup>1</sup>, Leonard T<sup>1</sup>, Sawatsky A<sup>1</sup>, Zhang Q<sup>2</sup>, Smith C<sup>2</sup>, Adam N<sup>2</sup>, Taylor WR<sup>2</sup>, Herzog W<sup>1</sup>

<sup>2</sup>Laboratory for Movement Biomechanics, ETH Zürich, Zürich, Switzerland

Email: [fransiska.bossuyt@ucalgary.ca](mailto:fransiska.bossuyt@ucalgary.ca)

#### Summary

In order to better understand the dynamic mechanical properties of sheep hindlimb tendons, this study aimed to test the use of a wireless passive electronic strain sensor (PESS) on cadaveric tendons under tensile loading. Forced longitudinal sinusoidal oscillations were applied with 2% and 4% peak strains at 1 Hz. Tendon hysteresis decreased from the 1<sup>st</sup> to subsequent loading cycles.

#### Introduction

Hysteresis or energy dissipation in tendons during cyclic loading is considered to be an important factor in the efficiency of movements [1]. However, previously reported tendon hysteresis values are inconsistent and have never been obtained in conjunction with the corresponding directly measured *in vivo* muscle forces. Our wireless, passive electronic strain sensor (PESS, Figure 1A) [2] allows for the direct measurement of tendon strains during cyclic loading and offers an opportunity to gain new insights into tendon properties and muscle-tendon interactions *in vivo*. The goal of this pilot study is to answer the question: What is the hysteresis of a sheep hindlimb tendon *in vitro* when defined locally with the PESS, and how does this local hysteresis relate to global tendon hysteresis obtained from a servo-hydraulic tensile testing machine (MTS)?

#### Methods

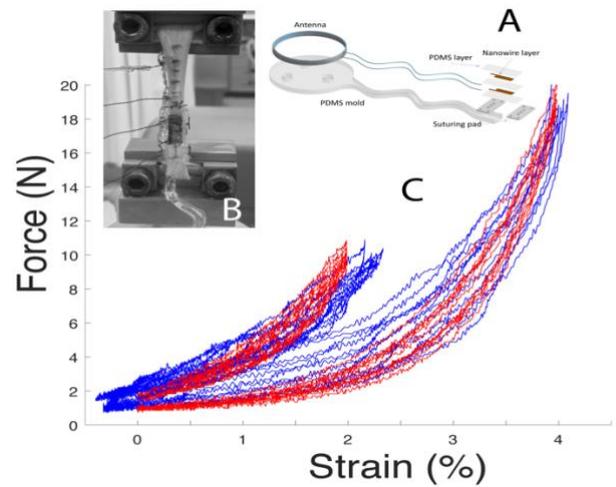

A cadaveric sheep medial gastrocnemius tendon was clamped in the MTS, instrumented with a 1 kN load cell, and preloaded with 6.3 N (0.272MPa \* 23.15mm<sup>2</sup> (cross-sectional area = mass / (density(1120 kg/m<sup>3</sup>) \* length<sub>tendon</sub>)) (Figure 1B). Upon suturing the PESS onto the tendon, and a 20-min rest period in the preload position, the protocol started. The protocol consisted of a warm-up condition (101 cycles to 1% strain at 0.5 Hz), followed by two test conditions separated by 5 min of rest: 51 cycles to 2% at 1 Hz, and 51 cycles to 4% strain at 1 Hz. The tendon was kept hydrated by spraying a solution of 0.9% sodium chloride in water every two min. The output resonant frequency signal of the PESS was calibrated to the strain produced with sonomicrometry crystals aligned with the PESS. The tendon hysteresis was defined as the percent area between the force-displacement loading and unloading curves relative to the area under the force-displacement loading curve.

#### Results and Discussion

**Table 1:** Hysteresis (%) of sheep medial gastrocnemius tendon for the first 6 cycles of different loading conditions

2% strain	1st	2nd	3rd	4th	5th	6th	4% strain	1st	2nd	3rd	4th	5th	6th
Hysteresis <sub>MTS</sub>	18.0	17.9	17.3	16.9	9.5	13.9	Hysteresis <sub>MTS</sub>	24.0	14.0	16.5	15.4	17.8	17.6
Hysteresis <sub>PESS</sub>	23.7	19.2	16.2	18.9	9.9	6.2	Hysteresis <sub>PESS</sub>	20.2	18.1	37.1	10.4	19.8	38.6

This pilot test demonstrated a reduction in hysteresis from the 1<sup>st</sup> to subsequent loading cycles due to a reduction in the loading curve with minimal changes in the work under the unloading curve (Table 1, Figure 1). Overall, hysteresis values are slightly larger as compared to data from previous *in vitro* studies [1], and local hysteresis varied from the global hysteresis. Implications of these observations remain unclear and require further testing.

**Figure 1:** Hysteresis of sheep medial gastrocnemius tendon *in vitro* defined from a passive electronic strain sensor (blue) and a tensile test machine (red), for the 2% and the 4% strain conditions.

#### Conclusions

This study presented local and global hysteresis of a sheep medial gastrocnemius tendon *in vitro*. Following work will directly compare the *in vivo* tendon properties in freely walking/running sheep with the corresponding properties obtained *in vitro* and aims to measure the detailed interaction between tendon strain, fascicle strains and muscle forces *in vivo*.

# Visual detection on simulated electromyography signals with varying signal-to-noise ratios: A training tool to enhance onset identification

Erik Kowalski<sup>1</sup>, Danilo S. Catelli<sup>1</sup>, Mario Lamontagne<sup>1</sup>

<sup>1</sup>Human Movement Biomechanics Laboratory, University of Ottawa, Ottawa, Canada

Email: mlamon@uottawa.ca

## Summary

The aim of this study was to determine if a training tool that used simulated electromyography signals could be used to help improve visual onset detection. Eight participants completed two sessions, separated by a week, where they selected 120 muscle onsets on a custom-made graphical user interface. Signals were presented randomly and had signal-to-noise ratios of 5, 10, 20 or 40 dB. Participants received visual feedback at the end of each session. Visual onset detection improved during the second session for all signal-to-noise ratios. The concept of a training tool to help improve visual onset detection is warranted for further exploration.

## Introduction

The detection of the onset of muscle activity is required to determine the temporal characteristics of muscle recruitment and its detection is accomplished by a variety of different methods including computerized methods or through visual detection (VD). Computerized detection methods were created to produce a reliable way to determine muscle onsets. However, when the signal-to-noise ratio (SNR) is low, researchers need to visually inspect these signals. VD is time-consuming, and its reliability has been questioned due to its poor reproducibility due to both human error and variability between researchers.

Having simulated electromyography (SIMEMG) would create a controlled repeatable environment where researchers could improve their VD ability. To assist and improve with VD, we have developed a training tool framework where researchers can practice detecting onsets on SIMEMG signals. The aim of this study was to determine if a training tool can improve visual onset detection.

## Methods

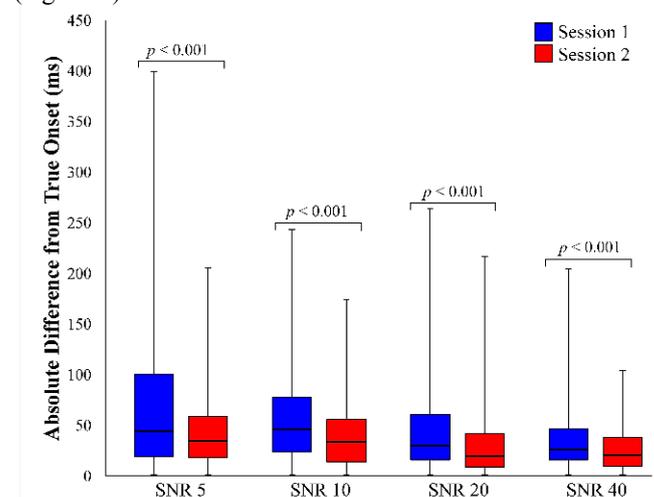

Electromyography (EMG) signals were simulated using previously reported methods which controlled many signal features [1]. A white noise process was added to each SIMEMG signal which allowed for the configuration of a desired SNR. Eight signals, each with five bursts of muscle activity were simulated to create signals with SNRs of 5, 10, 20 & 40 dB. The training tool was created with a custom-made graphical user interface (GUI) which presented the SIMEMG signals in random order and allowed users to select where they believed the onset of each burst was for each signal.

Eight individuals with at least one year of EMG VD experience ( $7.1 \pm 8.8$  years) participated in the study and completed two VD sessions, separated by one week. Using the training tool, the participants completed three sets of 10 - SIMEMG signals, at four different SNRs, for a total of 120 onset selections. Feedback between their selected onset and the true onset was visually provided at the end of each session.

The absolute difference between the true from SIMEMG and selected onset was determined for each signal burst. A Wilcoxon signed-rank test was conducted to determine the effect of the VD training tool between the two sessions on the absolute difference between true and selected onset at the various SNRs ( $p < .05$ ).

## Results and Discussion

The second VD session elicited a significant median decrease in absolute difference with the selected onset from the true onset compared to the first VD session at all SNRs ( $p < .001$ ) (Figure 1).

**Figure 1:** Absolute difference from true onset (ms) between the two VD sessions during SNRs of 5, 10, 20, and 40 dB.

The concept of a training method to improve VD muscle onset detection was shown with this small sampled study. The interquartile range was still large after the second session, so more training sessions are necessary to help further improve accuracy. Future improvements to the GUI are warranted to help improve learning outcomes, such as allowing users to select the SNR, providing immediate feedback instead of at the end of the session, as well as incorporating signal conditioning methods such as a Teager-Kaiser Energy Operator [2].

## Conclusions

This study presented a training tool that used SIMEMG signals to help train participants for visual onset detection. Significant improvements were made between the two sessions. Several improvements could be made to the GUI to improve learning, however, the concept of a training tool to help improve visual onset detection is warranted for further exploration.

### Summary

The International Womxn in Biomechanics (IWB) organization was recently formed to increase representation of womxn in biomechanics. Here, we present the results of an anonymous survey highlighting the needs and challenges faced by womxn in our field, and the current and future role of IWB in addressing them.

### Introduction

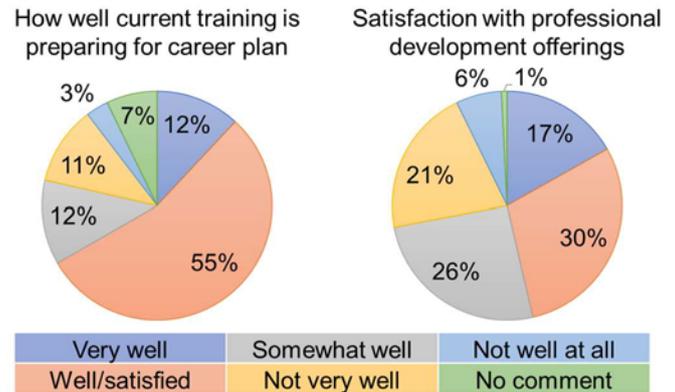

Women exit the professional pipeline at higher rates than men, in part due to challenges faced disproportionately by women (e.g. sexism and parental leave) and particularly during transitional periods, such as postdoctoral years [1]. Supportive environments and groups for women have shown women gain increased confidence, empowerment, and professional skills that enhance their career satisfaction and self-efficacy [2]. Thus, IWB was formed in June 2020 to increase the representation of women and non-binary individuals (collectively: womxn) in biomechanics. The purpose of this paper is to identify factors that contribute to the “leaky pipeline” in our field, and to discuss IWB’s ongoing and proposed efforts to support womxn in biomechanics.

### Methods

In August 2020, we conducted an anonymous survey to characterize the experiences of womxn in biomechanics and identify the issues and challenges they encounter. The survey was sent to all members of the organization, which at that time contained approximately 200 womxn. Survey questions focused on the topics of: opportunities for training; research collaborations and grants; professional development; long-term goals; and mental health and wellbeing.

### Results and Discussion

We received 128 responses from womxn at varying career stages (undergraduate students to faculty and industry professionals), with most recipients at the doctoral (54%) and postdoctoral (21%) stages. We identified common areas of concern for womxn biomechanists working in a male-dominated field. The most alarming of these included feeling a lack of respect, juggling personal and family commitments, overcoming discrimination, and dealing with sexism in the workplace. In addition, 48% of womxn believed stress and mental health challenges had a ‘high’ to ‘very high’ impact on their productivity. Finally, most (67%) respondents felt their current training was preparing them for their career goals; however, 47% of respondents were ‘somewhat’ or ‘not very’ satisfied with professional development offerings (Fig 1).

**Figure 1:** Survey responses related to career preparation (left) and satisfaction with professional development offerings (right).

IWB is providing a safe networking platform for our members (using Slack) to discuss career opportunities, professional development, feedback, advice, and professional support. Members use this platform to network, seek confidential support for personal and professional issues, celebrate each other’s successes, and learn from each other’s failures, among other things. We also host monthly meetings for our members, which, to date, have included topics such as applying for grants, fellowships, and awards (in collaboration with ASB, ISB, ISBS, and other biomechanics societies), discussing challenges faced by womxn in STEM, learning about racial and implicit bias in research spaces (in collaboration with the Black Biomechanists Association and Latinx in Biomechanics affinity groups). Many of these meetings are made freely available on our YouTube page for the biomechanics community [3].

As of January 2021, IWB includes over 500 womxn from over 20 countries. Our future efforts include (1) supporting our members’ personal and professional goals, (2) creating outreach opportunities to introduce young womxn to the field, and (3) empowering allies and advocates to create a more equitable workplace.

### Conclusions

IWB was created to address the needs of womxn in biomechanics. Through continued support from the broader biomechanics community, we are committed to increasing representation of womxn in biomechanics.

# Finite Element Modelling of the Abdomen in Developing a Robotic Patient for Palpation Examination Training

Florence Leong<sup>1</sup>, Siamak F. Khosroshahi<sup>1</sup>, He Liang<sup>1</sup>, Thilina D. Lalitharatne<sup>1</sup>, Simon de Lusignan<sup>2</sup>,  
Thrishantha Nanayakkara<sup>1</sup>, Mazdak Ghajari<sup>1</sup>

<sup>2</sup>Nuffield Department of Primary Care Health Sciences, University of Oxford, United Kingdom

Email: f.leong@imperial.ac.uk

## Summary

Abdominal palpation is a very challenging procedure for medical trainees as there is rarely any immediate feedback about the findings or diagnoses of abdominal conditions. We are developing a robotic platform for trainees to sharpen their skills effectively with the aid of a Finite Element Model (FEM) of abdominal palpation that informs them of the stresses on the internal tissues based on the palpation forces.

## Introduction

Physicians often perform palpation examination on patients to detect anomalies in the abdomen. This technique requires years of experience for accurate perception and diagnoses. Simulation-based learning platforms (e.g. manikins and virtual reality systems) are used for medical training in place of patients but they lack the flexibility to realistically simulate a patient's condition, and to provide required haptic and visual feedback desired for training [1]. Hence, we are developing a robotic patient (RoboPatient) that incorporates haptic [2] and visual feedback, i.e. facial expression [3] and that informed by FEM of palpation for training. We are constructing a high-fidelity FEM to simulate abdominal palpation to observe internal stresses (on the liver in this context) and to obtain information for the robot design. Our aim is to train a surrogate model based on FEM results using machine learning to provide real-time visual feedback (see Fig 1a) with respect to palpation forces and pain levels.

## Methods

A high-fidelity FEM of the abdomen is constructed from 3D images generated by XCAT program, and is simplified to a lumped abdomen with ribs and liver. The simulations are set up in LS-Prepost (Fig 1b) using material properties in the GHBM model [4] for the flesh and ribs, and the Ogden parameters in [5] for the liver. A dummy finger is added to visualize the contact with the abdomen. Simulations are performed with indentation up to 20mm on the abdomen, and lateral motion across the liver emulating the palpation

motion we hypothesize physicians would feel the liver with. The resulting stresses on the liver are observed.

## Results

From the simulation, we observed the largest principal stress on the liver of over 5kPa with a maximum resultant contact force of 10N at 20mm deformation on and across the abdomen. The displacement and stress on the liver tissue can be observed through the simulation with respect to the contact forces on the fingertip (Fig 1c), demonstrating that the finger perceives reaction forces from the liver and ribs translated from within the abdomen. The simulated stress can be mapped to real-time palpation forces measured using force sensors on RoboPatient system, and the corresponding abdominal pain levels for informed visual feedback.

## Conclusions

The FEM simulations show that the internal stresses on the tissues inside the abdomen can be observed based on the palpation forces. This visual feedback allows physicians and trainees to condition their fingers behaviour to reduce pain onto patients while receiving immediate feedback on their finding. The model will also be simulated with different patient conditions for optimal RoboPatient platform design.

## Acknowledgments

## Using hula hooping as a discussion point for STEM education and outreach

I. Bold<sup>1</sup>, C. Holt<sup>1</sup>, P. Blaikie<sup>1</sup>, D. Syrop<sup>1</sup>

<sup>1</sup>Cardiff University School of Engineering, Cardiff, Wales

Email: blaikiep@cardiff.ac.uk

### Summary

The aim of this project was to develop a public engagement Science Technology Engineering and Mathematics (STEM) activity using Hula Hooping to introduce subjects including Biomechanics and Medical Engineering. The activity is intended to demonstrate a wider range of STEM careers available to young people, their parents, and teachers. It also provides an opportunity to include broader science and maths concepts and skills, and how learning about them can help people and improve lives.

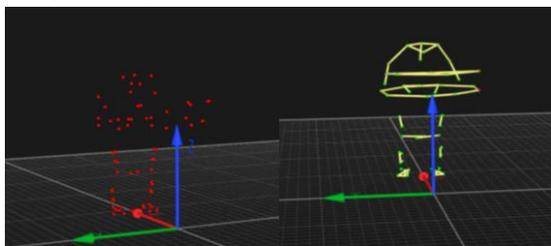

### Introduction

The UK is facing a skills gap in STEM which is effecting how industry operates and their ability to recruit and train their workforce.

ASPIRES [1], a large scale survey of children from age 10 to 14, showed that while 70% would class science as one of their favourite subjects and 90% would like a job that helps others, less than 20% would actually think about pursuing a career in science. The report showed that this was due to several reasons including, how much interaction young people have with science at home, the idea that science is for 'clever people' and whether there was a STEM club at school. The aim of this project was to develop a public engagement Science Technology Engineering and Mathematics (STEM) activity using Hula Hooping to introduce subjects including Biomechanics and Medical Engineering.

### Methods

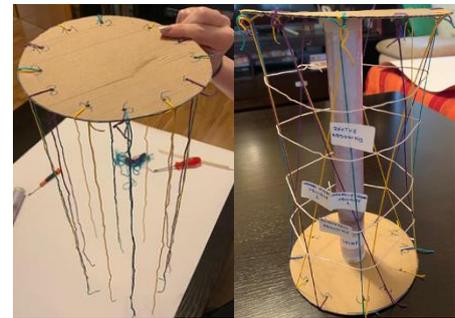

Three dimensional motion analysis was performed on one professional hula hoop instructor using 10 Oqus 700+ Cameras (Qualisys, Sweden). EMG (Delsys Inc.) and force data (Berotec, USA) was also collected in the session. This data was processed using QTM 2020.3 (Qualisys, Sweden) and MATLAB 2020a (MathWorks Inc.). The participant wore a CAST marker set, with additional markers included on the upper body, and lower limb EMG sensors applied following the SENIAM guidelines. Two hula hoops were used one with 8 markers and one with 6 to allow identification during post-processing (see Figure 1).

**Figure 1:** An example of the hula hooper with two hoops before and after processing.

The motion analysis data was used for several purposes. Firstly to demonstrate the stages of data processing (see Figure 1), and the creation of wire model videos to show how the hula hooper is moving. Secondly using marker trajectory, force and EMG data to create sounds associated with the different waveforms. Thirdly, to demonstrate muscle activation associated with human movement.

A literature review undertaken to assess the availability of information on hula hoop biomechanics found a small number of studies, including a trial to develop a robot that can hula hoop [2]. The design that was developed for the robot which shows the abdominal muscles was developed into a craft activity (see Figure 2).

**Figure 2:** An example of the steps and final abdominal muscle model craft activity

### Results and Discussion

The main output of the project to date is the creation of a craft activity (Figure 2) and an interactive webinar for Cardiff Science Festival due to launch on 19<sup>th</sup> Feb 2021. Feedback recorded from this pilot public engagement event will be then used to inform activities for National Biomechanics Day 2021 which is likely to be a virtual event.

Further work is required, with the aspiration to recruit more hula hoopers, to develop this as a resource pack for schools or youth groups.

### Conclusions

Hula hooping is an activity that can be used as a starting point from which to talk about physics, engineering, and biomechanics. This work aims to demonstrate the breadth of careers in STEM, how maths and science concepts that young people are learning at school can be applied to interesting questions, and to highlight the range of different careers and opportunities available in the field of medical engineering.

## Using a physical sarcomere model to demonstrate titin's contributions to residual force enhancement

Heron B. O. Medeiros<sup>1</sup>, Heiliane B. Fontana<sup>1,2</sup>, Walter Herzog<sup>3</sup>

<sup>1</sup>Biomechanics Laboratory, Federal University of Santa Catarina, Florianópolis, Brazil

<sup>2</sup>Morphological Sciences Department, Biological Sciences Center, Federal University of Santa Catarina, Florianópolis, Brazil

<sup>3</sup>Human Performance Laboratory, Faculty of Kinesiology, University of Calgary, Calgary, Canada

Email: [heronbomed@gmail.com](mailto:heronbomed@gmail.com)

### Summary

We built a physical sarcomere model aimed at helping students and trainees in understanding the role of titin in the production of active force in skeletal muscle. Using a simple sarcomere prototype we are able to demonstrate actin-myosin cross-bridges interactions and illustrate the different ways of force production by titin in the active and passive muscle. Specifically, the model illustrates the role of titin in residual force enhancement through calcium binding to titin and titin binding to actin. The model is simple, and demonstration to students resulted in positive feedback about the clarity and improved understanding of a complex molecular mechanism.

### Introduction

Titin is a structural protein in striated muscle sarcomeres. Recently, titin has been associated with active force regulation in muscles, specifically during eccentric (lengthening) contractions, resulting in increased force and reduced metabolic cost for eccentric compared to isometric or concentric contractions [1]. However, the molecular mechanisms causing titin's force regulation remain unknown, although it is generally accepted that it has to do with an activation or a force-dependent change in **titin's stiffness** [1].

In order to illustrate the complex manner in which titin is thought to contribute to active force regulation, we built a physical sarcomere prototype that allows for illustration of titin's proposed function specifically as it relates to the residual force enhancement (RFE) property of skeletal muscle [2]. Thus, the aim of this educational outreach research was to build a physical model of a sarcomere that illustrates the proposed action of titin in RFE.

### Methods

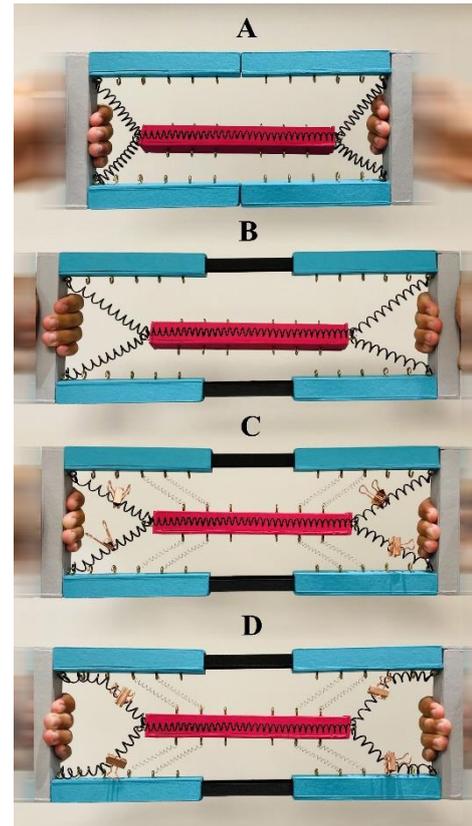

The physical sarcomere prototype contains a Z-band structure (2 cm x 15 cm x 2 cm), actin filaments (15 cm x 2 cm x 2 cm), myosin filament (20 cm x 2 cm x 2 cm), cross-bridges interactions represented by small, stiff springs, and titin, represented by long, soft springs. We used a sole paper of 3 mm to build the sarcomere structure (Figure 1) to arrive at a mostly 2D model with some 3D representation.

The small, stiff springs representing cross-bridge connections between actin and myosin can be attached to three hooks on actin spaced by 2.5 cm and three corresponding hooks per half-myosin, also spaced by 2.5 cm (attached only two cross-bridges in the figure). To allow for rotational and planar stability of the sarcomere model, opposing actin filaments were connected using 30 cm x 1.2 cm x 1.2 cm insert piece (in black).

### Results and Discussion

The primary mechanisms of titin's contribution to the RFE property are related to *changes in titin's inherent stiffness* through binding of calcium to selected immunoglobulin and glutamate regions and by *binding of titin to actin*, thereby

reducing its free spring length, upon muscle activation [1]. The increased titin stiffness with calcium binding is represented by clips in the model that prevent small segments of the titin spring from elongating (Figure 1C). The increased titin stiffness caused by titin binding to actin is represented by hooking the proximal segment of titin to actin (Figure 1D).

**Figure 1:** Three-filament sarcomere model bordered by the Z-bands (gray), myosin filament (pink), actin filaments (blue), titin (black spring), and cross-bridges (small gray springs). (A) passive sarcomere, short length; (B) passive sarcomere, long length (titin elongates unrestricted); (C) active stretch with cross-bridges attached and calcium bound to titin; (D) active stretch with cross-bridges bound, calcium bound to titin, and titin bound to actin.

### Conclusions

The prototype sarcomere model with a titin whose stiffness can be changed through calcium-titin binding and titin-actin binding allows for a visual, macro-structural representation of titin's force regulation mechanisms in muscle – a complicated process. Class demonstrations have proved successful and resulted in positive feedback.

### Summary

Muscle synergies can be characterized by electromyographic (EMG) activities of muscles represented by combinations of time-dependent coefficients (motor primitives) and time-independent weights (motor modules). The motor modules and motor primitive represent together the modular organization. It is currently unknown if modular reorganization (i.e., merging of muscle synergies) does occur if not the central nervous system, but the musculoskeletal system is affected. The aim of this study was to assess short-term (immediate to a few minutes following application) and long-term (years) effects of a constraint of the knee ROM on the modular organization of gait. For this purpose, we used the Non-negative matrix factorization (NNMF) to extract muscle synergies from EMG data of eleven leg muscles in healthy subjects with an artificial knee joint constraint and people with a similar but chronic knee joint constraint. This study showed that in the short-term a knee constraint does not affect the modular organization of gait, but that constraining the knee long-term results in modular reorganization.

### Introduction

It is currently unknown if modular reorganization (i.e., merging of muscle synergies) does occur if not the central nervous system, but the musculoskeletal system is affected. We hypothesize that the modular organization of gait will not be affected in the short-term, but substantially changed in the long-term. For this purpose, we assessed (i) the acute effects of an artificial knee joint constraint on the modular organization in healthy subjects; (ii) the differences in modular organization between healthy subjects with an artificial knee joint constraint and people with a similar but chronic knee joint constraint.

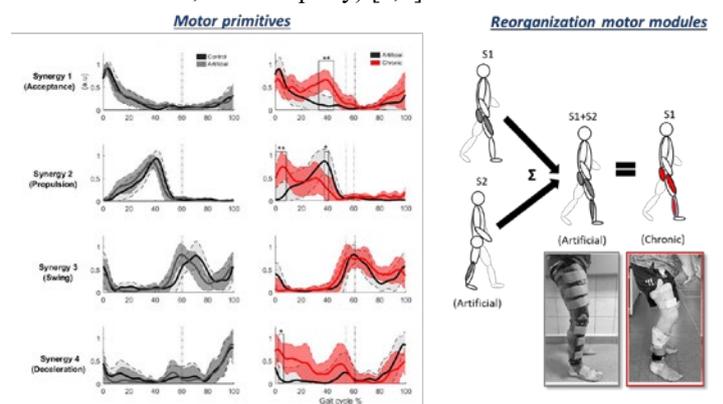

### Methods

Eleven healthy subjects and eight people with a chronic knee joint constraint due by haemophilic arthropathy walked overground at 1 m/s. The healthy subjects also walked with an articulated knee brace limiting knee movement to 20°. NNMF was used to extract muscle synergies from EMG data of eleven leg muscles [1]. Ten cycles corresponding to the middle 10 meters of the 30-meter corridor were used for data analysis (20 cycles in total). The total variance accounted (tVAF) for one to four synergies and modular organization were assessed. Two independent assessments were made: (a) comparison between control group no constraint (control) and

artificial knee joint constraint (artificial) (b) and between artificial joint constraint and people with chronic knee constraint (chronic constraint).

### Results and Discussion

The distributions of number of synergies were not significantly different between groups. The tVAF and modular organization of gait were not significantly affected by the artificial knee constraint. A higher tVAF for one and two synergies, as well as merging of synergies (i.e., acceptance and propulsion, and acceptance and deceleration) were observed in the chronic knee constrain group (Fig 1). The finding that modular reorganization occurred only after long-term exposure to a joint constraint may be explained by secondary changes in the musculoskeletal and the central nervous systems. Up to now, such merging of synergies has been reported only in people with neurological diseases (i.e., chronic stroke, cerebral palsy) [2,3].

**Figure 1.** Motor primitives and reorganization of motor modules. \* $<0.05$ . \*\* $<0.001$ . S1, acceptance synergy. S2, propulsion synergy.

### Conclusions

We conclude that merging of muscle synergies may also occur when changes in the mechanics of the musculoskeletal system is the primary cause of the motor impairment. The present results offer a new perspective on the adaptations of the central nervous system to joint restriction.

## Effect of Low and High Intensity Strength Training on Muscle Forces During Walking In Adults With Knee Osteoarthritis

### Summary

An 18 month, randomized clinical trial (RCT) with 377 adults with knee pain and radiographic knee osteoarthritis (OA) were enrolled into either low- (N=126) or high- (N=127) intensity strength training (ST) or attention control (N=124) groups. Muscle strength, knee pain, and gait biomechanics during walking were analyzed at 0, 6, and 18-months. Low- and high-intensity ST groups had greater quadriceps and hamstrings strength vs control at 18-months, but pain and maximum quadriceps and hamstrings forces during walking were not statistically significantly different between groups.

### Introduction

Since quadriceps muscle weakness is prevalent with knee OA, standard of care often includes ST to strengthen this and other muscles [1]. Additionally, ST also reduces pain and disability in this population [1]. The actual mechanisms for these beneficial outcomes remain unknown but are thought to be due to improved muscle function in gait after strengthening [2]. Recent preliminary evidence suggests however that strengthening does not alter lower extremity muscle forces during locomotion [3]. The purpose of this study was to compare the effects of low and high intensity ST and attention control on muscle strength, knee pain, and muscle forces during level walking in adults with knee OA.

### Methods

An 18 month RCT on 377 adults (40% women, BMI: 31kg/m<sup>2</sup>, Age: 65 yrs) with knee pain and radiographic knee OA and enrolled into low- (N=126) or high- (N=127) intensity ST or an attention control (N=124) group was completed. with tests at baseline, 6 and 18 months. Muscle strength was assessed with isokinetic dynamometry, knee pain with WOMAC questionnaire, and gait data with 3D motion capture and force plate. A musculoskeletal model [4] predicted quadriceps and hamstrings forces during level walking at self-selected speeds. Data were analyzed with a mixed-effects model including time (0, 6 and 18 months), treatment group, time by treatment interaction while adjusting for sex, baseline BMI and baseline outcome values.

### Results & Discussion

Quadriceps strength increased 10, 18 and 25% in control, low and high intensity groups over 18 months and was significantly greater in high vs control group at 18 months,  $p<0.002$ . Hamstrings strength followed a similar pattern, increasing 6, 13, and 17% in the three groups over 18 months

and was statistically significantly greater in both ST groups compared to control at 18 months,  $p<0.001$ . ST groups did not differ in hamstrings strength at 18 months. Knee pain was not significantly different between groups at 18 months,  $p<0.22$  and improved on average 33% over 18 months in all groups.

The primary results for this abstract were maximum quadriceps and hamstrings muscle forces during level walking. Despite increased strength in both muscles in ST groups relative to attention control at 18 months, neither low or high intensity ST altered maximum muscle forces during walking relative to attention control,  $p<0.99$  &  $0.44$ , figure 1.

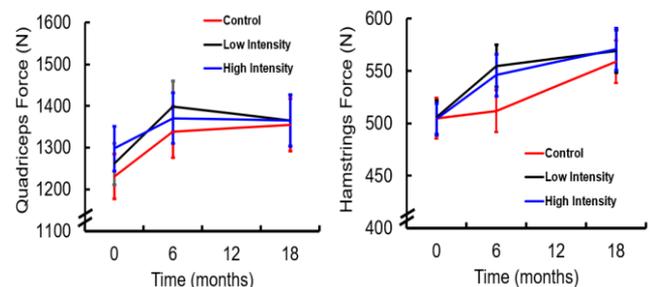

Figure 1. Maximum quadriceps and hamstrings forces during stance phase of walking.

Present results confirm previous data [3] showing that despite increased muscle strength, muscle function during locomotion was not altered after ST. These data also agree with our report that knee joint compressive force was not significantly different among these groups at 18 months [5].

### Conclusions

Both low- and high- intensity ST increased muscle strength relative to attention control after 18 months but did not alter muscle function through maximum muscle forces during level walking relative to attention control in adults with knee OA. The mechanism of reduced pain and disability after ST remains elusive.

## Gait asymmetries following ACL reconstruction differ based on sex and gait speed

Lindsay Slater<sup>1</sup>, Joe Hart<sup>2</sup>

<sup>1</sup>Department of Physical Therapy, University of Illinois at Chicago, Chicago, Illinois

<sup>2</sup>Exercise and Sport Injury Laboratory, Department of Kinesiology, University of Virginia, Charlottesville, Virginia  
Email: slaterlv@uic.edu

### Summary

Sex differences have been previously reported in gait symmetry following anterior cruciate ligament reconstruction (ACLR) in knee and hip kinematics. The purpose of this study was to investigate sex differences in limb asymmetry in knee, hip, and trunk kinematics in walking and running gait. Females demonstrated more knee extension, knee valgus, hip abduction, and lateral trunk flexion towards the contralateral side on the ACLR limb compared to the contralateral side during walking. In contrast, females demonstrated more knee external rotation, hip external rotation, trunk extension, and trunk rotation towards the contralateral side on the ACLR limb compared to the contralateral limb during running. Sex differences exist in knee, hip, and trunk triplanar kinematics in both walking and running gait up to two years following ACLR. Gait asymmetries are not uniform based on sex and gait speed in individuals with unilateral ACLR.

### Introduction

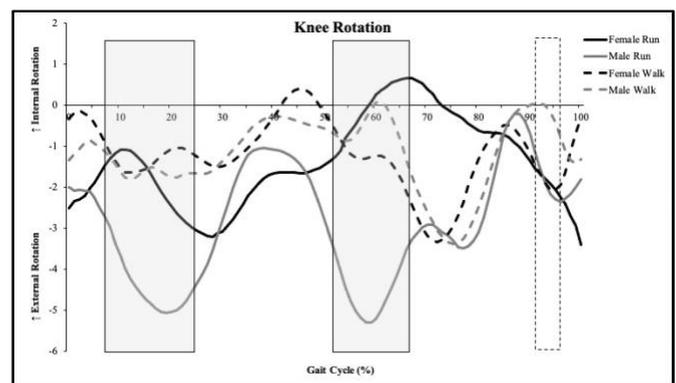

Gait symmetry is often measured following ACLR as an indicator of restoration of normal gait patterns and readiness to return to activity. There is some evidence to suggest sex differences are present in knee gait asymmetries following ACLR [1,2], however there is little information regarding triplanar proximal gait asymmetries following ACLR. Further, gait speed varies between studies. Therefore, the purpose of this study was to identify limb differences based on sex in knee, hip, and trunk kinematics during walking and running gait in individuals with unilateral ACLR.

### Methods

Twenty-two females and 11 males with primary, unilateral, uncomplicated ACLR (19.9±2.2 years, 170.4±8.4 cm, 68.3±10.9 kg, 22.7±23.3 months postop) walked (1.34m/s) and ran (3.33m/s) on a split-belt instrumented treadmill with eight clusters of reflective markers attached to the thorax, sacrum, bilaterally over the lateral mid thigh, midcalf, and forefoot. Twelve nonconsecutive strides were analyzed for each speed and limb. Kinematic data were reduced to 101 points to represent 0-100% of the gait cycle, with 40% representing toe off during running and 60% representing toe off during walking. Heel strike was defined as the point when vertical ground reaction forces exceeded 20N. Kinematics were presented as limb differences by subtracting the contralateral healthy limb from the ACLR limb. Mean limb differences and 90% confidence intervals were calculated for each 1% of the gait cycle. Mean differences (degrees) and associated pooled standard deviations were calculated for periods of the gait cycle when confidence intervals did not overlap for three or more consecutive points.

### Results and Discussion

Females demonstrated more knee extension (2.06°), knee valgus (2.86°), hip abduction (1.44°), lateral trunk flexion towards the contralateral side (2.03°), and trunk rotation towards the contralateral side (1.65°) on the ACLR limb compared to males during walking gait. During running gait, females demonstrate more knee external rotation (4.32°, Figure 1), hip external rotation (1.77°), trunk extension (1.68°), and trunk rotation towards the contralateral side (3.09°). Sex differences in gait asymmetries exist in both walking and running gait following ACLR, however asymmetries in walking gait tended to be more evident in sagittal and frontal planes while running asymmetries tended to be larger in transverse plane motion. These sex differences suggest that asymmetrical gait observed during walking and running gait are not interchangeable and gait profiles depend on both sex and gait speed even two years following ACLR.

**Figure 1:** Sex differences in limb symmetry following ACLR during walking (dashed line) and running gait (solid line). Negative values indicate the ACLR was more externally rotated compared to the contralateral limb and boxed areas are where 90% confidence intervals did not overlap for at least three consecutive points during walk (open box) and run (grey box) gait.

### Conclusions

There are significant sex differences in limb symmetry during gait in those with unilateral ACLR. Sex differences are largely present in knee mechanics, however larger differences are present in transverse plane and more proximal joints during running. These results suggest that walking and running are not interchangeable when evaluating gait asymmetries following ACLR.

## Lower Back Demands During Load Carriage with Induced Asymmetric Gait

Jacob J. Banks<sup>1,2</sup> and Graham E. Caldwell<sup>2</sup>

<sup>1</sup>Center for Advanced Orthopedic Studies, Beth Israel Deaconess Medical Center & Harvard Medical School, Boston MA, USA

<sup>2</sup>Department of Kinesiology, University of Massachusetts, Amherst MA, USA

Email: jbanks3@bidmc.harvard.edu

### Summary

Are L5/S1 vertebral joint forces (VJF) during load carriage with an artificially induced gait asymmetry different than during normal ‘symmetric’ gait? To test this, participants carried dumbbells in one or two hands while walking on a treadmill with and without a walking boot on their right lower leg. VJFs were estimated with a musculoskeletal model incorporating participant-specific muscle recruitment strategies. Results indicated that several key metrics of VJF demand were generally larger during load carriage in asymmetric compared to symmetric gait.

### Introduction

Asymmetric gait is related to a high incidence of lower back pain (LBP)[1]. Though force and repetition are often synonymous with LBP risk[2], biomechanical studies on those with asymmetric gait have been inconclusive[3]. However, most studies have focused on amputees during unloaded gait and applied a generic muscle recruitment algorithm to estimate muscle forces[2-5]. Such studies are limited by between group heterogeneity, the assumption that unloaded gait is the primary LBP catalyst, and the inherent limitations of static optimization[2-4]. Therefore, the purpose of this research was to examine VJF demands in able-bodied participants during load carriage with and without an artificially induced lower limb asymmetry, using a computer model with participant-specific muscle recruitment strategies.

### Methods

Twelve healthy participants consented to have their biomechanics recorded while carrying loads on a treadmill with and without a ~1kg ankle restricting walking boot worn on the right ankle (Figure 1). Dumbbells of 7.5% and 15% of bodyweight were carried uni- and bilaterally with the treadmill set to 90% of preferred symmetric unloaded walking speed. Based on previous work showing location differences[3], unilateral asymmetric carries were conducted with the dumbbell in the left hand.

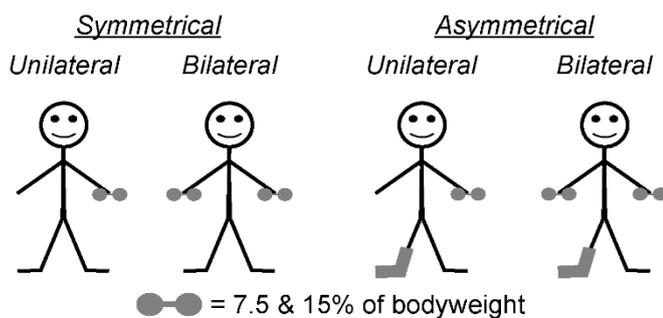

Figure 1: Cartoon of experimental carrying conditions.

A full-body OpenSim[5] model estimated bodyweight normalized peak and average L5/S1 VJF compression and resultant shear averaged from three consecutive strides. The model incorporated a custom EMG optimization[4] API to resolve the indeterminate muscle forces and had been evaluated for gait applications[3]. Three-way ANOVAs compared ( $\alpha < .05$ ) VJF metrics for main effects of gait (a)symmetry, carrying location, and dumbbell load.

### Results and Discussion

VJF peak and average resultant shear and compression forces increased with dumbbell load ( $p$ -values all  $< .01$ ). Carrying location impacted VJF, with one hand carries resulting in mostly larger metrics ( $p$ -values  $< .02$ , except for peak compression force  $p = .10$ ). Overall, gait asymmetry tended to increase VJF metrics (Table 1;  $p$ -values .03 to .42), but only average compression force was significantly different.

Table 1: L5/S1 VJF (% bodyweight) gait (a)symmetry effects.

		Symmetric	Asymmetric	$p$
Resultant	Peak	52.2 (12.6)	53.8 (13.8)	.42
	Average	34.7 (6.8)	36.0 (8.4)	.10
Compression	Peak	348.1 (67.0)	358.8 (62.7)	.10
	Average	261.2 (39.5)	271.2 (45.7)	.03

Previous work has demonstrated similar load carriage and location effects with symmetric gait[6]. Load carriage with a lower limb asymmetry could impact VJFs during weight transfer from the less comfortable lower limb, with acceleration differences and inertia of the carried load increasing kinetic demands. Although not all VJF metrics were different and are below joint acute failure tolerances, repeated steps in conjunction with non-neutral postures and small VJF increases could be a potential catalyst for LBP[2].

### Conclusion

Load carriage with gait asymmetry induced by a walking boot led to increases in some VJF metrics. Therefore, in addition to encouraging lower load and bilateral carries, clinicians and ergonomists aiming to reduce lower back demands should also consider gait asymmetry in their recommendations.

# The Use of the Reference Finite Helical Axis and High-Speed Biplanar Videoradiography to Characterize Knee Kinematics

Tomasz Bugajski<sup>1</sup>, Jessica Kupper<sup>2</sup>, Gregor Kuntze<sup>3</sup>, Janet Ronsky<sup>2</sup>

<sup>1</sup>Biomedical Engineering Graduate Program, University of Calgary, Calgary, Canada

<sup>2</sup>Department of Mechanical and Manufacturing Engineering, University of Calgary, Calgary, Canada

<sup>3</sup>Faculty of Kinesiology, University of Calgary, Calgary, Canada

Email: tbugajsk@ucalgary.ca

## Summary

The reference finite helical axis (rFHA, the FHA relative to a reference frame) provides different kinematic measures than Cardan angles and has distinguished healthy and osteoarthritis (OA) prone knees. The rFHA has not been used to assess walking, a daily task that may influence OA progression. To understand its ability to distinguish kinematics during walking, it is first important to understand the variability of healthy walking rFHA measures. This study used the rFHA, in conjunction with high-speed biplanar videoradiography (HSBV), to determine the variability of specific rFHA outcomes during walking. The variability of the rFHA outcomes were similar in magnitude to Cardan angles, showing promise as a supplemental source of information to kinematic analyses.

## Introduction

The rFHA (FHA relative to a reference frame) has shown to be a useful kinematic measure in optical camera systems, providing different information to Cardan angles. It has distinguished kinematics of healthy and OA prone knees during leg swings and single leg squats [1]. Walking, a daily activity that may influence OA progression [2], has not been assessed with the rFHA. To understand the rFHA's ability to distinguish kinematics during a walking task, variability of healthy rFHA measures must first be known. Therefore, the purpose of this study was to determine what variability of measures the rFHA provides (using HSBV to record direct bone movement) within a healthy sample during walking, and how it compares to the variability of the Cardan angles.

## Methods

Five healthy males ( $25.8 \pm 1.9$  years) were recruited for this ethics approved study (REB15-0554). Magnetic Resonance images (GE 3T Discovery 750, Steady State Free Precision) of the right limb were captured and segmented (AMIRA, Germany), providing bone models of the femur and tibia. HSBV images were recorded (120 Hz) while walking ( $1.2 \text{ ms}^{-1}$ ) on a treadmill. Bone movements were quantified using 2D-3D registration (Joint Track Biplane, USA). The rFHAs of the knee were calculated from heel strike to mid-stance (0-25% of the gait cycle) relative to a reference position ( $60^\circ$  knee

flexion in swing phase). The rFHA was computed using a custom MATLAB program (MathWorks, USA) and included four outcomes: **location** - mean anteroposterior (AP) and proximodistal (PD) intersection of the rFHA and femoral sagittal plane, **translation** - summed translation along the rFHA throughout the movement, **orientation** - mean angle between the rFHA and femoral transverse plane, and **dispersion** - mean angular deviation of each rFHA from the average rFHA [3]. Variabilities (i.e. standard deviations [SD]) across participants for the rFHA outcomes and maximum Cardan angles were compared.

## Results and Discussion

The rFHA location showed large variability (AP location: 40.68 mm, PD location: 31.36 mm, Table 1). Conversely, the translation, orientation, and dispersion had small variability (SDs of 1.92 mm, 2.31 deg, and 0.32 deg, respectively, Table 1). Abnormal knees, such as injured or arthritic, may reveal different variabilities in these kinematic outcomes [3]. The Cardan angles showed slightly greater magnitudes of variability compared to the rFHA outcomes, with SDs ranging from 4.83 deg - 5.62 deg. The rFHA may provide useful measures of knee kinematics and support traditional methods such as Cardan angles.

## Conclusions

The rFHA and Cardan angles provided similar magnitudes of variability during walking in a healthy group. This may provide the framework of future comparisons to other knee conditions, such as aged or injured knees. The application of the rFHA to these conditions may supplement Cardan angles for distinguishing biomechanical markers of the knee (e.g. joint stability).

## Tibial Damage and Osteogenic Effects of High Intensity Interval and Prolonged Running

S. Meardon<sup>1</sup>, A. Vahdati<sup>2</sup>, C. Campbell<sup>1</sup>, D. Sampson<sup>1</sup>, J. Willson<sup>1</sup>

<sup>1</sup>Human Movement Analysis Laboratories, East Carolina University, Greenville, NC, United States

<sup>2</sup>Multi-disciplinary Mechanics and Modeling Laboratory, East Carolina University, Greenville, NC, United States

Email: meardons@ecu.edu

### Summary

Tibial stress during prolonged running was compared to a HIIT protocol of high-speed running with walking recovery bouts. HIIT was more osteogenic with lower cumulative peak stress and damage formation. These results suggest HIIT may be a safe alternative to prolonged running for bone health.

### Introduction

Bone stress injury results from microdamage accumulation associated with repetitive high-impact load cycles in activities like long distance running. Inserting bouts of rest into high impact activity, like those inherent to high intensity interval training (HIIT), may retain the high impact stimulus needed for bone formation while reducing damage accumulation. Evidence related to biomechanical effects of HIIT running protocols is limited. The purpose of this study was to compare cumulative peak stress, osteogenic potential and damage formation rates during a HIIT run protocol to a prolonged run.

### Methods

On day 1, 20 runners (10M, 10F; 25.3±2.6 years; 22.6±2.9 kg/m<sup>2</sup>) completed 5 repetitions of a HIIT protocol consisting of 2-minute run periods at a 95% estimated VO<sub>2</sub> max speed and 3-minute walk periods at preferred speed. On day 2 (>48 hours later), runners completed a 25-minute prolonged run at their self-selected 5k training pace. 3-dimension motion capture and ground reaction force (GRF) data from 5 stance phases were collected in the last minute of each HIIT run and walk period and every 3 minutes during the prolonged run. Kinematics and kinetics were input to an anthropometric-scaled musculoskeletal model to determine internal forces at the distal 1/3 tibia, a common site of injury. Tibial forces and moments were applied to scaled, sex-specific cross-sectional

distal tibia models to estimate compressive and tensile tibial stress using a combination of prismatic beam theory and finite element analysis [1,2]. Peak stress and the number of strides per period were input to cumulative stress, osteogenic index [3] and damage formation rate equations [4]. Session effects were examined with paired t-tests ( $\alpha=0.05$ ) and effect sizes ( $d_z$ ).

### Results and Discussion

Peak compression and tension were greatest in the HIIT run condition (-148±27; 115±23 MPa), followed by preferred run (-136±24; 104±29 MPa) and walk (-61±8; 43±6 MPa). Fig. 1 a and b illustrates that HIIT resulted in lower cumulative peak tibial stress ( $p<0.01$ ,  $d_z=3.28-3.52$ ) and damage formation rates ( $p<0.01$ ,  $d_z=0.61-0.88$ ) than a time-matched, 25-min run. The beneficial effects of HIIT were likely due to fewer high-impact load cycles relative to prolonged running (873±60 vs. 2299±150). To the extent that walking is osteogenic in this population, HIIT was also more osteogenic (Fig. 1b) than prolonged running ( $p<0.01$ ,  $d_z=4.66-4.68$ ).

### Conclusions

While not without risks, incorporating periods of walking into HIIT running bouts appeared to offset the cumulative damage effects of prolonged running while maintaining, and possibly, increasing osteogenic potential.

Email: rickywatari@usp.br

### Summary

The purpose of this study is to identify subgroups of foot-ankle (FA) kinematic patterns among recreational runners and investigate whether differences in baseline movement patterns can influence the mechanical responses to a foot-core exercise intervention program. This is a secondary analysis from a randomized controlled trial investigating the effects of a foot-core exercise program. The kinematic time-series during treadmill running, based on a multi-segment foot model, underwent principal component analysis, and the reduced data was used in a hierarchical cluster analysis. Two clusters of FA running patterns were identified, with cluster 1 (n=36) presenting forefoot abduction, while cluster 2 (n=49) displayed a rearfoot adduction and midfoot abduction throughout the stance phase of running. Runners from cluster 1 (n=16) who underwent foot-core exercises presented changes in foot kinematics that approximated them to the patterns displayed in cluster 2 (n=13). The findings of this study indicate that individual FA patterns can influence the response to exercise interventions.

### Introduction

Foot-core exercise intervention has been shown to reduce running-related injury (RRI) incidence in recreational runners [1]. However, the response to an exercise-based therapeutic approach can present individual differences that could be related to baseline biomechanical patterns. Thus, the aim of this study is to identify homogenous subgroups of foot-ankle (FA) kinematic patterns among recreational runners and further investigate whether differences in FA movement patterns can influence the mechanical responses to a foot-core exercise program.

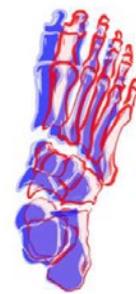

### Methods

This is a secondary analysis of data from a single-blind parallel controlled trial (clinicaltrials.gov - NCT02306148), in which the effects of a foot-core exercise program on the incidence of RRIs were investigated [2]. 3D kinematic data was acquired from 85 recreational runners, using the Rizzoli Foot Model [3], during barefoot treadmill running. Joint angle time-series from the angles between shank and calcaneus (Sha-Cal), calcaneus and midfoot (Cal-Mid), and midfoot and metatarsal bones (Mid-Met) were calculated; kinematic features were extracted using principal component analysis; and the resulting principal components (PCs) served as input to a hierarchical cluster analysis. Optimal cluster division was determined based on the Silhouette index. PCs that presented significant differences between the formed clusters were used to analyze the mechanical differences between them. Data from runners that underwent the foot-core intervention (n = 29) were compared between baseline and week-8 (post-

intervention) assessments, also based on the PCs that presented significant differences.

### Results and Discussion

The optimal cluster division presented a two-cluster solution. Cluster 1 (n=36) and cluster 2 (n=49) had significant differences at baseline in PC1 (p<0.001) and PC3 scores (p=0.037). Cluster 1 maintained the rearfoot and midfoot closer to neutral position and a forefoot abduction during the stance phase of running, whereas cluster 2 presented greater rearfoot adduction and midfoot abduction, while keeping the forefoot closer to neutral position (Figure 1).

**Figure 1:** Between-cluster differences of foot and ankle movement patterns. Cluster 1 is represented in red and cluster 2 in blue.

There was a significant cluster X intervention interaction only for PC1 scores (p=0.01), wherein only cluster 1 presented a significant change after the foot-core exercise protocol. Runners from cluster 1 presented an increase in rearfoot adduction and a decrease in forefoot abduction, making their movement pattern more similar to the runners in cluster 2.

### Conclusions

We identified two clusters of FA movement patterns among recreational runners, with one subgroup presenting a more pronounced forefoot abduction, while the other displayed greater rearfoot adduction and midfoot abduction. There was a different response to a foot-core exercise-based intervention between clusters, indicating that individual foot biomechanical patterns can influence the response to exercise interventions.

### Summary

The aim of this study was to investigate the influence of a foot-core strengthening protocol on medial longitudinal arch (MLA) biomechanics in recreational runners. Multi-segment foot kinematics was recorded from 87 runners randomly allocated in control or intervention group. Significant interaction effect was found for metatarsus-calcaneus angle on frontal plane, and intervention group exhibit less inverted metatarsus, suggesting that the strengthening protocol has a positive effect on foot control.

### Introduction

The intrinsic foot muscles contribute to regulation of foot stiffness during running [1], allowing the MLA storage and return elastic energy and contributing to metabolic energy savings. The inefficient active support of the foot caused by dysfunction or weakness of those muscles is related to injuries in runners [2]. Thus, the aim of this study was to investigate the influence of a foot-core strengthening protocol on MLA biomechanics in recreational runners.

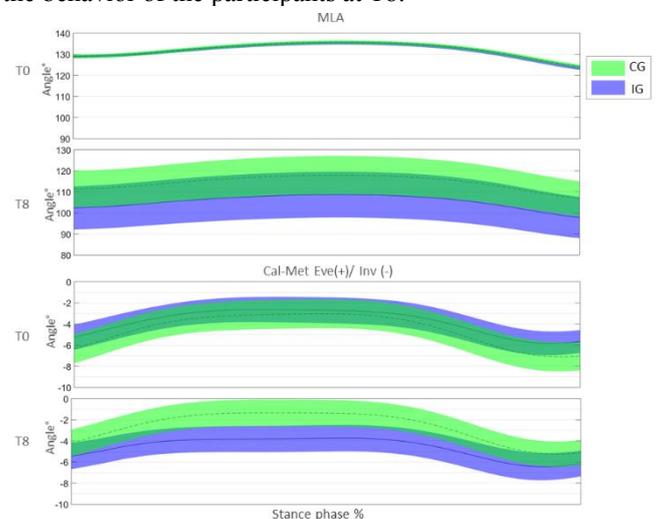

### Methods

A total of 87 injury-free runners (42M, 45F; 40.3±6.9 yrs) with at least 1 year of running experience, running in traditional running shoes, minimum weekly training volume of 20 km, were enrolled to a larger single-blind parallel controlled trial (clinicaltrials.gov - NCT02306148). Runners were randomly allocated in a control group (CG, n=46) or an intervention group (IG, n=41). Kinematic data were collected while running on an instrumented treadmill at self-selected speed (2.7±0.24 m/s). Runners were evaluated at baseline (T0), and after 8 weeks of foot-core training (T8). Participants in the IG went through an 8-week foot-core training exercising 3-times/week while the CG followed a placebo stretching protocol. In order to provide detailed insights into the contribution of individual foot segments to the running biomechanics, MLA and metatarsus with respect to the calcaneus (Cal-Met) angles were calculated in the sagittal, frontal and transverse planes [3]. Joint angles time series were compared using statistical parametric mapping with two factors, 1 repeated (SPM{F}, posthoc SPM{t}) [4].

### Results and Discussion

Following SPM, significant interaction effect was observed in Cal-Met angle on frontal plane between 12.5% and 80% stance phase (p=0.008). The IG showed a larger metatarsus inversion at T8 compared to the CG, suggesting that the IG

was able to increase the foot deformation during stance phase after foot-core training (Figure 1). The range of motion of Cal-Met angle increased, suggesting that the foot improved its stiffness capability on IG. A larger metatarsus inversion may represent a better contribution of the foot structures in transferring and dampening forces during running. The Cal-Met angle on sagittal and transverse planes did not present significant differences. As expected, the MLA, in agreement with the Cal-Met sagittal result, did not show interaction effect. Both groups, IG and CG, showed a large dispersion in the behavior of the participants at T8.

**Figure 1:** MLA (top plot) and Cal-Met angle (Inv/Eve) in frontal plane (bottom plot) waveforms at T0 and T8 for control (green) and intervention (light purple) groups.

### Conclusions

There was a positive effect of the foot-core training on the foot dynamics during running. Foot-core exercises can help the foot structure regarding control of its segments and maintaining stiffness during running.

## Internal Tibial Forces and Moments During Graded Running

Michael Baggaley<sup>1</sup>, Timothy R. Derrick<sup>2</sup> W. Brent Edwards<sup>1</sup>  
<sup>1</sup>Faculty of Kinesiology, University of Calgary, Calgary, Canada  
<sup>2</sup>Department of Kinesiology, Iowa State University, Ames, USA  
 Email: michael.baggaley1@ucalgary.ca

### Summary

The forces and moments acting on the tibia during running play an essential role in the development of tibial stress fractures. The present study observed that downhill running resulted in lower tibial forces and moments compared to level and uphill running. Small reductions in tibial axial and medio-lateral force were observed between steep uphill and level running, yet this did not translate to differences in bending moments. Considering that bending moments are responsible for most of the normal stress placed on bone, these results suggest that downhill running may be associated with a lower risk of tibial stress fracture than either level or uphill running.

### Introduction

Internal bone loads play an important role in stress fracture development. Stress fractures frequently occur at the tibia, and while several studies have examined internal tibial loads in level running, little is known about tibial loads in up- and downhill running. Graded running is associated with large alterations in gait mechanics [1], which are likely to influence the magnitude and orientation of forces and moments acting on and within the tibia. While recent studies have quantified the axial force acting on the tibia to infer bone load and injury risk [2,3], the bending and torsional moments acting on the tibia are responsible for the majority of the stress experienced by the tibia in running [3] and may be more indicative of injury risk. The purpose of this study was to examine the influence of running grade on internal tibial forces and moments.

### Methods

17 (9M/8F, 25.7±6.9 yrs, 22.3±2.1 kg/m<sup>2</sup>) participants ran on an instrumented treadmill while motion-capture and force platform data were collected. Participants ran at 0°, ±5°, and ±10° in a random order at a speed of 3.33 m/s. Ankle joint contact force was estimated using inverse dynamics-based static optimization [4] with muscle moment arms, orientations, and force bounds obtained from a scaled musculoskeletal model [5]. Internal tibial forces and moments were quantified at a cross section located at the distal 1/3<sup>rd</sup> of the tibia, by ensuring static equilibrium with all applied forces and moments. Linear mixed models were used to evaluate the effect of grade on peak forces and moments. Post-hoc testing was performed using Bonferroni adjusted pair-wise comparisons (adjusted  $\alpha=0.005$ ).

### Results and Discussion

Internal tibial moments were lower in downhill running than level running and both uphill running conditions ( $p<0.001$ ), while internal forces were lower in downhill running than

level and shallow (+5°) uphill running ( $p<0.001$ ). Only axial and medio-lateral forces were lower in steep uphill running than level running ( $p\leq0.005$ ). Differences between conditions were driven by changes to the magnitude and orientation of forces acting on the tibia. Specifically, the resultant ankle joint contact force was lower during ±10° and -5°, compared to 0°. However, the lower contact force in +10° did not result in lower bending moments due to changes in the orientation of the contact force vector. During +10°, the contact force was oriented more in the anterior-posterior, which acted to reduce the axial force, while maintaining a similar anterior-posterior tibial force ( $p<0.001$ ) and sagittal plane moment ( $p<0.001$ ) (Figure 1). During downhill running, the changes in forces and moments were mainly the result of the large reduction in contact force magnitude, as orientation of the contact force was only different during -10°. However, this explains the large reduction in bending moments (Figure 1) observed in -10°, as the change in orientation would result in more force acting in the axial direction, thereby producing a lower moment. Overall, graded running altered the forces and moments acting on the tibia. Downhill running may be associated with a lower risk of tibial stress fracture than either level or uphill running.

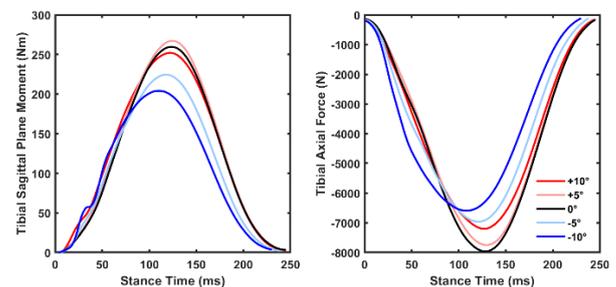

Figure 1: Tibial sagittal plane bending moment (left) and axial force (right) during running.

### Conclusions

Changes to gait mechanics during graded running alter the forces and moments acting on the tibia. However, only downhill running resulted in both lower tibial forces and moments compared to level and uphill running, suggesting that it may be associated with a lower risk of tibial stress fracture development.

# Achilles Tendon and Patellofemoral Kinetics Following A Long Hilly Run in Traditional and Maximal Cushioning Shoes

James Becker, Christopher Casillas

<sup>1</sup>Neuromuscular Biomechanics Laboratory, Montana State University, Bozeman, MT, USA

Email: james.becker4@montana.edu

## Summary

This study evaluated Achilles tendon (AT) and patellofemoral (PF) kinetics before and after a long hilly run in traditional (TRAD) and maximal cushioning (MAX) shoes. AT impulses increased following the run in both shoes while knee extensor moments and PF contact forces were greater in the MAX shoes, both before and following the run. These results add to a growing body of literature suggesting running in MAX shoes may load the PF joint more than traditional shoes.

## Introduction

Several studies have evaluated loading at common injury sites such as the AT or PF joint while running in MAX shoes [1,2]. However, these studies used level ground running over short durations. Both running over graded terrain [3] and long durations [4] has been shown to influence loading at common injury sites. Therefore, the purpose of this study was to compare AT and PF kinetics before and after a long hilly run (LHR) in TRAD and MAX shoes. We hypothesized that MAX shoes would have lower AT and greater PF loading before the run and this difference would increase following the run.

## Methods

Seventeen highly trained trail runners (13 male/ 4 female, age: 26.4 ± 8.2 years, weekly volume: 65.4 ± 22.2 km) were randomly assigned to run in either TRAD (n=8) or MAX (n=9) shoes. After a 10-minute warmup, participants completed a 16 km LHR on an instrumented treadmill. The grade varied to match the elevation profile of a popular local trail run, with a total gain and loss of 337.8 m and 918.8 m, respectively.

Whole body kinematics (250 Hz) and ground reaction forces (1000 Hz) were collected during 2-minutes of level running before and immediately following the completion of the course. Kinetics of the AT and PF joint were calculated using

a musculoskeletal model [5]. Differences in AT and PF kinetics were evaluated using a 2x2 mixed ANCOVA, with time to complete the run used as a covariate.

## Results and Discussion

There were no significant shoe x time interactions for any variable. AT impulse was greater following the LHR (p=.028, Table 1). Both peak knee extensor moments (p=.032) and PF contact forces (p=.042) were greater in the MAX shoes (Table 1).

The increased knee extensor moments in MAX shoes adds to the growing body of literature showing that running in MAX shoes loads the PF joint more than TRAD shoes. Additionally, compared to TRAD shoes, highly cushioned MAX shoes are not protective against potentially detrimental changes in mechanics which occur with fatigue following long graded running.

## Conclusions

Changes in running mechanics following a LHR are similar between TRAD and MAX shoes, however MAX shoes result in greater PF joint loading when running both fresh and fatigued.

## Hierarchical Inverse Kinematics via Bayesian Inference

Andrew J. Pohl<sup>1</sup>, Reed Ferber<sup>1</sup>, Matthew R. Schofield<sup>2</sup>

<sup>1</sup> Faculty of Kinesiology, University of Calgary, AB, Canada

<sup>2</sup> Department of Mathematics and Statistics, University of Otago, New Zealand

Email: andrew.pohl@ucalgary.ca

### Summary

Bayesian inference is applied to a novel hierarchical model to solve an inverse kinematics problem for a set of stance phases collected from a healthy runner. Uncertainty in the resulting joint angle estimates is  $2^\circ$  less than when a hierarchical model is not used. Estimated stride to stride variability suggests that movement variability is reduced in the vertical direction but highest for the angle of the shank.

### Introduction

Recently Bayesian inference has been suggested as an effective approach to solving inverse kinematics problems related to determining gait pose parameters from noisy marker position data [1-2]. A valuable contribution of Bayesian inference, not yet explored with regards to inverse kinematics problems, is the ability to effectively model the hierarchical manner in which data is collected, including parameters to describe stride-to-stride, often ignored in a standard biomechanical analysis. Therefore, we aim to develop a hierarchical model which describes the stride to stride variability in kinematics along with underlying measurement noise and fit this model via Bayesian inference. Secondly, we wish to explore differences in stride to stride variability across the stance phase of gait hypothesising that variability will be lowest for movement in the vertical direction and will decrease for distal segments.

### Methods

3D marker trajectories were extracted from a pre-existing database of gait kinematics [3] for one healthy female runner running on a treadmill. Marker trajectories were projected into the sagittal plane where 20 stance phases were identified and time normalized to 101 points [4]. To determine the typical kinematics and the associated stride-to-stride variability the lower limb was modelled as an  $i = 3$  link kinematic chain and the observed positions of  $j = 1, \dots, 4$  markers for  $k = 1, \dots, 20$  strides ( $\mathbf{y}_{ijk}$ ) were modelled via a multivariate Gaussian distribution where the expected position of markers results from rigid body transformation  $\alpha_{ijk}$  acting on the known positions of markers within their local coordinate system  $\mathbf{x}_{ij}$  with variation determined by measurement noise  $\sigma$ :

$$\mathbf{y}_{ijk} | \mathbf{x}_{ij}, \mathbf{q}_k, \sigma \sim \text{Multivariate-Normal}(\alpha_{ijk}, \sigma^2 I_2) \quad (1)$$

$$\alpha_{ijk} = \mathcal{J}_{ik}(q) + \Gamma(\theta_{ik})\mathbf{x}_{ij},$$

where  $\mathcal{J}_{ik}(q)$  defines the position of each joint:

$$\mathcal{J}_{ik}(q) = \begin{cases} \mathbf{r} & i = 1 \\ \mathcal{J}_{i-1,k}(q) + \Gamma(\theta_{i-1,k})[L_{i-1}, 0]^T & i > 1 \end{cases} \quad (2)$$

and  $\Gamma(\theta_{ik})$  defines a planar rotation matrix given angle  $\theta_{ik}$  with  $L_i$  the known length of link  $i$ . In the second stage, pose parameters  $\theta_{ik}$  and  $\mathbf{r}_{ik}$  are modelled as having arisen from a Gaussian distribution with mean  $\omega_i$  and  $\mu$  and stride to stride variance and  $\kappa_i, \varepsilon$ :

$$\begin{aligned} \theta_{ik} &\sim \text{Normal}(\omega_i, \kappa_i) \\ \mathbf{r}_{ik} &\sim \text{Multivariate-Normal}(\mu, \varepsilon I_2), \end{aligned} \quad (3)$$

For unknown parameters weakly informative prior distributions were used and 10000 samples from the respective posterior distribution were obtained using Markov Chain Monte Carlo methods [5].

### Results and Discussion

This model resulted in more accurate measures of average kinematics with less uncertainty than when a single stride was modelled in isolation. For example, uncertainty of knee and ankle angles was reduced by  $2^\circ$  likely in response to increased information being available for parameter estimation. Stride to stride variance highlighted in Figure 1 demonstrates partial support of our hypothesis with significantly greater variation in the horizontal direction ( $\varepsilon_x$ ) than the vertical direction. In addition the variability in foot angle was less than that of the shank and thigh, however, the variability of the shank segment is greater than that of the thigh segment.

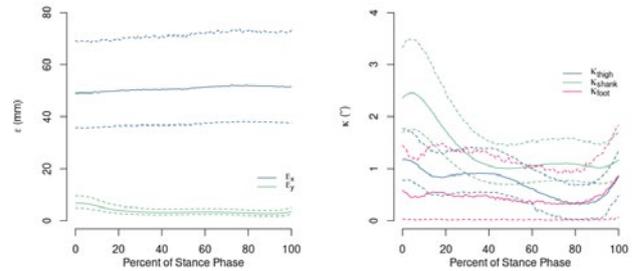

Figure 1: Stride to stride variance across the stance phase for hip joint center (left) and segment angle (right)

We suggest that observed reductions in variability are likely in response to constraints imposed by the length of the lower limb. However, further analysis of such variation may provide insights as to the control of the lower limb during gait.

### Conclusion

A hierarchical model, fit using Bayesian inference, was successful in reducing uncertainty with respect to key kinematic quantities and partitioning stride to stride variance. Such an approach may lead to future insights into the motor control of the lower limb and also present researchers with improved statistical methods in which to analyse the effects of gait interventions.

## Computational Simulation of Sideswipe Collisions to Predict Head Injury Metrics

Shaun B. Jeffs<sup>1</sup>, Dominic R. Demma<sup>1</sup>, Karla J. Petroskey<sup>1</sup>, Megan L. Bland<sup>1</sup>, Steven A. Rundell<sup>1</sup>

<sup>1</sup>Explico Engineering Co., Novi, Michigan, USA

Email: [sjeffs@explico.com](mailto:sjeffs@explico.com)

### Summary

Subjective allegations of mild traumatic brain injury (mTBI) are common following low-energy motor vehicle collisions. In particular, sideswipe collisions between passenger vehicles and heavy trucks often result in substantial vehicle damage and significant claims of injury. Full-scale crash testing of these collisions on a case-by-case basis is not financially feasible. Therefore, we present a validated computational method to predict biomechanical responses of an occupant's head during a sideswipe collision. Vehicle accelerations from published instrumented sideswipe tests were applied to a digital model of the test vehicle in MADYMO. A virtual anthropometric test device (ATD) predicted head injury metrics, which compared favorably with those recorded in the physical tests. The head accelerations were of the same magnitude as those experienced during benign activities of daily living (ADLs). This simulation technique can provide a valuable resource in assessing occupant injury risk during sideswipe collisions.

### Introduction

The considerable physical damage that may be sustained by passenger vehicles during sideswipe collisions with heavy trucks is often disproportionate to the loading experienced by the occupant. Due to characteristically long impact durations during sideswipes, vehicle accelerations are typically lower than in other collision modes. Nonetheless, substantial injuries are often claimed by sideswipe occupants.

Few studies have sought to quantify occupant loading through full-scale sideswipe collision tests. Fittanto et al. conducted four low-speed sideswipe collisions between a tractor-semitrailer and a sedan with an instrumented ATD driver [1]. The ATD responses at various body regions, including the head, were evaluated by Rodowicz et al. [2].

As medical diagnoses of mTBI, i.e. concussion, are generally based on subjective complaints, biomechanical analyses are useful in providing a quantitative means for determining the likelihood of sustaining mTBI. The objective of this study was to establish a validated simulation technique that accurately computes occupant head injury metrics in a sideswipe collision given known vehicle dynamics.

### Methods

A simplified model of the occupant compartment of a 1990s-era Ford Taurus was built in MADYMO based on images from a published crash test (NHTSA #5981). A digital 50<sup>th</sup> percentile male Hybrid III (HIII) was positioned to match the tested ATD (Fig. 1A). This configuration was consistent with the setup used in Fittanto et al. Baseline seat properties were based on literature values [3].

Vehicle acceleration data from sideswipe Test 1A of the Fittanto et al. study were digitized and applied to the model. Linear head acceleration (LHA) and head injury criterion (HIC) 15 were evaluated. Seat properties were then modulated slightly (within real-world ranges) in order to optimize the head accelerations between the physical test and simulation. Once acceptable agreement was found, vehicle dynamics from the remaining three Fittanto et al. tests (1B, 2A, and 2B) were simulated using the same model properties for further validation.

### Results and Discussion

The MADYMO ATD LHA data from Test 1A matched the physical test data with a high degree of fidelity (Fig. 1B). Although the physical test data showed greater noise than the MADYMO data, the peak resultant LHA differed by less than 0.1 g, while HIC varied by only 0.4 (Table 1). Further, the MADYMO ATD's head contacted the head restraint in a similar fashion as described by Rodowicz et al. [2].

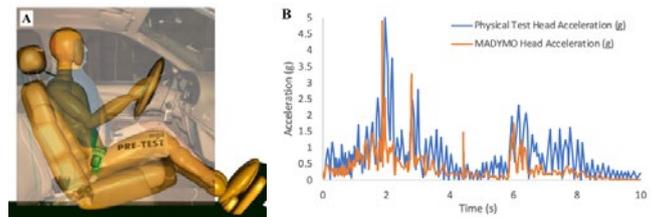

Figure 1: (A) MADYMO setup. (B) Resultant head accelerations.

Table 1: Peak LHA and HIC for physical tests and simulations.

Test No.	Physical Tests				MADYMO Simulation			
	1A	1B	2A	2B	1A	1B	2A	2B
LHA (g)	5.0	2.6	2.2	1.6	5.0	1.7	1.2	1.2
HIC-15	0.7	0.1	0.1	0.0	0.3	0.0	0.0	0.0

For Tests 1B, 2A, and 2B, LHA and HIC differed by a maximum of 1.0 g and 0.1, respectively, between simulation and physical test data. The LHA values across all tests were within a range associated with benign ADLs (e.g. sitting in a chair, hopping) and far below mTBI thresholds [4].

### Conclusions

The present MADYMO simulation predicted occupant head injury metrics during staged sideswipe collisions within a reasonable degree of accuracy. Thus, this technique may be applied to forensic investigations of low-speed sideswipe collisions to assess mTBI risk.

### Summary

The aim of this study was to develop surrogate models of the non-linear elastic behaviour of six lumbar intervertebral discs for implementation in a multi-body spine model. Based on greedy kernel approximations in combination with force-displacement datasets from detailed finite element disc models, the surrogates were capable of predicting level-specific disc forces exerted onto the adjacent vertebra endplates in the full physiological range of motion and for coupling of all six degrees of freedom of an intervertebral joint.

### Introduction

Computer modelling and simulation is a key technique for research in spine biomechanics, where soft tissue elements like ligaments, muscles, and intervertebral discs (IVDs) play a major role. IVDs as a sub-model in multi-body (MB) spine models are typically implemented as a force-torque element acting on the adjacent vertebrae while being dependent on the vertebrae's relative translational and rotational displacements. Disregarding the non-linear characteristics of this soft cartilaginous tissue, the elastic responses are commonly estimated by (bi-)linear spring-damping elements [1]. Even though these so-called 'bushing elements' do not allow for coupling of different degrees of freedom (DOFs), they are the currently most sophisticated approach for modelling elastic IVD responses in MB simulation frameworks in terms of considering basic physical principles. By deriving vectorial forces and torques from a single scalar force potential [2], they conserve mechanical energy in spine simulations. Alternative surrogate models of IVDs include coupling of several DOFs and the non-linear behaviour by fitting force-displacement data for single force or torque components separately, e.g. with polynomials [3] or kernel approximations [4]. Due to the lack of a common force potential and, by that, a loss of physical information, such models violate energy balance.

We, here, combine the physical approach with machine learning techniques based on recently developed greedy kernel methods [5] to mathematically describe the mapping of displacements in all six DOFs of an intervertebral joint to the six elastic response forces and torques exerted by an IVD. To account for energy conservation, we generate kernel models for the force potential of individual IVDs rather than for single force and torque components.

### Methods

Following the procedure presented in [6], a biomechanical finite element (FE) model of a healthy spine was built using anatomical landmarks selected from CT scans of the Visible Human Project (National Library of Medicine, Bethesda, USA, 1994). FE models of the six lumbar IVDs (from sacrum to the lowest thoracic vertebra) were separated from this thoracolumbar spine model. Afterwards, FE simulations of every single IVD were performed in ABAQUS 6.14, representing different load cases: translational and rotational

displacements of the upper IVD endplate along single axes, along two DOFs simultaneously and full 6-dimensional movements. This resulted in datasets of response forces and torques onto the adjacent vertebra endplates and their corresponding displacements. Greedy kernel methods, as described in [5], were applied to create one surrogate model of the force potential for every IVD. Finally, the six level-specific models were included in a MB generic spine model [7]. During simulated spinal movements about different rotation axes, the elastic IVD forces and torques are constantly derived from their corresponding force potential surrogates.

### Results and Discussion

The kernel model generates forces, which are in good agreement with the FE simulation results not only for training data but even for unseen data and coupled DOF motions. At the same time, it is a fast and efficient method to map the non-linear force-displacement characteristics of an IVD. The six-dimensional kernel basis enables to include kinetic coupling of DOFs while the development of surrogate models for the force potential ensures physical validity. Since the underlying FE model only captures elastic behaviour of IVDs, all dissipative processes are neglected in the presented models. Further-more, the assumption of generic IVD material parameters might not hold for different subjects. Instead, the kernel approximation algorithms could be applied to in vivo data of elastic IVD responses or other soft tissue elements in the human body.

### Conclusions

With the established algorithm, we are capable of predicting the non-linear characteristics of subject- and level-specific IVDs in a multi-body spine simulation. Using this approach, it is also possible to generate IVD surrogates for pathological geometric deformations, such as scoliotic spines.

### Summary

Advances in machine learning have increased demand for large, biomechanical datasets. Musculoskeletal simulation techniques, such as computed muscle control (CMC), have the potential to quell this demand at little expense. Yet, calculating one second of muscle activations using CMC can take minutes. We tested the accuracy of using inverse distance weighting (IDW) to approximate muscle activations across models scaled by mass and height. Our results suggest that IDW can accurately predict muscle activations with little cost.

### Introduction

Given sufficient data, machine learning approaches can elucidate complex biomechanical relations. Physics-based simulations provide one approach for generating these large datasets. However, some simulation approaches have a high computational cost, thereby hindering the number and type of observations achievable in a reasonable time. For example, CMC, which computes muscle activations from target kinematics and forces [1], can take minutes to simulate seconds of movement. Across thousands of simulations, this can result in weeks of calculations. In contrast, interpolation methods, such as IDW, are computationally fast. The objective of this work was to investigate the utility of IDW for interpolating muscle activations from sparse CMC datasets.

### Methods

We generated three CMC datasets with different levels of sparsity. Briefly, using OpenSim v. 4.1, we scaled a generic thumb model [2] across uniformly-spaced combinations of 30 masses and 10 heights chosen to represent 5<sup>th</sup>-95<sup>th</sup> percentile adults [3]. For each model, muscle activations to achieve a 40 N lateral pinch force were calculated using CMC. 117 CMC simulations ran to completion, providing muscle activations for a population roughly 63-103 kg and 1.72-1.88 m tall. This dataset was divided into three uniformly-spaced grids: 17 masses by 7 heights (high density), 9 masses by 4 heights (medium density), and 5 masses by 3 heights (low density).

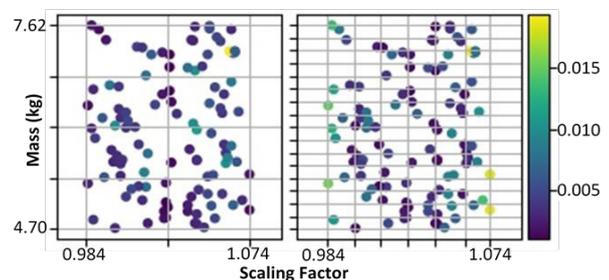

To evaluate IDW's ability to approximate muscle activations, we selected 108 random mass-height pairs that did not correspond to the 117 computed grid vertices. We scaled the thumb model to each mass-height pair and identified the 3 closest grid vertices on a normalized scale. We used IDW with an inverse power weighting function [4] and power parameter of 1 to interpolate the 108 sets of activations. This approach preferentially weighted activations from closer grid vertices. We repeated this procedure for all three grid densities.

To compare against the interpolated muscle activations, we simulated lateral pinch using CMC for each randomly selected

mass-height pair. We quantified the root mean square error (RMSE) between the interpolated activations and the CMC activations. We report the mean RMSE for each simulation (averaging across all muscles) as well as the mean RMSE for each muscle (averaging across simulations).

### Results and Discussion

IDW approximated muscle activations in lateral pinch with minimal error and substantially less computational cost than CMC alone. Fig. 1 illustrates the low density and high density RMSE results. The RMSE associated with interpolated muscle activations never exceeded 4%. Increasing the grid density slightly decreased RMSE, which averaged 0.33%, 0.40%, and 0.45% for high, medium, and low density grids, respectively. At the grid boundaries, the high density grid had higher RMSEs. As CMC simulations outside the grid failed to run to completion, CMC solutions at the boundary may have been less stable. The *flexor pollicis longus* and *extensor carpi ulnaris* had the highest mean RMSE, peaking at 3.2% and 3.7%, respectively, on the low-density grid. No other muscles exceeded a mean RMSE of 1.5%. Furthermore, computation time for CMC simulations averaged 4.22 core-minutes, while IDW averaged 0.95 core-seconds per mass-height pair.

**Figure 1.** Mean RMSE of interpolated muscle activations across each randomly selected mass-height pair (colored). Muscle activations from CMC were calculated at the grid vertices (gray).

### Conclusions

The present work proposed and tested a method for efficient and accurate estimation of muscle activations using a grid of CMC simulations and IDW. This work indicates IDW is a powerful approach for rapidly estimating muscle activations from sparse CMC datasets. Rapid generation of data will facilitate machine learning analyses of human movement.

### Summary

In this study we examined how energy is distributed through whole muscle tissue during cyclic contractions, and how this impacts the external mechanical work done, using a three-dimensional (3D) continuum model of muscle. We found that muscles with higher initial pennation angles stored more energy in the aponeurosis and base material during contraction, and this was associated with higher muscle mechanical work per cycle. These results highlight that the structural and material properties of whole muscle tissue affect the mechanical performance of a muscle.

### Introduction

Skeletal muscles are the motors that drive human and animal locomotion. While muscles have historically been assumed to behave as massless one-dimensional actuators, whole muscles deform and change shape in all three dimensions during contraction [1]. Energy is stored in the tissue as it deforms which alters the amount of energy that is available to do external mechanical work during contraction. Here we examine the distribution of energy through whole muscle in three dimensions during contraction, and how this alters the overall performance of the muscle in the longitudinal direction.

### Methods

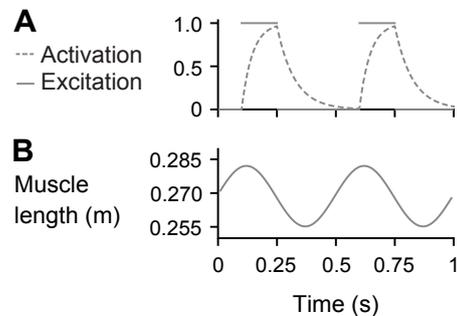

To simulate the behaviour of whole muscle, we used a 3D continuum model (Figure 1) that is fully dynamic and accounts for the effects of tissue mass, velocities, and accelerations [1,2]. The model is composed of one-dimensional fibers embedded in an isotropic base (or background) material, resulting in an overall anisotropic tissue behaviour. We chose the size of the geometry to approximate the dimensions of a human medial gastrocnemius muscle.

**Figure 1:** Image of 3D continuum model of muscle during an active cyclic contraction. The color gradient shows the deformation of the tissue, with red and blue representing greater and lesser deformation, respectively.

We examined the deformations and flow of energy through the muscle tissue during cyclic contractions (Figure 2) with different initial fibre pennation angles (11.5 to 22.7 deg), cycle strain amplitudes (2.5 to 7.5%), and maximum excitations (40 and 100%). We additionally explored how

these tissue deformations and energies were associated with changes in mechanical work per cycle.

**Figure 2:** Sample traces of prescribed excitation (solid) and activation (dashed) (A) and muscle length (B) over time.

### Results and Discussion

For simulations with maximal excitation and a cycle strain amplitude of 5% of the muscle resting length, the energy of the active contractile elements increased as the activation increased, and this was greater for more pennate muscles (with higher initial pennation angles). The base material, which represented the extra- and intra-cellular material besides the contractile elements, and the aponeurosis both had greater peak energy storage during the contraction cycles for muscles with higher initial pennation angles. In terms of the mechanical work, we found that muscles with higher initial pennation angles did greater mechanical work per contraction cycle, possibly due to the greater energy storage in the aponeurosis and base material.

### Conclusions

This study shows how the 3D shape of muscle, and the storage of energy in the tissue during contraction, has important implications for its mechanical behaviour.

## Statistical Prediction of Spinal Injury Using CIREN Data

Sean Pham<sup>1</sup>, Sean D. Shimada<sup>1</sup>  
<sup>1</sup>Biomechanical Consultants, Davis, CA  
 Email: [sean@motionsandforces.com](mailto:sean@motionsandforces.com)

### Summary

To compensate for the lack of available research defining the lateral shear thresholds for spinal injury, crash injury data from 2017 to 2019 was surveyed to develop statistics to gauge the likelihood of spinal injury due to side impact.

### Introduction

This investigation was motivated by the lack of research defining lateral shear thresholds for spinal injury. The goal of this study was to develop probabilistic measures to predict spinal injury occurrence based on crash data from the current Crash Injury Research Engineering Network (CIREN) compiled for years 2017 to 2019. Though there have been studies that use crash data from national databases to separately study side impact [1] and spinal injury [2], the literature correlating side impact dynamics to spinal pathology is sparse.

### Methods

110 incidents, involving a total of 1216 injuries, were surveyed in the current CIREN database. Non-horizontal impacts and incidents with no reported delta-v were excluded. The remaining incidents were indexed for spinal injuries and extracted with accompanying data on impact delta-v, clock direction, spinal section, and injury type. Statistics were calculated based on these parameters to develop Bayesian probabilities for the determination of spinal injury in side impacts.

### Results and Discussion

After downselecting based on the aforementioned criteria, 33 incidents were found that resulted in a total of 78 spinal injuries. Lumbar fractures, including fractures of the vertebral body, spinous, and transverse processes, were the highest likelihood injury with a 51.3% incidence across all impact conditions (Figure 1). Fractures amongst all spinal sections were the prevalent injury mechanism.

To classify side impact injuries, clock directions of 2-4 o'clock (right) and 8-10 o'clock (left) were considered. 24 spinal injuries from 8 side impacts were identified. Injuries were further classified into four delta-v bins (0-25 km/h, 25-50 km/h, 50-75 km/h, 75-100 km/h). Using Bayes' Theorem, the probability of an injury in a specified spinal section for a side impact at a given delta-v was approximated (Table 1).

**Table 1:** Summary of Injury Probabilities for Given Delta-V Classes.

	0-25 km/h	25-50 km/h	50-75 km/h	75-100 km/h
Cervical	6.95%	8.67%	17.1%	2.50%
Thoracic	6.10%	4.15%	8.49%	0.00%
Lumbar	4.67%	43.5%	3.68%	4.67%

### Conclusions

The crash data compiled in the CIREN database provides a good basis for developing statistical tools for accident reconstruction. However, the current CIREN repository lacks sufficient data to adequately gauge the likelihood of a lateral shear spinal injury; the sample size for side impact crashes is small, and the reported injuries do not cover a broad spectrum of injury mechanisms, locations, or severities. Because of the lack of data for high delta-v impacts, the injury probabilities appear artificially low. Addition of data in the 50+ km/h regime will provide more robust probabilistic characterization of spinal injury. Future work will focus on incorporating data from the older CIREN database to build more reliable metrics to capture the dynamics of lateral shear spinal injury. A more diverse array of spinal injuries would allow for further discrimination based on vertebral location and injury severity, amongst other parameters, to improve the precision of spinal injury prediction.

### Summary

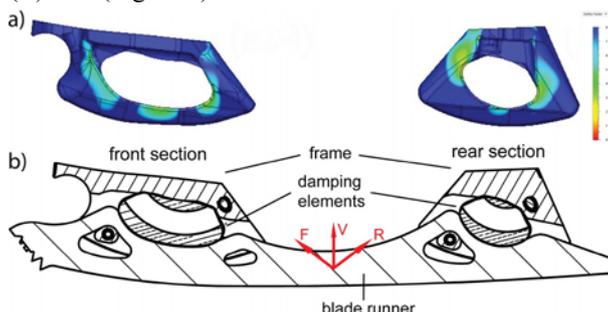

In this study, a new figure skating (FS) blade with an integrated damping system (FSB-IDS) was developed, assisted by a needs analysis, computer-aided design and finite element analysis. The FSB-IDS enables a blade runner to slide upwards inside a frame against elastic damping elements that deflect under the impact load, reducing landing accelerations. Furthermore, the blade runner interacts with the direction and the location of the force vector during the individual phases of the landing impact. Prototype damping elements of stiffnesses relevant for high landing impacts (about 3000 N), with minimal effect on propulsive forces at take-offs (about 1000 N), were tested using a universal test system. A landing impact from a 60 cm high box onto artificial ice using the FSB-IDS prototype verified the intended functionality. In addition, the FSB-IDS can be considered as a lightweight blade.

### Introduction

Today's FS blades have more or less the same characteristics as those from more than a century ago. Apart from incorporating new materials in the construction of the blade, the innovation and emphasis on injury prevention have been inconsistent with the increase in the jump demands of today's competitive FS and the associated rising frequency of chronic overuse injuries. The chronic overuse injuries in singles and pair skaters are attributed to the high loads absorbed during repeated take-offs and landing impacts [1, 2]. Furthermore, the FS equipment contributes to the high impact forces and injury risk, due to its stiff characteristics [3, 4].

### Methods

Based on the requirement specifications, computer models (Fusion 360, Autodesk Inc.) of different FSB-IDS designs ( $n=3$ ) were developed, all consisting of a frame, a blade runner and damping elements. The permissible movement of the blade runner is in vertical direction (V), and diagonally upwards forward and rearward along the (F) and (R) axis (Figure 1).

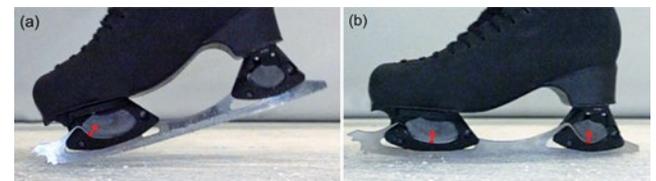

**Figure 1:** a) FEA, Safety factor of FSB-IDS frame under 1000 N perpendicular load to the frame; b) Cross-sectional view of the FSB-IDS, the red arrows indicate the direction of the permissible movement of the blade runner inside the frame (V), (F) and (R).

Finite element analysis (FEA: nonlinear static stress simulation, Fusion 360) was used to initially assess the performance of different shapes and materials, placement of damping elements, including stress distribution. Prototypes of the selected damping elements (thermoplastic polyurethane (TPU) 90 A shore hardness) were evaluated in regards to force-displacement in an electromechanical universal test system (MTS Criterion C42.503). Finally, the prototype of the FSB-IDS was tested during simulated landing impact (replicating a waltz jump from a 60 cm high box) to verify the functionality.

### Results and Discussion

The FSB-IDS concept uses two thick elastic damping elements of TPU material that compress during the impact and thereby reduces the acceleration of the impact [5, 6]. A simulated landing impact using the FSB-IDS prototype showed that the blade runner slides inside the frame and interacts with the direction and the location of the force vector during the individual phases of the landing impact as the damping elements deflect under the load (Figure 2).

**Figure 2:** a) Initial contact of the FSB-IDS with the ice surface; b) Full contact of the FSB-IDS with the ice surface.

Theoretical displacement of the blade runner supported by two damping elements ranged from  $1.1 \pm 0.4$  mm under a load of 1000 N to  $4.8 \pm 2.4$  mm under a load of 3000 N.

### Conclusions

The current FSB-IDS has a simple, compact design in which the combined effect of low weight and damping is adequate to the demands of high-performance FS today.

### Acknowledgments

This work was supported by the Swedish Research Council for Sport Science under Grant P2019-0078. A patent (pending) application was submitted on the FSB-IDS.

Email: kaz11@ic.ac.uk

### Summary

Zimmerman et al., show using video and computational modelling analysis of head impacts leading to a mild TBI in the National Football League, patterns of brain deformation (strain) differ based on whether players lost consciousness or not. In particular, strain was higher in the thalamus and brain stem in players who lost consciousness compared to those who did not.

### Introduction

Sports traumatic brain injury (TBI) can produce transient neurological signs such as loss of consciousness (LOC) and dystonic posturing. However, it is unknown why impacts produce a range of neurological effects. Video surveillance allows the biomechanics of impacts to be calculated from impact reconstructions. The biomechanics can then be used to estimate the patterns of strain produced in different brain regions. Here we use a 3D model of brain injury biomechanics to investigate the strains produced by National Football League impacts that produce mild TBI leading either to LOC, dystonic posturing, or producing no neurological signs. We test the hypotheses that LOC is associated with high strain within the brainstem and thalamus, whereas dystonic posturing is associated with high strain in the motor cortex.

### Methods

82 videos of mild TBIs in the NFL were classified as showing either LOC (20), posturing (21) or no neurological signs (No Signs - 41). Videos were analysed and impacts simulated using previously published methodology [1]. In brief, video analysis was used to estimate impact velocity and location/orientation. Laboratory reconstructions using Hybrid III headforms with mounted accelerometers were used to capture head impact kinematics (Fig 1A). A 3D finite element model was used to calculate brain deformations from each head impact (Fig 1B). The estimated magnitude and location of mechanical strain in specific brain regions were then statistically compared across the groups.

### Results and Discussion

Impacts leading to LOC had significantly higher impact kinematics and whole brain measures of brain deformation compared to No Signs impacts. A voxelwise analysis of brain deformation corrected for the magnitude of strain showed regions of disproportionately higher strain in the thalamus, brain stem and cerebellum in impacts leading to LOC compared to No Signs (Fig 1C). Impacts leading to posturing also showed regions of higher strain, however these areas

were constrained to the cortical regions including the motor cortex.

#### A. Impact reconstruction

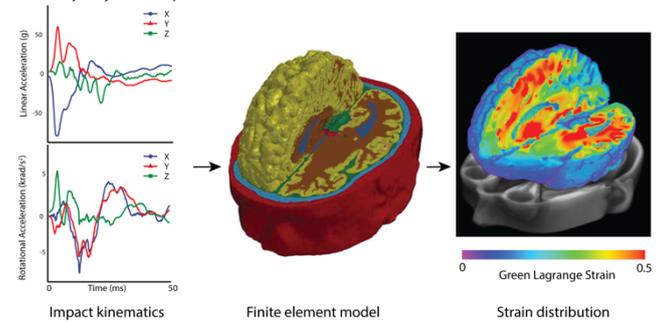

Impacts analysed on video for visible signs post injury, impact velocity, location and orientation

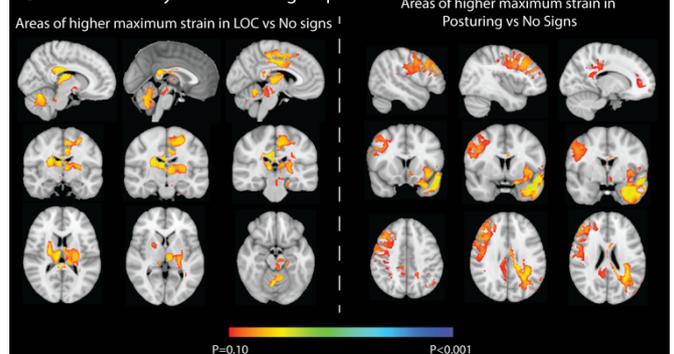

Videos used to guide laboratory reconstructions with mounted accelerometers

#### B. Computational modelling of traumatic brain injury

Case study: Player who experienced loss of consciousness: kinematics and brain deformation

#### C. Voxelwise analysis across the groups

**Figure 1:** A. Impact reconstruction and physical simulation B. Finite element modelling of brain injury biomechanics. C. Maximum strain comparison across groups.

### Conclusions

We show that strains are particularly high in the thalamus and brain stem in those players who lose consciousness. In contrast, impacts leading to posturing appear to disproportionately affect cortical regions, including the motor cortex. These results provide evidence that loss of consciousness is produced by head impacts that produce high strain in the brainstem and thalamus.

## Modelling of the Pelvis and Lumbar Spine in High-Rate Axial Loading

Corina Espelien<sup>1</sup>, Katarzyna Rawska<sup>1</sup>, Rob Salzar<sup>1</sup>

<sup>1</sup>Center for Applied Biomechanics, University of Virginia, Charlottesville, USA  
Email: cme2kd@virginia.edu

### Summary

This study creates a framework to efficiently evaluate the injury risk in an underbody blast (UBB) impact with computational human body models (HBM). Input curves examined in this study varied in terms of peak acceleration and loading rate, as well as HBM posture and axial loading angle. Relative trends of peak forces and accelerations, in addition to the probability of injury, are discussed.

### Introduction

UBB are extremely high rate and high magnitude loading events that can occur in the combat theater, where personnel are subjected to axial loadings due to the detonation of an explosive beneath a military vehicle. While the vehicle can shield occupants from projectiles and blast shock waves, there is a massive amount of energy imparted from the floor and seats of the vehicle directly to the occupants.

Post-mortem human subject (PMHS) testing has helped identify the pelvis and vertebrae injuries from a UBB motivated loading and develop injury risk curves [1]. For any given loading scenario, the injury risk curves use an input variable, such as resulting pelvic acceleration, to determine the probability of injury. Using computational HBM, resultant accelerations, forces, and moments can be approximated for a given load curve. Comparing these resultant metrics to the injury risk curves from PMHS testing provides a low-cost and efficient screening method to determine the types of inputs that may be injurious or not injurious.

### Methods

Simulations in MADYMO, a multibody solver, used with a passive musculature, 50<sup>th</sup> percentile male model were performed to obtain the resultant accelerations and forces of the pelvis and lumbar spine. The peak values for these metrics were compared to the appropriate injury criteria. A finite element model (FEM) of the isolated pelvis and lumbar spine of the 50<sup>th</sup> percentile male model was run in LS-Dyna to assess the strain distribution in the cortical and trabecular bone and the corresponding locations likely to fracture.

The test space and corresponding injury risks were bracketed by two baseline triangular acceleration curves of approximately equal energies, defined by peak accelerations and time-to-peaks. The first baseline impact curve, based on a pilot ejection seat, typically does not result in injury (given the appropriate alignment), with a peak of 17g in 107 ms. The second baseline impact curve, based on average UBB acceleration curves, is considered injurious with a peak of 730g in 2.5 ms. The tilt of the pelvis and the tilt of the entire seat pan relative to the global coordinate system were considered, as they have potential analogs to injury concerns and mitigation strategies.

### Results and Discussion

The MADYMO model output pelvic accelerations for the ejection seat (low-rate) and UBB (high-rate) curve corresponded to injury probability of 0% and 100%, respectively. Compared to a nominal position of the pelvis, an anterior positional tilt resulted increase of L5/sacrum peak axial force by 16%. Reclining the entire seat decreased the peak forces at L5/sacrum and T12/L1 by 24% and 59%, respectively. The FEM strain maps of the cortical bone illustrate the differences resulting from the low-rate and high-rate inputs (Figure 1).

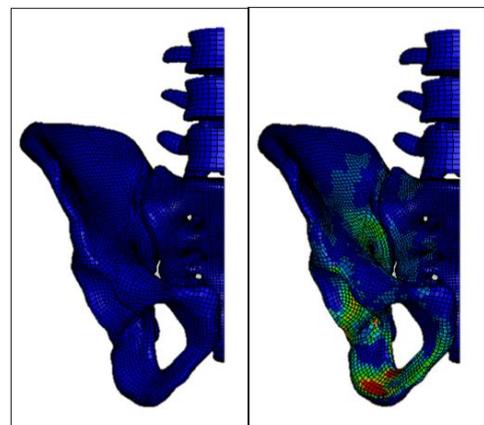

Figure 1: Strain of cortical bone at 5 ms for low-rate (left) and high-rate (right) load input curves. Scale from 0% to 0.3% strain.

### Conclusions

The MADYMO model can quickly output metrics which can be used to assess the probability of injury risk to the pelvis or lumbar vertebrae, while the FEM provides more detailed information about locality of strains. This framework provides a method to assess potential injuries for a given high-rate axial load curve, which can be modified based on UBB mitigation strategies.

### Acknowledgments

The authors are grateful to the University of Virginia School of Engineering and Applied Sciences and Luna Innovation, Inc., for supporting the work leading to the development of this work.

Email: quennev@mcmaster.ca

## Summary

The back-face deformation caused by small arm projectiles impacting ballistic shields used by military and police members can contact the arm, potentially causing an upper extremity injury. This study modified an Anthropomorphic Test Device (ATD) to be used for the characterization of behind ballistic shield blunt impact loading profiles. It was then used to comparatively assess the protective capabilities of two shields with the same ballistic protection rating. The shields exhibited different deflections and loading profiles, indicating a need for a back-face injury metric.

## Introduction

Behind Armor Blunt Trauma (BABT) is a non-penetrating injury that results from contact from back-face armor deformation to the body. Standards have been developed to specify allowable back-face deformation on worn body armor, but these do not directly relate to ballistic shields. When a ballistic shield is struck by a projectile, even if there is no perforation, the back-face deformation may result in fractures of the upper limb. A tool for measuring loading behind shields to assess injury risk and develop appropriate standards to evaluate shield protective capabilities is needed. The purpose of this work was first to modify an ATD to quantify impact responses behind ballistic shields and second, to assess two types of composite ballistic shields (flat and curved), both with the same ballistic protection rating in NIJ 0108.01 [1].

## Methods

Four vulnerable locations were identified: elbow, forearm, wrist and hand. A World SID 50th percentile upper extremity (Humanetics Innovative Solutions) formed the basis of the new device, including integrated six-axis (forearm) and two-axis (elbow) load cells. Uniaxial piezoelectric washer-style force sensors (PCB Piezotronics, Model 201B05, 22.24 kN capacity) were added at the wrist and elbow to measure the applied force. A new hand employed to facilitate gripping of the handle and was similarly instrumented (PCB sensors).

Ballistic testing was conducted at Defence Research and Development Canada (RDDC) - Valcartier Research Centre (VRC), where the ATD, positioned behind the composite shields, was subjected to ballistic impacts (projectile mass 9.6 g, velocity  $847.7 \pm 9.8$  m/s, mean  $\pm$  SD). Impacts were delivered to the elbow and hand, at two stand-off distances (defined as the distance between the back of the shield and the surface of the ATD's sensor). For each impact, the peak forces, moments, and impact duration were recorded, and a high-speed camera (Photron, Fastcam SA-X2, 20,000 fps) was used

to characterize and compare the responses of the shields. The apex of the deformation profile was tracked to determine the total shield displacement and velocity.

## Results and Discussion

For the flat shield, the maximum deflection was  $1.77 \pm 0.3$  cm, whereas the curved shield was  $3.84 \pm 0.3$  cm. Furthermore, the flat shield had a 32% lower ( $p=0.022$ ) peak back-face velocity compared to the curved shield. The four elbow impacts at each of the two stand-offs (10 mm and 20 mm) for the flat shield showed impact force increased by 40% (although not significantly,  $p=0.18$ ) when decreasing the stand-off distance. The five hand impacts at each of the two stand-offs (30 mm and 40 mm) for the curved shield, showed the peak force increased significantly by 44% ( $p=0.0022$ ) when decreasing the stand-off.

Each of the ballistic shields were designated Level III under NIJ 0108.01 [1]; however, they performed very differently under the same testing conditions as their resulting back-face response differed greatly. There is no BABT criterion or specification under this standard, only perforation performance. The curved shield required a greater stand-off to keep loading on the arm consistent, as compared to the flat shield. Increasing stand-off distance is a potential method for manufacturers to reduce loading to the upper limb, to a certain point. A standard is needed (along with injury criteria for these regions of the upper limb) to evaluate shields so that consideration is given to both the risk due to projectile penetration, and the back-face deformation.

## Conclusions

This represents the first highly instrumented ATD upper limb capable of evaluating high energy, short duration impacts typical of BABT. This newly developed ATD quantified the back face loading experienced by the upper limb for two different shields with the same ballistic protection rating. Although rated the same, they had very different deflections which affected their loading at altered stand-off distances, and thus may have different protective capabilities for BABT of comparable impacts.

### Summary

Patellofemoral osteoarthritis (OA) after ACL reconstruction (ACLR) is prevalent. Limited evidence suggests patellofemoral underloading in the involved limb (vs. uninvolved) occurs early after surgery; however, it is unknown if this underloading persists with time. 10 participants underwent motion analysis during overground walking at 6 and 24 months after unilateral ACLR. Muscle forces from a validated EMG-driven musculoskeletal model, in combination with kinematic and anthropometric information, were used to calculate patellofemoral contact forces. Statistical parametric mapping was used to conduct a 2x2 repeated measures ANOVA (Limb x Time) to evaluate patellofemoral contact forces. A significant interaction effect was observed early in stance. Patellofemoral underloading was present at 6 months but did not persist with time. It remains to be seen if this loading pattern is related to eventual OA development.

### Introduction

Patellofemoral osteoarthritis development after ACLR is common; however, the pathogenesis of the disease remains unknown [1]. Underloading of the involved limb has been associated with tibiofemoral OA development after ACLR [2]. Limited evidence suggests a similar underloading mechanism may be occurring within the patellofemoral compartment [3]. However, it is unknown if this underloading persists with time. Thus, the purpose of this study was to examine how patellofemoral contact forces change from 6 to 24 months after ACLR. We hypothesized that there would be involved limb underloading (vs. uninvolved) at 6 months but not at 24 months.

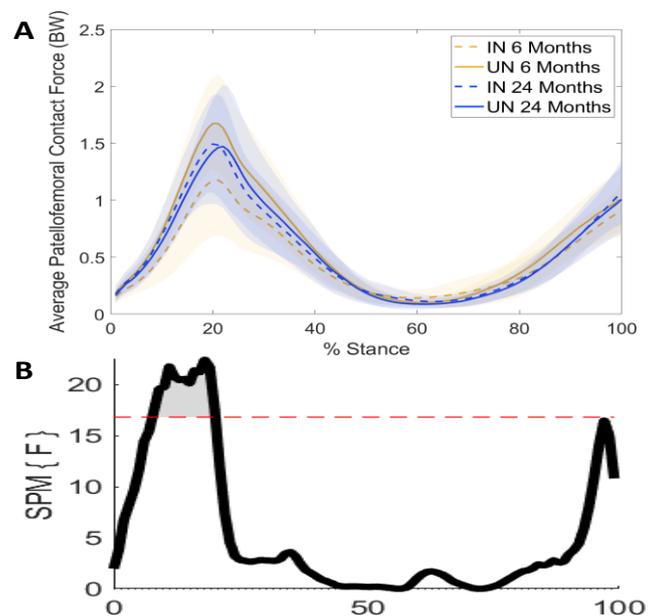

### Methods

10 participants (5 female, mean age:  $21 \pm 5$  yrs) underwent motion analysis during walking at 6 and 24 months after unilateral ACLR with a bone-patellar tendon-bone graft. Kinematic, kinetic, and electromyography (EMG) data were collected bilaterally and used as inputs into a validated, EMG-driven musculoskeletal model to determine subject-specific muscle forces [2]. These muscle forces, in conjunction with kinematic data and anthropometric information, were used to calculate patellofemoral contact force [4]. Statistical parametric mapping (SPM) was used to perform a 2x2 (Limb x Time) repeated measures ANOVA throughout stance ( $\alpha = 0.05$ ) in order to gain insight into patellofemoral forces throughout the entirety of the movement pattern.

### Results and Discussion

Our hypotheses were supported. Underloading of the involved limb's patellofemoral compartment (vs. uninvolved) occurred

6 months after ACLR during the early portion of stance; at 24 months the involved and uninvolved limb displayed similar patellofemoral contact forces (Figure 1A). No main effects of limb or time were observed. However, a limb by time interaction was seen during early stance (Figure 1B). Restoration of patellofemoral contact force symmetry with time is likely driven by restoration of quadriceps strength after surgery; however, this remains to be investigated. Future work should also determine if these changes in patellofemoral contact forces are associated with eventual OA development.

**Figure 1:** A. Involved limb (dashed) and uninvolved limb (solid) patellofemoral contact force at 6 (yellow) and 24 months (blue) after ACLR. Shaded boundaries represent  $\pm 1$  SD. B. 2x2 repeated measures ANOVA F statistic throughout stance for the interaction term; dashed red line indicates significance threshold ( $\alpha = 0.05$ ), shaded area represents significance.

### Conclusions

Involved limb patellofemoral underloading (vs. uninvolved) is present 6 months after ACLR but absent at 24 months. The implications of these loading changes in the context of patellofemoral OA development remains to be explored.

## Differences between loaded and unloaded bone kinematics of the foot and ankle complex

Michele Conconi<sup>1\*</sup>, Alessandro Pompili<sup>1</sup>, Nicola Sancisi<sup>1</sup>, Alberto Leardini<sup>2</sup>, Stefano Durante<sup>2</sup>, Claudio Belvedere<sup>2</sup>

### Summary

We investigated the motion of the foot and ankle bones from a series of static Weight Bearing CT (WBCT) scans, evaluating load related variation through principal component analysis (PCA). For the two investigated feet, unloaded motion can be explained with three synergies. When load is considered, a fourth synergy is needed. In both cases, all the bones participated to the overall foot motion. Synergies matched very well among the feet.

### Introduction

The human foot and ankle complex is a multi-joint mechanism that plays a fundamental role in limb-to-ground interaction. As reported in the literature, its behavior is load-dependent [1-3]. However, a description of the loaded 3D foot kinematics including all bones is still missing, mainly due to the complexity in accurately tracking the motion of all the bones at once. The aim of this work is to fill this gap, by reconstructing the foot bone motion from a series of static scans performed both with and without load. To provide a compact representation of the motion of the foot and ankle complex, data are analyzed through PCA to identify significant synergies among the bone kinematics.

### Methods

We analyzed two feet from cadaver dissection, free from anatomical defects. First, the legs were casted with extended knee (fig. 1.a), leaving the foot and ankle free to move. The feet were then scanned via Cone Beam CT (fig. 1.c) in 15 positions, varying ankle dorsiflexion among  $[-30^\circ -10^\circ 0^\circ 10^\circ 20^\circ]$  and foot supination among  $[-10^\circ 0^\circ 10^\circ]$  through a set of wedges (fig. 1.b), while keeping the leg vertical and suspended by cables, to make it unloaded. The same scans were repeated by applying a vertical load equal to the subjects' half weight (35 kg). Two additional scans were taken by rotating the tibia internally and externally to its max, with the foot in neutral position. CBCT scans were segmented through a semi-automatic procedure (DICE > 95%). Anatomical reference systems were defined for the neutral foot and registered automatically to those from the other scans (accuracy  $<0.5^\circ$  and 0.1 mm). Bone position and orientation were expressed through a cardanic sequence defined for this study (z-y-x). PCA was carried out on two different databases: one with only unloaded poses (15) and the other with all the poses (32).

### Results and Discussion

When foot is unloaded, 3 synergies explained more than 97 % of the variance in bone motion. To explain the same variance with load, a fourth synergy is needed. All the bones participate

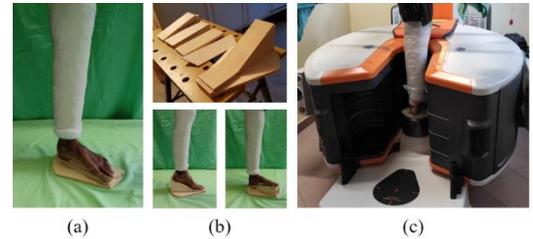

Figure 1: casted leg (a); wedges to set the foot pose (b); the leg in the CBCT (c)

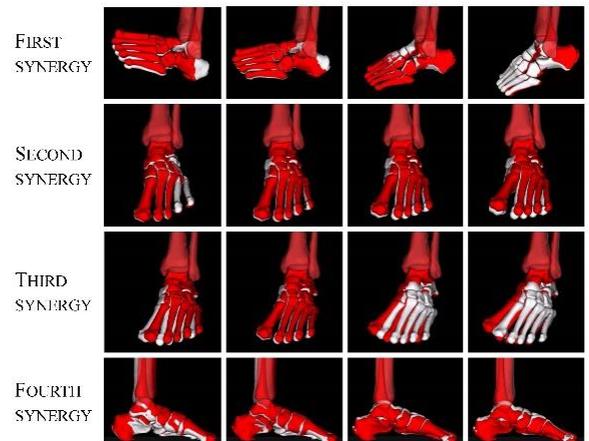

Figure 2: The first four foot without load (grey) and with load (red).

to the overall motion of the foot-ankle complex. The first synergy mainly maps ankle flexion, the second the overall foot pronation, the third abduction at the Chopart joint. These synergies are similar between unloaded and loaded dataset, although the ROM is typically wider for the second. The fourth synergy represents deformation of the foot arches, thus explaining why it is observable only under load (fig. 2). The motion of the two feet is mapped by the same four synergies, however with different variance, confirming that the joint mobility may change among individuals.

### Conclusions

This work reveals the complexity of relative motion among the bones of the foot and ankle complex and the need for weight-bearing CT based investigations, also in patients. While the tibiotalar and subtalar joints provide the main foot mobility about two almost decoupled directions, the other joints behave synergically to support loads and are thus essential to the functionality of the foot.

# The Non-Intuitive Contributions of Individual Quadriceps Muscles to Patellar Tracking

Seong-won Han<sup>1\*</sup>, Andrew Sawatsky<sup>1</sup>, Walter Herzog<sup>1</sup>

<sup>1</sup>Human Performance Laboratory, Faculty of Kinesiology, University of Calgary, Calgary, AB, Canada

## Summary (150 words)

The purpose of this study was to quantify the contribution of the individual quadriceps muscles to patellar tracking. The individual and/or combined quadriceps muscles were activated in rabbits (n=6) during knee flexion/extension. Three-dimensional patellar tracking was measured for the vastus lateralis (VL), vastus medialis (VM) and rectus femoris (RF) when activated alone, and when activated simultaneously. Our results showed that when all quadriceps muscles were activated simultaneously, the patella was shifted, rotated and tilted more medially, compared to when VL or RF were activated alone ( $p < 0.05$ ). Interestingly, VM activation alone produced a similar tracking pattern to that observed when all quadriceps muscles were activated simultaneously, even though the knee extensor torque of VM was much smaller than the torque produced when all quadriceps muscles were activated simultaneously. We conclude that VM affects patellar tracking in a distinctly different way than VL and RF.

## Introduction

Patellar tracking, the movement of the patella relative to the long axis of the femur during knee movements [1], has been found to depend significantly on the force applied to the joint exerted by knee extensors [2]. For example, the patella was found to shift and rotate more medially, as knee extensor torques increased by increasing the level of quadriceps muscle activation [2]. However, it is uncertain how the individual quadriceps muscles contribute to patellar tracking when they are activated individually in isolation.

Recently, we developed a novel technique whereby the individual quadriceps muscles of the rabbit can be stimulated in isolation or in synchrony in any manner desired [3].

The purpose of this study was to quantify the contribution of the individual quadriceps muscles to patellar tracking. Based on previous findings [2], we hypothesized that patellar tracking during knee extension for individual muscles is similar to conditions when all quadriceps muscles are activated simultaneously (this condition is hereafter referred to as "ALL").

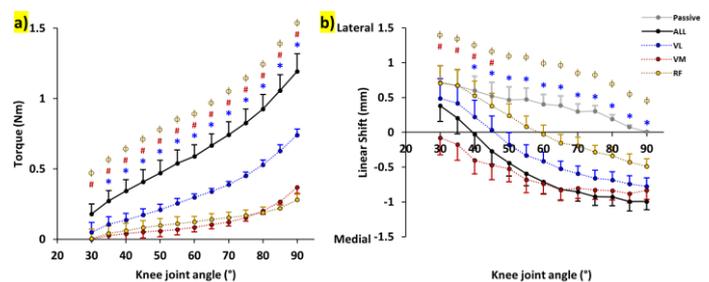

## Methods

All experiments were performed on skeletally mature New Zealand white rabbits (n=6). VL, VM, and RF were individually activated through home-built cuff-type electrodes that were implanted surgically [3]. Rabbit knees were held in place by bone pins, and a motor bar was used to move the knee joint from 30° to 90° (0° = full extension), and to measure the resultant knee extensor torque. Two high speed cameras were used for patellar tracking in three dimensions during knee flexion and extension while activating individual quadriceps muscles in isolation and simultaneously.

## Results and Discussion

The knee extensor torques for individual muscle activation were always smaller than those obtained for the ALL condition (Fig 1a;  $p < 0.05$ ).

As a representative result, the medial-lateral shifts of the patella are shown (Fig 1b). The patella always shifted medially upon muscle activation. Tracking in the medial-lateral direction differed between ALL and VL, and between ALL and RF ( $p < 0.05$ ), while it was similar for ALL and VM (Fig 1b).

**Fig 1. Mean ( $\pm 1$ SE) of knee extensor torque (a) and medial-lateral linear shift of the patella (b) during knee extension (from 90° to 30°).** Black circles with solid black lines represent the ALL condition; the blue, red, and yellow circles represent the VL, VM, and RF conditions, respectively. In figure (b), the grey circles with the grey line is the passive patellar tracking (no muscle activation). Statistical difference: \*, differences between ALL and VL; #, differences between ALL and VM;  $\phi$ , differences between ALL and RF.

If our hypothesis was correct, the medial-lateral shift for VM and RF should be similar, due to the similar force of these two muscles. However, patellar tracking differed between VM and RF. Furthermore, VM activation caused medial patellar shifts similar to the ALL condition, despite much smaller forces. These results suggest that VM plays a unique role in patellar tracking that cannot be achieved by any of the other muscles.

## Conclusions

We conclude that VM contributes in a unique way to patellar tracking, while VL and RF contribute as would be expected based on their force contributions to knee extension.

### Summary

The knee extension moment arm is often modelled using equations derived from cadaveric studies or using measurements limited to the sagittal plane. The objective of this study was to determine if out-of-plane motion affects moment arm length. Using a musculoskeletal model that optimizes three-dimensional patella kinematics, out of plane knee motions, and soft tissue forces, we determined the knee extension moment arm for walking and running across individuals. We found that out-of-plane motion explained a large range of inter-subject variation in the moment arms. This demonstrates the importance of fully describing patella and knee motion when determining the knee extension moment arm.

### Introduction

The patella increases the knee extension moment arm and allows for moment arm variation throughout gait as the patella and tibia articulate with the femur. The knee extension moment arm is measured between the tibiofemoral axis of rotation and patellar ligament [1]. Many models constrain the knee flexion axis and limit moment arm measurements to the sagittal plane. Therefore, these models do not account for all translational and rotational degrees-of-freedom at the knee. Cadaver studies have accounted for out-of-plane knee motions; however, they may not capture accurate *in vivo* behavior from activated muscles [2].

In this study we use a data driven musculoskeletal model with an optimizer that solves for three-dimensional patella mechanics, out of plane tibiofemoral kinematics, muscle and ligament forces, and cartilage contact in a 12 degrees-of-freedom knee [3]. The objective of this study was to determine if out-of-plane motion would affect moment arm length for a given degree of knee flexion.

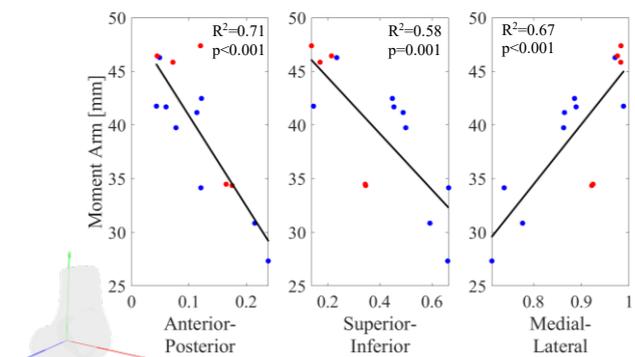

### Methods

We simulated of walking and running trials from ten subjects with a lower-limb MSK model with a twelve degrees-of-freedom knee [3]. The simulations were driven by marker-based optical motion capture and ground reaction force data. We scaled mean bone geometry from a previously collected dataset of fourteen asymptomatic knee MRIs [4] and incorporated the scaled geometry across all trials to focus on kinematic effects instead of morphology. The model specified tibiofemoral flexion from motion capture data and allowed other degrees of freedom at the tibiofemoral and patellofemoral joints to evolve based on optimization of contact, muscle, and ligament forces. We reduced inherent noise of the rotation axis by sectioning gait based on direction of knee motion. Poses of the tibia with respect to the femur at the beginning and end of each section were used to calculate the rotation axes.

We calculated the knee extension moment arm for each trial using a geometric method [1]. To compare the large variation in moment arms found among subjects, we selected 20° of knee flexion—common across all trials within stance—and determined the moment arm and direction cosines of the rotational axis for each trial. F-tests determined if the correlation between moment arm length and the direction cosines were non-zero with an alpha of 0.05. Paired t-tests compared simulated moments arms and moment arms calculated if the rotation axis was purely medial-lateral.

### Results and Discussion

Moment arms at 20° knee flexion varied by 42.3% and decreased as rotation axes became less aligned with the flexion-extension axis. Moment arms were larger if the rotation axis was more aligned with the medial-lateral axis of the knee ( $R^2=0.67$ ,  $p<0.001$ ). Moment arms decreased with anterior-posterior ( $R^2=0.71$ ,  $p<0.001$ ) and superior-inferior ( $R^2=0.58$ ,  $p=0.001$ ) rotational axis orientation. Moment arms were larger when isolating the rotation axis to the medial-lateral direction ( $p<0.002$ ).

**Figure 1:** Moment arms for walking (blue) and running (red) trials versus the directional cosines aligned with femur axes.

### Conclusions

Differences in out-of-plane knee motion across subjects explained the large range of inter-subject variation observed in the knee extension moment arm during both walking and running. These findings highlight the importance of using three-dimensional models that fully describe all translation and rotational degrees-of-freedom at the knee to properly describe the knee extension moment arm.

## Muscle-length dependence of residual force enhancement in the human patellar tendon during submaximal stretch-hold contractions

### Summary

Little is known about the influence of muscle length on residual force enhancement (rFE) following *in vivo* lengthening contractions. This is because only a limited range of muscle lengths has been tested and because rFE *in vivo* needs to be estimated from net joint torque measurements. We therefore estimated rFE within the patellar tendon using a new non-invasive technique known as shear-wave tensiometry [1]. Preliminary data shows that rFE can be detected within the patellar tendon and that rFE is affected by the length of the muscle.

### Introduction

rFE refers to a long-lasting force enhancement following active muscle lengthening compared with a fixed-end reference contraction at the same final muscle length and activation level [2]. *In vivo* rFE has been repeatedly observed in humans indirectly from net joint torque measurements [2]. However, the influence of muscle length on *in vivo* rFE remains unclear [3]. This is because the range of tested *in vivo* muscle lengths is limited and whether rFE occurs at very long muscle lengths is unknown. Further, net joint torque measurements to infer rFE can be problematic because torque is influenced by gravitational forces and forces generated by agonist and antagonist muscles. One potential solution for more directly quantifying *in vivo* rFE involves using a new non-invasive technique known as shear-wave tensiometry [1]. This technique estimates tendon load based on tendon wavespeed measurements. We therefore used this technique and compared it with net joint torque measurements to examine rFE at short, long and very-long muscle lengths.

### Methods

Preliminary data was recorded from one healthy participant who had their right shank fixed to the lever arm of an isokinetic dynamometer while they sat with 90° hip flexion (IsoMed2000, D&R Ferstl GmbH, GER). Net knee joint torque and crank arm angle were measured at 2 kHz and muscle activities of the vastus lateralis (VL), vastus medialis (VM), and rectus femoris (RF) were obtained at 2 kHz using surface EMG (sEMG; NeuroLog System NL905, Digitimer Ltd, UK). The participant performed a maximum voluntary contraction at 70° knee flexion and then fixed-end ramp contractions from rest to 50% of maximum combined knee extensor muscle activity (i.e., by matching their real-time sEMG level to a predefined trace displayed on a screen) at knee flexion angles ranging from 30° to 110° (10° increments). From the resulting wavespeed-angle

relationship ( $W_s-\theta-r$ ), we selected one target knee joint angle on the ascending limb (short muscle length) and two target knee joint angles on the descending limb (long and very-long muscle lengths) of the  $W_s-\theta-r$ . Then, 50% of maximum sEMG-controlled fixed-end contractions at the three target knee joint angles were performed. 50% of maximum sEMG-controlled stretch-hold contractions were also performed over a 15° ( $60^\circ\cdot s^{-1}$ ) stretch amplitude and ended at each target joint angle with an isometric-hold phase of 4-s. During both contraction types, patellar tendon wavespeeds were determined using a piezo-actuated tapper that delivered micron-scale impulses through the skin to the superficial patellar tendon, which induced a transient wave (i.e., transverse tendon motion). The transient wave was detected by two adjacent miniature accelerometers sampling at 100 kHz [1]. All data were synchronized using a 16-bit A/D card within a Power1401 data acquisition interface (Spike2, CED, UK). Calculated wavespeed was smoothed using a moving average over 200-ms. rFE was calculated based on torque and patellar tendon wavespeed data as the percent difference in mean knee extension torque/patellar tendon wavespeed from 2-2.5-s after stretch relative to the time-matched torque/wavespeed during fixed-end contractions.

### Results and Discussion

Based on torque measurements, preliminary results show no rFE at a short muscle length (1%) and similar rFE at long (9.5%) and very-long (8.1%) muscle lengths. Based on wavespeed data, rFE was not observed at a short (-9.4 %) muscle length and rFE was observed at long (5.9%) and very-long (8.2%) muscle lengths. Differences in rFE between net joint torque and wavespeed measurements might be due to axis misalignment of the knee joint relative to the dynamometer axis or might arise from force contributions from antagonist muscles.

### Conclusions

These preliminary results indicate that rFE can be observed within the patellar tendon using shear-wave tensiometry. Similar to *in vitro* experiments, there might be an increase in rFE from long to very long muscle lengths when *in vivo* rFE is assessed more directly via shear-wave tensiometry.

Email: [linmeng@tju.edu.cn](mailto:linmeng@tju.edu.cn)

### Summary

Locomotion recognition is of significance for adapting different control modes of assistive robots. In this study, we proposed a novel recognition method that incorporates electromyography (EMG) and 3-axis acceleration of body segments. Ten healthy young participants were enrolled in the experiment where they performed seven locomotion tasks including standing, sitting, walking, stair ascent, stair descent, ramp ascent and ramp descent. Four classifiers were used and their performance was compared. The results show that all four classifiers could recognize all locomotion tasks with high accuracy (>95%) and more importantly the method can predict movement intention (~229.91ms). The method is expected to significantly improve the effectiveness of a lower-limb assistive device.

### Introduction

Locomotion recognition is crucial for adaptive control of lower-limb assistive system, and detection of user's motion intention enables the wearable robot to deliver a smooth and seamless assistance. As electromyographic (EMG) measures muscle activation resulting in joint movements, intention of locomotion can be decoded based on EMG signals. However, due to its low signal-to-noise ratio and high variance between individuals [1], EMG-based recognition model usually has relative lower accuracy [2]. On the other hand, motion data has been widely used in locomotion modes identification with high recognition accuracy [3]. Therefore, we proposed a locomotion recognition method by combing EMG and motion signals in order to predict locomotion intention.

### Methods

10 healthy young participants (5 males and 5 females, 23.00±0.82 years old, 60.71±11.25 kg) were recruited in the experiment. Each participant wore 7 inertial sensors on the pelvis, thigh shank and foot while 16 muscles were selected, namely rectus femoris, vastus lateralis, biceps femoris, semitendinosus, tibialis anterior, lateral gastrocnemius, and medial gastrocnemius of both legs. They were required to perform 7 locomotion tasks, such as sit, stand, walk, stair ascent, stair descent, ramp ascent and ramp descent. During tasks, EMGs and tri-axis acceleration data were recorded by motion analysis system (Ultium EMG and myoMOTION, Noraxon U.S.A., Inc.) with a sample rate of 2000Hz.

The root mean square (RMS) amplitudes of EMG and acceleration were normalised within gait cycles. Sliding window analysis was used for feature extraction. The window length was set to 150 ms with a sliding step of 50

ms. Four classification methods were used for locomotion recognition, including Support vectors machine (SVM), K-Nearest Neighbor (KNN), linear discriminant analysis (LDA), and artificial neural networks (ANN). After models were trained offline, we tested and analysed real-time model performance on new data.

### Results and Discussion

The offline recognition performance of 7 locomotion tasks was shown in Table 1. The results demonstrated that all classifiers achieved high recognition accuracy (>96%), specificity (>95%) and sensitivity (>99%) and responded to locomotion transitions earlier of actual movements.

**Table 1:** Performance comparison of classifiers.

	SVM	KNN	ANN	LDA
<b>Accuracy (%)</b>	97.80±1.48	96.75±1.19	97.00±1.67	96.45±1.13
<b>Sensitivity (%)</b>	97.86±1.45	96.75±1.19	97.00±1.67	95.45±0.13
<b>Specificity (%)</b>	99.64±0.24	99.46±0.20	99.50±0.28	99.24±0.02
<b>Response Time (ms)</b>	-229.91± 289.80	-185.64± 349.08	-194.31± 287.98	-178.08± 213.70

### Conclusions

The proposed method achieved high accuracy of locomotion recognition and could predict locomotion tasks with combining EMG with acceleration data.

### Summary

Gait has been posited as a biometric for person re-identification (*re-ID*) in authentication and surveillance scenarios. A novel data fusion Siamese deep neural network (*GRFNet*) was developed and evaluated to determine the most discriminant kinetic components during self-selected speed walking in consistent footwear. Across ten runs of network evaluation, an average re-ID accuracy of  $92.33 \pm 1.53\%$  was obtained on 118 healthy participants. Findings from this study confirm the baseline utility of deep neural networks for force platform based gait recognition. The present system is appropriate for authentication tasks that require user cooperation.

### Introduction

Gait is expressed differently between individuals in accordance to their unique structure, physiology and behaviour [1]. State-of-the-art gait recognition systems employ deep neural networks (*DNNs*) to extract features on body appearance or motion from key frames of video data [2]. These systems depend on unreliable appearance features that encode at least some irrelevant, and perhaps confounding, information. Force platforms may be suitable for gait recognition because they record high-resolution kinetic data without influence from lighting conditions. The aim of this study was to develop and evaluate a gait recognition system that incorporates the most discriminant components of walking gait kinetics.

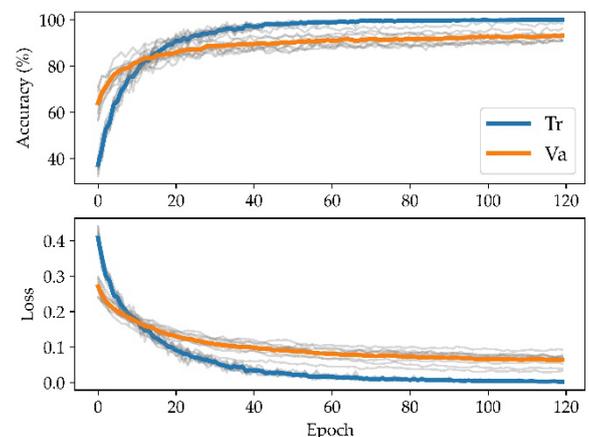

### Methods

The dataset contained 1168 trials of self-selected speed walking from 118 healthy participants with consistent (personal) footwear (57% M, age  $27 \pm 7$  years, mass  $71 \pm 17$ kg, height  $1.72 \pm 0.10$ m). Two sessions were attended within a two week period (3-14 days). Each sample contained *GRFs* ( $F_x$ ,  $F_y$ , and  $F_z$ ), *GRMs* ( $M_x$ ,  $M_y$ , and  $M_z$ ), and *COP* coordinates ( $C_x$  and  $C_y$ ) from two OPT400600-HP force platforms (AMTI, USA) at 2000 Hz. Signals were filtered using a fourth-order Butterworth low-pass filter (cut-off=30Hz) then interpolated to 400 frames. Samples were separated by stance side to prevent sequence bias and represent the asymmetry of walking gait. Finally, signals within each component were standardised ( $\bar{x}=0$ ,  $\sigma^2=1$ ). Neural architecture search and hyper-parameter tuning were conducted manually through bias-variance analysis. The network consisted of four convolutional blocks followed by one long-short term memory layer and one fully-connected layer. Left and right stance inputs were passed through the network in parallel and feature vectors were fused via element-wise summation. The

network was trained, validated and tested ten times for each condition using online batch hard triplet loss (margin=0.3) and AMSGrad optimiser. *Re-ID* accuracy was the primary performance metric.

### Results and Discussion

*GRFNet* was  $92.33 \pm 1.53\%$  accurate on test sets using  $F_y$  and  $F_z$  concatenated along the channel dimension. Training accuracy reached 100% and validation accuracy reached above 90% in all runs (Figure 1). Input-level fusion of sagittal plane GRFs and output-level fusion of stance side features appears to be an effective strategy for force platform based gait recognition.

**Figure 1:** Mean accuracy and loss of the dual component *GRFNet* during training (blue) and validation (orange) overlaid with individual runs (grey).

### Conclusions

This study provides evidence that *DNNs* can reliably extract useful features from multi-dimensional representations of force platform data. In future, force platform based gait recognition systems should be tested in unconstrained walking conditions to validate their utility for unobtrusive and discreet *re-ID*.

### Summary

Gait is one of the complex motor skills associated with neurological and musculoskeletal conditions. Understanding the association between musculoskeletal disease and gait kinematics is essential for the treatment of the disease. However, it requires training and expertise to read and understand gait kinematics graphs for clinical application. Here, we proposed a classification network architecture that predicts anomalous gait features from three-dimensional gait kinematics data. The first part of the network is an encoder that extracts a latent gait vector from high-dimensional gait kinematics data. The second part is a classifier for predicting anomalous gait features from the latent gait vector. The proposed method showed a classification accuracy of 83% on average for five different anomalous gait features.

### Introduction

The gait analysis has been used to assess musculoskeletal diseases [1]. However, clinical assessment of gait kinematics requires physicians trained for gait analysis. The gait deviation index can compare the differences in the patient's gait kinematics from those of the normal population using three-dimensional motion capture data. Still, it provides only a single value for the deviation [2]. Recently, there have been fast advancements in machine learning methods for classifying features using a neural network with high accuracy. The objective of the study was to develop a network model that could classify five anomalous gait features from 3D gait kinematics data.

### Methods

Four hundred eighty-eight subjects (248 males, 240 females, and average age:  $37.1 \pm 16.8$  years) participated in the experiment. Three-dimensional gait kinematics were captured at the subjects' self-selected walking speed using ten motion capture cameras. A physician trained for gait analysis labeled five anomalous gait features – out toe, hindfoot valgus, planovalgus, genu varum, and turtle neck – from using the gait kinematics data. The proposed neural network model and framework to perform anomalous gait feature classification are shown in Figure 1. A 4848-dimensional gait vector was created from a cycle of 3D gait kinematics. Four gait vectors were prepared for each subject. A variational autoencoder was trained to reduce the dimension of the gait vector to 256 dimensions to obtain a latent gait vector. A two-layer neural network was trained to classify the five gait features using

binomial logistic regression. The trained classification network calculated a gait feature vector with five components. The gait feature vector was rounded at 0.5 to classify the five anomalous gait features. The proposed method was compared with the reconstruction-based model in a previous study [3].

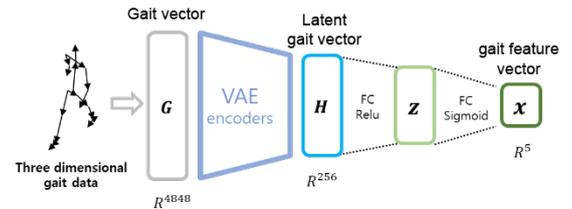

Figure 1: Anomalous gait feature classification network

### Results and Discussion

The classification performances of the proposed method and the method in a previous study were summarized as sensitivity, specificity, and balanced accuracy as shown in Table 1. The results show that the anomalous gait features could be predicted and classified through 3D gait kinematics, and that our proposed model has a high performance that is superior to the previous method. The five types of anomalous gait features had a slight kinematics difference that can only be detected by trained physicians.

### Conclusions

The five anomalous gait features could be detected from 3D gait kinematics data using a neural network with a balanced accuracy of 83% on average. Our method could provide assessments on five different clinical gait features. The features could increase if a larger cohort data is provided. It showed the possibility of using the proposed method as a clinical tool to screen subjects with potential gait-related disease.

### Summary

Obtaining accurate knee kinematics from inertial measurement units (IMUs) typically requires sensors on the thigh and shank and data fusion algorithms to obtain accurate orientation data. Here we present a machine learning model to predict knee flexion angles directly from raw acceleration and angular velocity data from two ankle-mounted IMUs. The model was compared to optical motion capture data on four patients who had undergone total knee arthroplasty. Our machine learning model showed an average root mean square error of 4.5 degrees. This approach is suitable for tracking knee flexion angles of patients outside of the gait laboratory.

### Introduction

Restoring normal knee kinematics is a primary outcome following total knee arthroplasty. Accurate estimation of knee flexion during gait typically requires optical motion capture (OMC), which restrict data collection to laboratory settings. Ideally, wearable sensors, such as inertial measurement units (IMUs) would provide these data to monitor patients in their home environment.

IMUs have been used as input to Kalman filters [1], to provide orientation information, which can then be used to estimate body segment kinematics. However, these require IMUs on multiple body segments with complicated calibration procedures. We present a machine learning approach to estimate bi-lateral knee flexion angles using shank mounted IMUs. The approach requires gait data to be collected for model training, but following training, can be used to obtain reliable and accurate kinematics in the field.

### Methods

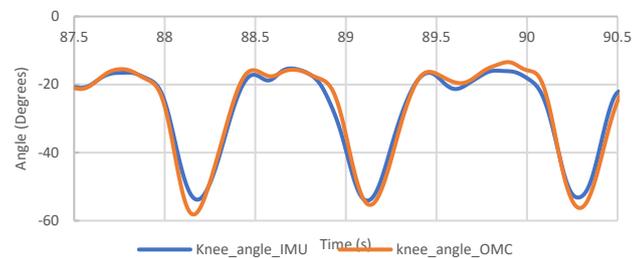

A modelling pipeline was developed using the Python package tsfresh [2] to semi-automate feature selection and extraction from IMU data [3]. We used a random forest regressor to generate person-specific models to estimate knee flexion angle from features extracted from IMUs mounted on the distal tibia of both limbs. Synchronised OMC and IMU data (VICON-IMeasureU) were collected from four knee arthroplasty patients walking at a self-selected speed over ground. A scaled OpenSim model [4] was used to obtain sagittal plane knee kinematics, which were used to train the surrogate model.

The model training involved the following steps: 1) parsing the IMU data for each of the recorded joint angles, 2) feature extraction using tsfresh, 3) feature selection based on their importance (we selected the top 100 features); and 4) fitting regression model to generate the final surrogate model.

We performed a temporal cross validation by training the models on 70% of the individual's data and comparing model predicted knee flexion of the last 30% to OMC-derived knee flexion. Root mean square error (RMSE) and coefficient of determination ( $R^2$ ) was used to compare the surrogate model to the OMC 'ground truth'.

### Results

The surrogate model predicted knee flexion angles to within 4.5 degrees with an average  $R^2$  of 0.93 (Table 1). An example of knee flexion angle prediction is presented in Figure 1.

**Figure 1:** Predicted knee flexion from IMUs compared to optical motion capture (Patient 3).

**Table 1:** Overground walking surrogate model's RMSE ( $R^2$ )

Patient #	1	2	3	4	Average
RMSE °	5.35°	4.61°	3.54°	4.56°	4.52°
$R^2$	0.92	0.95	0.95	0.91	0.93

### Conclusions

We developed a surrogate model capable of predicting knee flexion angles using only shank mounted IMUs in a small cohort of knee joint replacement patients. Our model showed close agreement to OMC-derived knee flexion, which indicates that this approach could be suitable for collecting kinematics in the field. Additional patient data is being collected for validating this approach.

## Summary

On-field athlete mechanical ‘workload’ monitoring is of high interest in sport to inform decisions about performance and injury risk management. However, the direct recording of mechanical workload is predominantly locked to laboratory environments, with field-based efforts inhibitive or unsafe for athletes, or otherwise restricted or regulated. This study aims to use an artificial neural network (ANN) to estimate three-dimensional (3D) ground reaction force components using two-dimensional (2D) video and human pose estimation. Results demonstrated the feasibility of machine learning techniques to remotely estimate ground reaction forces (GRFs) during walking and running for female Australian Rules Football (ARF) players.

## Introduction

The ability to quantify athlete mechanical workload is an integral part of a biomechanist’s role. These workloads can serve as an indicator of athlete performance and injury risk, and can help inform rehabilitation. Current approaches to monitor workload in sport settings have shown the feasibility of neural networks to predict kinetics using wearable inertial motion units (IMUs) and motion capture data [1, 2], although an ecologically valid method to estimate GRF remotely is still required. This study aims to remotely predict 3D GRF components using ANNs from 2D video inputs.

## Methods

Fifteen semi-professional and professional female ARF players (23±3.74 years, 62.77±5.41 kg) performed 10 walking and 21 running trials. Running trials were completed between 4.5 - 5.5 ms<sup>-1</sup>. 12 months following data collection a further four volunteers, ([2♀; 2♂] 25.75±4.69 years, 73.5±7.05 kg) completed three walking, and three running trials to test the trained ANN robustness. All participants provided informed consent with the study approved by the UWA Human Ethics Committee (RA/4/1/2593).

Three video data views were captured (Sony HDR-CX700, 25 Hz); anterior sagittal, sagittal and posterior sagittal. Force plate data was collected at 2000 Hz (Advanced Mechanical Technology Inc., Watertown, MA, USA). Estimated joint centers, or ‘keypoints’, were determined using OpenPose [3] and were used as input data to the ANN. The full video dataset comprised 1130 walking and 1219 running trials. Network architecture is displayed in Table 1.

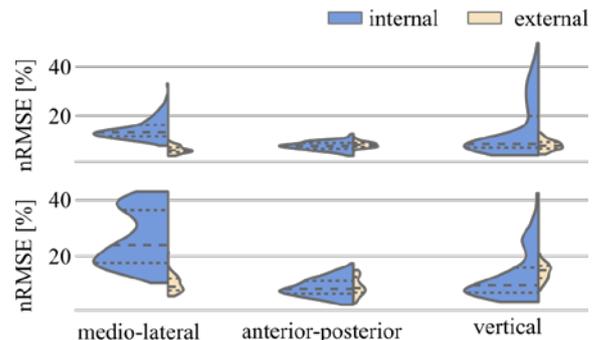

**Table 1:** Neural network hyperparameter search conditions.

Network Architecture	Hyperparameter Search	Walking Architecture	Running Architecture
Dropout	0.1 - 0.7	0.3	0.3
Layer size	8 - 650	500-400-900	500-350-900
Learning rate	3E-02 & 1E-02 - 3E-05 & 1E-05	3E-03	3E-03
No. epochs	1, 11, 21, 31	31	31

ARF player data was used for training and internal validation, performing 3-fold cross validation without data leakage. The additional volunteer data was used to externally validate the ANN, consisting of 34 walking and 20 running trials.

## Results and Discussion

Figure 1 shows that high mean correlation coefficients were achieved for all GRF component estimates for walking ( $r_{\text{med-lat}} = 0.843$ ,  $r_{\text{ant-post}} = 0.988$ ,  $r_{\text{vert}} = 0.957$ ), however only two components for running ( $r_{\text{med-lat}} = 0.501$ ,  $r_{\text{ant-post}} = 0.981$ ,  $r_{\text{vert}} = 0.978$ ). The same trend was observed for external validation, walking ( $r_{\text{med-lat}} = 0.864$ ,  $r_{\text{ant-post}} = 0.989$ ,  $r_{\text{vert}} = 0.969$ ) and running ( $r_{\text{med-lat}} = 0.678$ ,  $r_{\text{ant-post}} = 0.892$ ,  $r_{\text{vert}} = 0.962$ ). The lowest prediction accuracy was in the medio-lateral direction. Vertical and anterior-posterior predictions showed similar accuracy to other machine learning approaches utilising wearable sensors [1, 2].

**Figure 1:** Violin plot of the distribution of normalised RMSE for internal and external validation datasets. Walk (top), run (bottom). X axis = force components X, Y, Z.

## Conclusions

This novel machine learning method to predict 3D GRF components outlines a feasible approach to the remote estimation of mechanical workloads from 2D video.

### Summary

Femoroacetabular impingement syndrome can result in impaired movement patterns and muscle strength. This study aimed to explore the relationships between hip muscle strength and running biomechanics in adults with femoroacetabular impingement syndrome.

### Introduction

Femoroacetabular impingement (FAI) syndrome is a motion-related condition associated with an increased risk of developing hip osteoarthritis [1]. Biomechanical impairments (i.e., kinematics and kinetics) have been shown in FAI syndrome compared to controls during walking and squatting [2]; however, hip biomechanics during higher impact tasks (e.g., running) have yet to be examined.

As well as altered movement patterns, people with FAI syndrome have demonstrated lower hip strength compared to controls [3]. Importantly, hip strength has been shown to relate to self-reported symptoms [3]; thus, hip strengthening is often recommended as a non-surgical treatment strategy. The relationship between hip strength and running biomechanics has been examined in numerous healthy and clinical cohorts, but not in FAI syndrome. If a relationship exists, this will provide further impetus to the prioritization of hip strengthening as a treatment strategy in FAI syndrome.

The aim of this study was to explore the relationship between hip strength and hip biomechanics during running in FAI syndrome, and whether relationships were dependent on sex.

### Methods

This study involves a subset of participants enrolled in a large RCT investigating physiotherapist-led treatment for FAI syndrome. Data were collected at the baseline (pre-randomization) assessment. Inclusion criteria were adults aged 18-50 years, hip-related pain ( $\geq 3/10$  on a numerical pain scale for  $\geq 6$  weeks), cam morphology ( $\geq 60^\circ$  alpha angle), and a positive flexion-adduction-internal rotation test. Exclusion criteria were recent physiotherapy treatment or intra-articular hip injections, previous or planned surgery, radiographic hip osteoarthritis, or other musculoskeletal conditions. All participants provided written informed consent and ethical approval was obtained from the institutional ethics committee.

Overground running biomechanics data were collected with a 10-camera motion capture system (Vicon, UK) and an embedded force plate (AMTI, USA). Participants underwent overground running trials at a target running velocity of 3 to 3.5m/s. Marker trajectories and ground reaction force data were filtered using a fourth-order low-pass Butterworth filter with zero-lag and a cut-off frequency of 10Hz as per previous

research [4]. A previously used biomechanical model [4] was used to calculate joint angles and ‘external’ joint moments over the stance phase of the gait cycle. Discrete variables of interest included peak hip joint angles, and peak and impulse of the hip joint moments.

Following biomechanical assessment, a hand-held dynamometer (JTECH Medical, USA) was used to assess the isometric strength of the hip abductors and adductors (supine), extensors, internal rotators, and external rotators (prone), and flexors (seated). A single assessor performed all strength testing. Three maximal efforts for each muscle group were recorded, with the peak of the three trials used in the analyses.

Relationships between hip strength and hip running biomechanics were explored using linear regression models. Biomechanical variables ( $^\circ$ , Nm) acted as the dependent variable, with muscle strength (N), body mass (kg), velocity (m/s), and sex (men/women) entered into the model as independent variables. A sex\*strength interaction term was examined; if significant, data were dichotomized by sex and examined in separate models, and if non-significant, the interaction term was omitted.

### Results and Discussion

Forty-two participants with FAI syndrome were analyzed (22 men and 20 women;  $36 \pm 9$  years of age;  $73 \pm 15$  kg;  $1.7 \pm 0.1$  m;  $73 \pm 8^\circ$  alpha angle). During the stance phase of running, a significant negative relationship was observed for hip frontal range of motion and peak hip external rotation strength, independent of sex ( $P=0.03$ ). Furthermore, an interaction effect was observed for the relationship between peak hip external rotation strength and peak and impulse of the hip extension moment ( $P=0.04$  and  $0.02$ , respectively), with stronger external rotators related to increased ‘external’ hip extensor moments in women but not men.

### Conclusions

This study is the first to explore the relationships between hip strength and running biomechanics in FAI syndrome. We found relationships to be minimal, with external rotation the only strength measure to demonstrate significant relationships to hip biomechanics during running. Due to the cross-sectional nature of this study, causation is unable to be determined. Future FAI syndrome research should explore changes in hip strength and biomechanics after intervention.

### Summary

Mechanical loading plays a fundamental role in osteoarthritis (OA) worsening and is potentially modifiable through movement retraining. This feasibility study evaluated whether hip load could be modified by changing external biomechanical parameters with assistance from real-time biofeedback during walking in people with hip OA. Most participants with hip OA could immediately alter their hip loading through personalised movement retraining and reported a clinically meaningful improvement in pain after a 6-week intervention.

### Introduction

Non-surgical and non-drug treatments are recommended globally for management of hip OA, despite many patients reporting only small-to-modest improvements in symptoms [1]. These poor outcomes exist because targets for treatment are not well defined, not personalised, and largely extrapolated, inappropriately, from studies of people with knee OA. Mechanical loading plays a fundamental role in OA worsening [2] and is potentially modifiable through movement retraining. Lower hip loads are characteristic of individuals with mild-to-moderate hip OA [3], who are early in the disease course and therefore prime candidates for targeted disease modifying interventions. This study aimed to determine: 1) whether hip load could be increased by changing external biomechanical parameters with assistance from real-time biofeedback during walking; (2) which biomechanical parameter(s) are most effective for increasing hip load; and (3) any associated change in pain following 6-weeks of walking using a personalised load modification strategy.

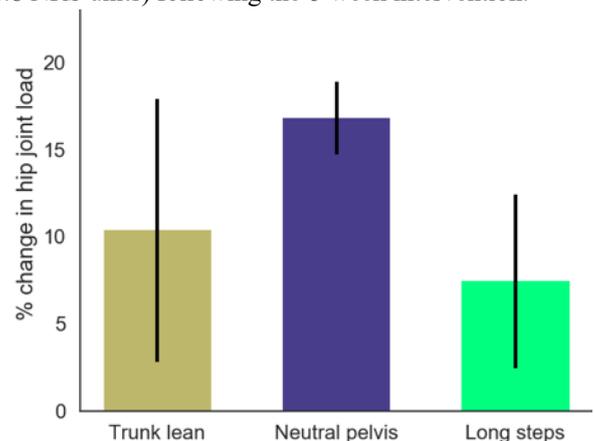

### Methods

Seven participants (age=57.6±4.9 yrs, BMI=30.8±5.8 kg.m<sup>-2</sup>, 57% male) walked on an instrumented split-belt treadmill (Bertec Corporation, USA) while three-dimensional whole-body motion (Vicon, UK), ground reaction forces, and surface electromyography (Cometa, ITA) of 14 lower limb muscles were synchronously recorded. Participants walked for 5-minutes at a self-selected pace, then under each of the following conditions: (i) neutral trunk lean; (ii) neutral pelvis; and (iii) increased step length. For each condition, the biomechanical parameter of interest and a corresponding target value was displayed in front of the treadmill in real-time. The personalised target was calculated from the normal walk condition and was set to increase hip load by ~5%. Participants were asked to rate their pain and confidence on 11-point numerical rating scales (NRS, 0=none, 10=extreme) following each condition. A decision tree, based on

competence, confidence, and pain, was used to assign a personalised load modification strategy to each participant for integration into their walking routine over 6-weeks. A calibrated EMG-assisted model [3] was used to estimate hip contact forces (i.e. load, N) across five gait cycles per walking condition. Peak hip load was compared between walking conditions using a repeated measures analysis of variance ( $p < 0.05$ ).

### Results and Discussion

Five of seven (71%) participants increased peak hip load >5% when walking using their personalised load modification strategy (Figure 1). Walking under all conditions increased peak hip load compared to normal walking, albeit not a statistically significant amount ( $p > 0.05$ ). All but one participant reported a clinically important difference in pain (>1.8 NRS units) following the 6-week intervention.

**Figure 1:** Percent change ( $\pm 1$  standard deviation) in hip load relative to normal walking when participants with hip OA walked under three load modifying conditions (neutral trunk lean  $n=3$ ; neutral pelvis  $n=2$ ; increased step length  $n=2$ ) with assistance from real-time visual biofeedback.

### Conclusions

Most participants with hip OA could immediately increase their hip loading through personalised movement retraining and reported a clinically meaningful improvement in pain after 6-weeks. However, the hip's load response to each biomechanical condition was not universal, emphasising the need for an intervention customised to the individual.

# Femoral Offset Shortening After Nailing of Hip Fractures Does Not Correlate with Pelvic Control During Gait

Arjun Sivakumar<sup>1</sup>, Mark Rickman<sup>1,2</sup>, Dominic Thewlis<sup>1</sup>

<sup>1</sup>Centre for Orthopaedic & Trauma Research, The University of Adelaide, Adelaide, SA, Australia

<sup>2</sup>Department of Orthopaedics & Trauma, Royal Adelaide Hospital, Adelaide, SA, Australia

Email: [arjun.sivakumar@adelaide.edu.au](mailto:arjun.sivakumar@adelaide.edu.au)

## Summary

Femoral nailing of elderly trochanteric fractures often result in shortening of the femoral neck, negatively impacting patient function and spatiotemporal parameters of gait. This study aimed to determine if femoral offset shortening is associated with pelvic control during gait. Results from this interim analysis showed a trend towards a significant correlation between the amount of femoral offset shortening and contralateral pelvic drop.

## Introduction

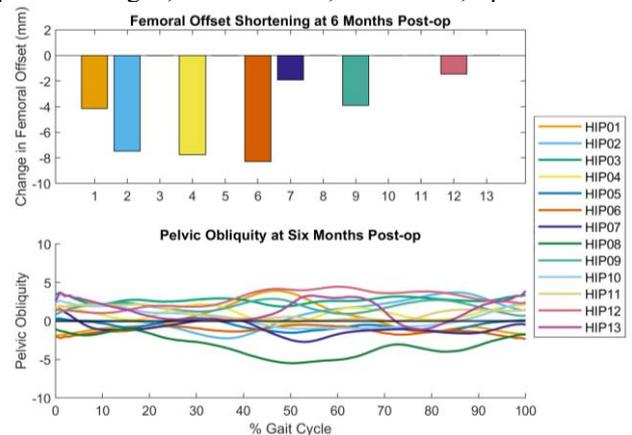

Intertrochanteric (IT) fractures are commonly treated with proximal femoral nails (PFN) that promote compression at the fracture site during loading. While desirable for fracture stability and healing, shortening of the femoral neck is commonly reported postoperatively [1], negatively impacting physical functioning scores [2] and spatiotemporal parameters of gait [3]. Theoretically due to shortening of the hip abductor moment arm, there exists no published literature on gait kinematics in geriatric trochanteric fracture patients to date, leaving this recovering cohort poorly understood. In particular, the relationship of femoral offset shortening on pelvic control during gait remains unclear. This study aims to determine if femoral offset shortening is associated with pelvic control during stance phase of gait after femoral nailing of intertrochanteric fractures.

## Methods

Thirty elderly patients (n=30) sustaining IT fractures were prospectively enrolled and treated with a PFN. Patients were followed up at six months post-operatively where radiographs of the affected hip and three-dimensional gait analysis data were collected. An OpenSim lower limb model (gait2392) was scaled using an atlas based statistical shape modelling method (MAPClient) [4] by fitting principal components of an articulated shape model to landmarks collected from the motion capture static trials. Segment angles were calculated for each patient according to ISB recommendations [5]. The amount of contralateral pelvic drop/rise at midstance (30% of the gait cycle) was calculated by subtracting the degree of pelvic obliquity at midstance from that at footstrike of the operated limb. Femoral offset (FO) was measured at baseline using post-operative image intensifier radiographs and at six months using flat panel radiographs. The change in FO was then calculated between the immediate post-operative and six-month time points. A Pearson correlation was used to assess the relationship between the FO shortening and contralateral pelvic drop (Trendelenburg sign) during the stance phase of gait.

## Results and Discussion

The results presented are an interim analysis of thirteen patients. The measured change in FO at six months post-operative and pelvic obliquity across a gait cycle is shown for each patient in (Figure 1). For measured increases in FO and changes < 2 mm, FO shortening was assumed to be 0 mm, due to limitations in accurately measuring FO from plain film radiographs. Up to 8 mm of FO shortening was measured at six months postoperative. Degree of contralateral pelvic drop from footstrike to midstance ranged between -2 to 2 degrees. There was a minor trend between FO shortening and contralateral pelvic drop during the stance phase of gait,  $r = 0.420$ ,  $n = 13$ ,  $p = 0.153$ .

**Figure 1:** Changes in femoral offset per patient at 6 months postoperative and pelvic obliquity over the gait cycle.

## Conclusions

The magnitude of FO shortening varied between individuals and presented a trend towards a significant correlation with contralateral pelvic drop during the stance phase of gait. Analysis of the updated dataset is required to better discern whether this is statistically significant. Patients exhibited rigid angular pelvic motions, likely resulting from age related changes to pelvic, trunk and lower limb motions, reported by previous authors. [6]

## Summary

A three-dimensional finite element model of a diabetic neuropathic foot with hammer toe deformity was constructed. The geometry of the FE model was formed based on segmentation and reconstruction of MRI images. A multi-body musculoskeletal simulation based on 3D gait analysis was carried out for predicting six muscle forces. Validation of the derived muscle forces were performed using EMG. FE simulations were run at five stages of stance phase of gait. The derived muscle forces and measured GRFs during gait were added to the model as boundary conditions. The validation of FE results indicated a good agreement between simulated plantar pressures (PP) against the measured values from pressure plate. The analyses showed that the presence of hammer toe causes stress concentration on metatarsals. However, the stress concentration seems to shift from the 5<sup>th</sup> metatarsal to the 3<sup>rd</sup> metatarsal as the gait progresses from early stance to toe-off.

## Introduction

Finite Element analysis can overcome the restriction of experimental methods, by providing a mean to measure internal stresses [1,2].

The aim of this study was to investigate the effects of hammer toe on the internal stress distribution on the bone during walking.

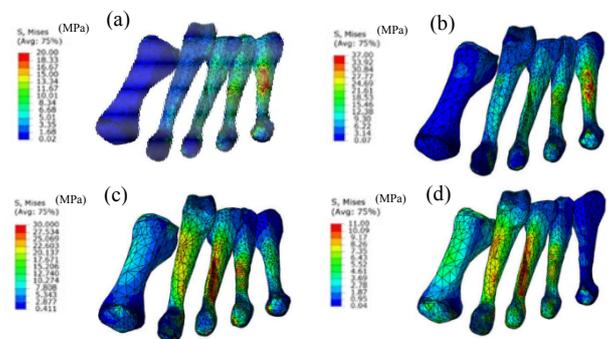

## Methods

A participant (male; age: 53 years; BMI: 34 kg/m<sup>2</sup>) with diabetic neuropathic diabetic foot with non-deformed right foot and hammer toes deformity in the left foot, participated in this study. Following informed consent, MRI scan and 3D gait analysis were carried out. To predict the muscle forces, 'gait 2392' model in OpenSim software was used [3]. A 3D model consisted of a soft tissue and 30 bony structures were reconstructed based on MRI images using mimics software (Materialise, Leuven, Belgium). The obtained model was then imported to ABAQUS software (SIMULIA, Providence, USA) where the plantar fascia and ligaments were modelled as 2174 truss elements, while 74 layers of cartilage was added to the model. The material properties were assigned based on previous study [1]. The 3D foot orientation angles were obtained from the gait analysis of the participant. As boundary conditions, the GRFs were applied at the COP while the muscle forces (including: lateral gastrocnemius, medial

gastrocnemius, tibialis posterior, tibialis anterior, soleus, peroneus longus) were applied at the corresponding insertions points at five stages of stance phase of gait (5%, 25%, 50%, 75% and 90%)

## Results and Discussion

The FE model showed to be able to predict peak plantar pressure with less than 11% errors. FE results showed internal stresses distribution in bony structures (Figure 1). As shown in this figure, maximum Von-misses (internal) stress occurred at 3<sup>rd</sup> metatarsal during of late stance phase of gait.

**Figure 1:** Finite element internal stresses in metatarsals at four walking events. Early stance (a), mid-stance (b), late stance (c) and toe off (d).

## Conclusions

In a foot with hammer toe deformity stress concentration appears to be on the 5<sup>th</sup> metatarsal during the early and mid-stance stages of gait. The stress concentration shifts to 3<sup>rd</sup> metatarsal during the late stance and toe-off. The findings can have practical implications in clinical management of hammer toe deformity.

### Summary

We used statistical shape modeling, and developed a novel method called statistical fibre modeling, to determine the effects of strength training on the three-dimensional (3D) shape and fibre architecture of the vastus lateralis muscle. Mean muscle shape and architecture, and their main modes of variations, were determined from magnetic resonance and diffusion tensor imaging scans obtained before and after eight weeks of strength training. Shape modes that were closely associated with changes in volume were significantly affected by training. The two major modes of variation in fibre orientations were significantly affected by training, suggesting complex three-dimensional fibre reorientations when muscles hypertrophy.

### Introduction

The effect of strength training on muscle architecture is typically measured as the change in volume, cross-sectional area, thickness, mean fascicle length and/or pennation angle of a muscle [1]. However, these measures do not capture the potentially complex changes in 3D shape and architecture when muscles hypertrophy.

Here, we apply *statistical shape models* (SSM) – an analysis technique to describe and analyze complex geometrical properties of shapes [2] – to determine the effects of knee extensor strength training on vastus lateralis shape. We also introduce statistical fibre models – a method to describe and analyze changes in 3D fibre orientations – and use these models to determine how fibres of the vastus lateralis reorient following strength training.

### Methods

We created surface models of the left vastus lateralis from segmentations of the muscle on mDixon MRI scans of the upper legs of 11 healthy participants (9 females, age 21±2 years; height 163±7 cm), before and after eight weeks of progressive knee extensor strength training. Distance maps of all surface models were transformed with a b-spline transformation to a reference model. Using statistical shape modeling techniques (principal component analysis), all shapes were expressed as weighted deviations, from the mean shape, of a series of principal shape modes.

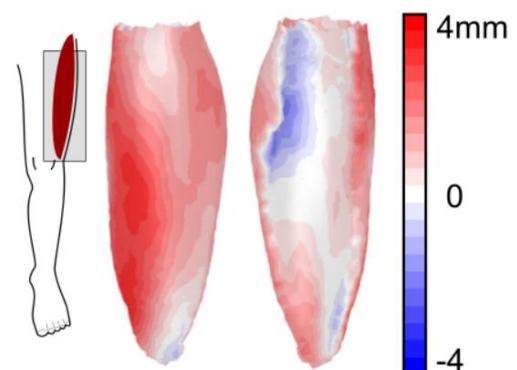

Similar to statistical shape modeling methods, but now using fibre orientation vectors instead of surface node locations, we created *statistical fibre models*. Muscle fibre orientation vectors, derived from diffusion tensor imaging data, were sampled at corresponding locations in muscles at a resolution of 3×3×3 mm. The mean fibre orientation (per location) and

the major modes of variation were then determined. Fibre orientations in each muscle were expressed as weighted deviations, from the mean fibre orientations, of a series of principal fibre orientation modes.

Shape weights and fibre weights of muscles before and after training were compared using paired sample t-tests, using Bonferroni correction to adjust the significance level for comparing multiple modes.

### Results and Discussion

Muscles increased in volume by 14±9% (mean±SD, across participants,  $p < 0.01$ ). Training significantly altered shape weights of modes that were strongly correlated with muscle volume. Visualisation of the patterns of hypertrophy revealed some degree of regional variations in shape change (Fig. 1). Fibre weights associated with the two major modes of variation in fibre orientations changed significantly with training. These modes were associated with complex patterns of fibre reorientations.

**Figure 1:** Lateral (left) and medial view of the vastus lateralis muscle, colored to visualise the effect of strength training on muscle shape. Red/blue shades indicate the distance between the (mean) muscle surface after and before training (red=local expansion, blue=local contraction).

### Conclusions

We demonstrated the use of statistical shape and fibre models for comprehensive investigations of shape and architectural changes in human muscles. We propose the further use of these techniques for future investigations into architectural adaptations of muscles, and to inform anatomically realistic continuum models of skeletal muscle.

## Triceps surae muscle fascicle dynamics as a function of walking speed in young and older adults

### Summary

A decline in plantarflexor muscle function is considered a key contributing factor to age-related gait impairments. The loss of plantarflexor muscle function may be partially due to compromised muscle-tendon interaction resulting in unfavorable alterations in muscle fascicle dynamics. Here, we investigated *in vivo* muscle fascicle dynamics of the soleus and medial gastrocnemius at a wide range of walking speeds in young and older adults. We were able to detect age-related differences in soleus muscle fascicle velocity with potential implications for walking performance in older adults.

### Introduction

A decline in plantarflexor muscle function is considered a key contributing factor to age-related gait impairments such as reduced maximal and preferred walking speeds and increased energy cost of walking. Previous studies suggest that alterations in muscle-tendon interaction and muscle fascicle dynamics may partially explain the decline in plantarflexor muscle function [1,2]. However, the current knowledge is based on observations from a narrow range of walking speeds and the contribution of gastrocnemius and soleus muscles to the decline in ankle function is not clear. This study aimed to examine age-related differences in medial gastrocnemius (MG) and soleus muscle fascicle dynamics at a wide range of walking speeds.

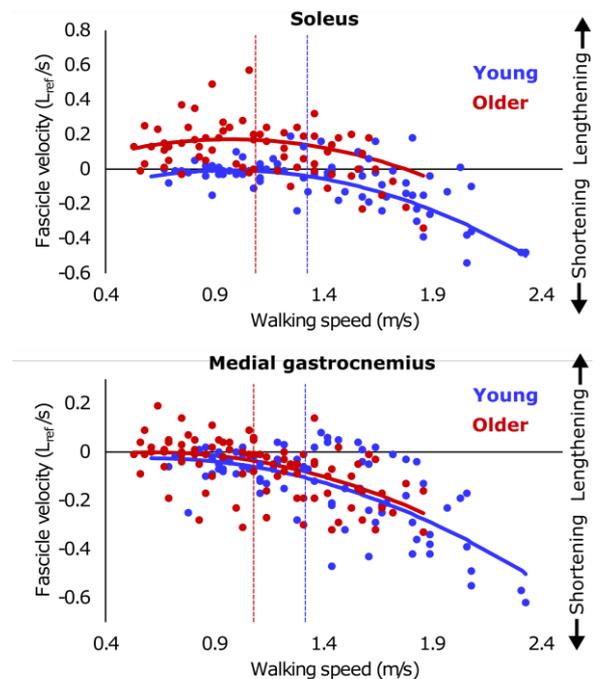

### Methods

Thirteen young ( $24.4 \pm 3.7$  y) and 13 older ( $73.5 \pm 3.7$  y) males walked on a treadmill at seven speeds ranging from -45% to +45% of the preferred walking speed in random order for four minutes per speed. During the last minute at each speed, ground contact timing (footswitch), ankle and knee kinematics (electrogoniometers), and B-mode ultrasound images (80 Hz) of the medial gastrocnemius (MG) and soleus muscles were collected. Ten strides were identified, and muscle fascicle lengths were tracked [3]. Fascicle lengths and velocities were extracted from the time instant of peak tendinous tissue lengths, approximating the time instant of peak muscle force, and normalized to the resting fascicle lengths measured in passive condition with the knee extended and neutral ankle. Linear mixed-effects models were used to investigate the effects of age and walking speed on fascicle dynamics.

### Results and Discussion

MG fascicle length at the instant of estimated peak force generation was unaffected by age ( $p=0.446$ ) and invariant to changes in walking speed ( $p=0.128$ ). Soleus fascicle length was not affected by age ( $p=0.142$ ) but showed a linearly de-

creasing trend with an increase in walking speed ( $p<0.001$ ). Both MG and soleus showed a curvilinear increase in the fascicle shortening velocity with an increase in walking speed ( $p<0.05$ , Figure 1) with no difference between age groups in MG ( $p=0.422$ ) In soleus, fascicle velocity differed between groups ( $p<0.001$ ). The lengthening behavior of the fascicles at the instant of estimated peak force generation observed in older adults was absent in young adults.

**Figure 1:** Soleus and medial gastrocnemius muscle fascicle velocities at the instant of estimated peak force generation during walking at different speeds. The curves represent the values predicted by the linear mixed-effects models. The vertical dotted lines represent the preferred walking speeds for both age groups.

### Conclusions

Using data from a wide range of walking speeds we were able to identify the effects of age and walking speed on triceps surae muscle fascicle dynamics. The observed lengthening behavior of soleus at the instant of peak force generation in older adults may negatively affect elastic energy storage and return and have a role in age-related walking impairments.

### Summary

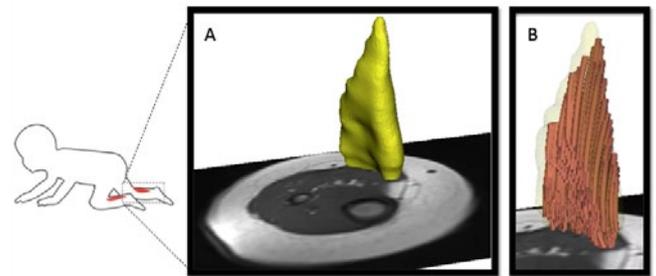

There is a paucity of data on muscle architecture in human infants. This study used magnetic resonance and diffusion tensor imaging (MR-DTI) methods to describe, for the first time, the three-dimensional (3D) architecture of the medial gastrocnemius (MG) muscle in human infants *in vivo*. Mean muscle volume, physiological cross-sectional area (PCSA), and fascicle length were 68, 19 and 3 times smaller, respectively, in infants than in adults.

### Introduction

Several studies have measured muscle architecture in children to investigate childhood muscle growth. To our knowledge, only one study (on cadaveric muscle from a 6-month old [1]) has quantified skeletal muscle architecture in human infants, so little is known about the “starting point” of postnatal muscle development. In this study we used anatomically constrained DTI tractography to measure the 3D architecture of MG muscles from two infants *in vivo*.

### Methods

Two healthy infants (S1 & S2), both aged 3 months, were firmly swaddled and, while sleeping, placed supine in a 3-T MRI scanner. T1-weighted MRI and DTI scans were obtained from both lower legs of participants but only one leg was used for analysis (S1: left; S2: right). The MRI protocol has been described elsewhere [3]. A 3D surface model of the MG, from which muscle volume was calculated, was created from manual segmentations of the T1 scan (Fig. 1A). Anatomically constrained tractography [3] was used to reconstruct and quantify the 3D architecture of the MG (Fig. 1B). The average fascicle length and pennation angle were calculated for each muscle. PCSA was calculated by dividing muscle volume by mean fascicle length. Shank length was measured as the distance from the lateral femoral condyle to the lateral malleolus.

**Figure 1:** (A) 3D surface reconstruction and (B) fascicle reconstruction of the MG muscle.

### Results and Discussion

Data from the current study and two previous studies [1-2] are given in Table 1. The mean MG muscle volume measured here was >3 times greater than MG muscle volume measured on the cadaver of one 6-month old infant. Mean muscle volume, PCSA, and fascicle length were 68, 19 and 3 times smaller, respectively, than in adults. Normalized to bodyweight, the infant MG volume was 7 times smaller than in adults. Normalized to shank length, the infant MG fascicle length was similar to (9% longer than) in adults.

### Conclusions

We demonstrated feasibility of using MR-DTI for measuring infant muscle architecture. To a rough approximation, fascicle length, PCSA and volume scaled with the first, second and third powers of tibia length, respectively. The generality of this scaling needs to be further tested with more data.

# Gender Difference in Architectural and Mechanical Properties of Medial Gastrocnemius-Achilles Tendon Unit

**Liqin Deng, Xini Zhang, Faning Zhang, Weijie Fu**  
 School of Kinesiology, Shanghai University of Sport, Shanghai, China  
 E-mail: [fuweijie@sus.edu.cn](mailto:fuweijie@sus.edu.cn)

## Summary

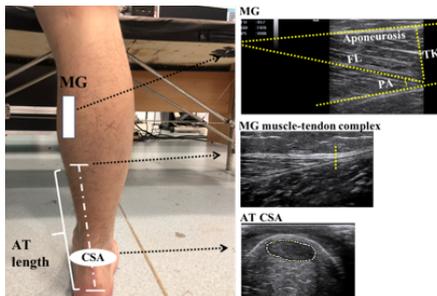

In this study, the gender difference in architectural and mechanical properties of medial gastrocnemius-Achilles tendon unit (MTU) was explored. The results showed the pennation angle ( $PA_{MG}$ ), thickness ( $TK_{MG}$ ), stiffness ( $k_{MG}$ ) of the medial gastrocnemius (MG), and Achilles tendon (AT) length ( $L_{AT}$ ) and cross-sectional area ( $CSA_{AT}$ ) was greater or longer in males. Besides, females had greater MG logarithmic decrement ( $D_{MG}$ ). The results indicated males potentially had greater MG force-producing capacities, mechanical efficiency, and AT load-bearing capacities, while less compliance of MG.

## Introduction

As the largest muscle-tendon unit, the architectural and mechanical properties of the MTU could affect sport performance and the incidence of MG & AT injury. One of the major influence factors for the architectural and mechanical properties of the MTU is gender. It was reported males tended to have greater absolute strength and better performance in speed and strength-oriented sports compared to females [1]. Nevertheless, the majority of AT and MG sports injuries occur in males [2]. Thus, the purpose of this study was to explore the gender difference in the architectural and mechanical properties of the MTU.

## Methods

18 healthy male (age:  $25.1 \pm 1.6$  yrs) and 18 healthy female (age:  $24.4 \pm 2.1$  yrs) collegiate students with no training experience were recruited.

**Figure 1:** Diagram and ultrasound images of medial gastrocnemius (MG) and Achilles tendon (AT).

The MG fascicle length ( $FL_{MG}$ ),  $PA_{MG}$ ,  $TK_{MG}$ ,  $L_{AT}$ , and  $CSA_{AT}$  were acquired by ultrasonography. The ultrasound imaging was analyzed via the Image J software (Figure 1). Stiffness and logarithmic decrement of MG ( $k_{MG}$  and  $D_{MG}$ )

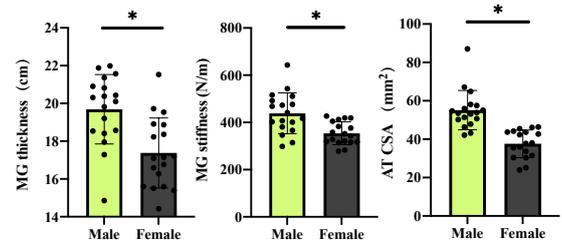

and AT ( $k_{AT}$  and  $D_{AT}$ ) was measured by MyotonPRO at MG belly and 3cm above AT insertion point, where  $D_{MG}$  and  $D_{AT}$  represents the dissipation of the mechanical energy.

Independent *t*-tests were used to quantify the gender effect on the architectural and mechanical properties of the MTU.

## Results and Discussion

For architectural properties, the  $PA_{MG}$ ,  $TK_{MG}$ ,  $L_{AT}$ , and  $CSA_{AT}$  were significantly greater or longer in males than females ( $p < 0.05$ ). These results indicated the MG force-producing capacities, mechanical efficiency, and AT load-resisting capacities, and performance were greater in males (Figure 2).

For mechanical properties, females had significant smaller  $k_{MG}$  and greater  $D_{MG}$  than males ( $p < 0.05$ ). The former may explain the lower AT injuries rate of females [3]. However, no gender differences were observed in  $k_{AT}$  and  $D_{AT}$  (Table 1).

**Figure 2:** Gender difference in medial gastrocnemius (MG) thickness, stiffness, and Achilles tendon cross-sectional area (AT CSA) (\*:  $p < 0.05$ ).

## Conclusions

Compared to females, males had greater or longer  $k_{MG}$ ,  $PA_{MG}$ ,  $TK_{MG}$ ,  $L_{AT}$ , and  $CSA_{AT}$  and had smaller  $E_{MG}$ . These findings indicated males had larger MG and potentially had greater MG force-producing capacities, mechanical efficiency, and load-resisting capacities of AT. However, the higher  $k_{MG}$  might be a reason for the higher injury risk of AT in males.

## Summary

Shape changes allow skeletal muscle to extend its functional range, yet we still lack an understanding of how internal constraints play a role in this process. Using aging as a model, the aim of this study was to determine the effects of muscle shear modulus (an index of stiffness) and muscle architecture (volume and pennation angle) on muscle shape changes and fibre rotation during isometric plantarflexion contractions. We found internal muscle properties such as, muscle volume, resting pennation angle, and muscle shear modulus to not be affected by age, however all muscle properties had a significant effect on changes in pennation angle at 100% contraction level in the medial gastrocnemius.

## Introduction

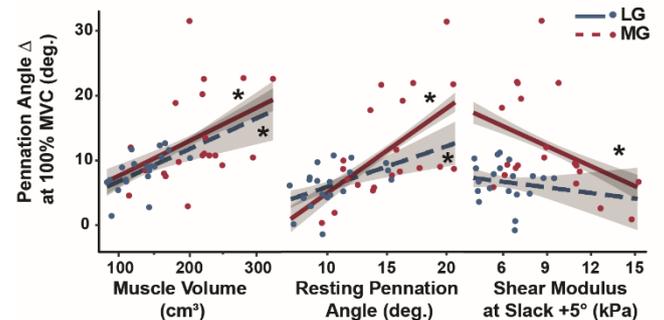

A muscle's ability to produce force across a wide range of mechanical demands is due, in part, to changes in pennation angle and muscle shape. Muscle fibre rotation and muscle bulging allows belly shortening to be uncoupled from fibre shortening during a contraction, optimizing the fibre's ability to produce force and power [1]. Our recent work has shown synergistic muscles have different shape change patterns at similar contraction levels [2]. However, the degree to which muscle changes shape may be due to internal constraints such as connective tissue properties and resting muscle architecture and remains untested in humans [3]. Aging is often associated with greater muscle stiffness, lower resting pennation angle, and lower muscle volume [4]. The aim of this study was to determine the effects of passive muscle shear modulus (an index of stiffness) and resting muscle architecture, such as volume and pennation angle, on muscle shape change and fibre rotation during isometric contractions *in vivo* in humans.

## Methods

10 younger ( $23.6 \pm 3.6$  yrs) and 10 older ( $70.3 \pm 2.9$  yrs) adults participated in this study. Each participant underwent a T1-weighted MRI scan (3T Magnetom Prisma, Siemens, Germany) of the dominant lower limb. MRI images were segmented to determine volume of the medial (MG) and lateral gastrocnemius (LG). Passive muscle shear modulus was measured from  $20^\circ$  plantarflexion to  $15^\circ$  dorsiflexion using shear wave elastography (Aixplorer, Supersonic Imagine, Aix-en-Provence, France). Participants performed isometric plantarflexion contractions at 10%, 30%, 50% and 100% of maximum voluntary contraction. A dual probe B-mode ultrasound (Telemed, Lithuania) configuration was used to image MG and LG during each contraction. Linear mixed effects models were used to determine the effect of Muscle Volume, Resting Pennation Angle and Shear Modulus at slack  $+5^\circ$ , on changes in pennation angle and muscle thickness. Differences were considered significant at  $p < 0.05$ .

## Results and Discussion

Age did not have a significant effect on muscle volume, resting pennation angle, or shear modulus (All:  $p > 0.05$ ). Muscle had a significant effect on all three muscle properties, with the MG displaying greater muscle volume ( $p < 0.001$ ), greater resting pennation angle ( $p < 0.001$ ), and greater shear modulus ( $p < 0.001$ ), compared to the LG. We found an effect of Muscle Volume, Resting Pennation Angle and Shear Modulus on the change in pennation angle only at higher contraction levels of 50% and 100% MVC. In both muscles, there was a positive relationship between muscle architecture (volume and resting pennation angle) and change in pennation angle at 100% MVC. A negative relationship between shear modulus and change in pennation angle was found only in the MG at 100% MVC (Figure 1). There was no relationship between Muscle Volume, Resting Pennation Angle, and Shear Modulus on the change in muscle thickness.

**Figure 1:** Relationships between internal muscle properties and change in pennation angle at 100% MVC. \* $p < 0.05$

## Conclusions

Internal muscle properties influence muscle fibre rotation at high contraction levels such that muscles with greater volumes and higher resting pennation angle display more fibre rotation while muscles with greater shear modulus display less fibre rotation. It is likely that differences in internal muscle properties are related to the differing shape change and fibre rotation behaviors in synergistic muscles at similar contraction levels.

Email: hzar638@aucklanduni.ac.nz

### Summary

Musculoskeletal models can estimate joint moments from electromyography (EMG), but these are subject-specific, with a time-consuming training process, and are not capable of forward prediction. In this study, we developed a generic model to use a unique set of features to train a regression model to predict ankle moments across ten participants and compared this to a subject-specific feature set.

### Introduction

Musculoskeletal modeling can be used to estimate joint moments from EMG. However, because of the nonlinear relationship between muscle activation and joint torque, model calibration is computationally expensive and unsuitable for real-time applications. Machine learning (ML) models show promise as an alternative method to predict joint moments [1]. However, these models are subject-specific, and training each individual's model is tedious and time-consuming. The objective of this study is to introduce a generic model to have a smooth and continuous prediction of ankle moments, 30 msec forward in time, during walking at a constant speed, which applies to multiple individuals. This model can be used to control assistive robots.

### Methods

Ten healthy participants were asked to walk at the constant speed of 1 m/s for 30 seconds on a force-instrumented treadmill. Motion capture cameras were used to reconstruct lower limb kinematics. Muscle activities from vastus lateralis, medial, gastrocnemius, tibialis anterior, soleus, and medial hamstring were recorded. Motion capture data and ground reaction forces were low-pass filtered at 10Hz and used as input for OpenSim to calculate the right ankle's kinematics and moments [2]. The input time series for the ML model included 1-sec length and 0.01-sec sliding length of; right ankle angle, angular velocity, and muscle activity (full-wave rectified and low-pass filtered at 6Hz).

The proposed pipeline for using EMG signals and kinematic features as input to predict ankle moments comprises three main steps; a) feature extraction, b) feature selection, and c) regression model development. The Python-based package TSFRESH (Time Series FeatuRe Extraction on basis of Scalable Hypothesis tests) was used for feature extraction [3]. The features were sorted based on their importance score in the feature selection phase. The top 50 features were selected to represent each window of input signals. To generate a generic feature set, cross-validation was used by leaving one subject out and using the rest to select the features (generic feature set), then the regression model was trained and tested for the unseen individual. A random forest regression model correlated selected features to the desired output, which was

given as calculated joint moments from the inverse dynamics. The model performance was assessed under three scenarios: 1) train the regression model based on the selected feature set for the same individual (personalized feature set), 2) generic feature set, and 3) using the tuned feature set of one participant and train and test the regression model for another individual (mismatched feature set). The regression model accuracy was reported using a coefficient of determination ( $R^2$ ), and root mean square error (RMSE).

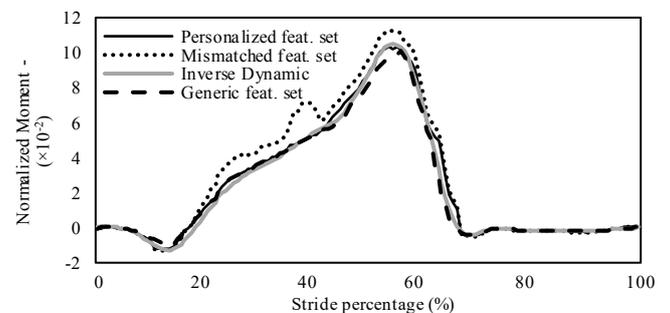

### Results and Discussion

Using the generic set of features to develop the regression model increased the accuracy of moments prediction compare to the mismatched feature set. Also, the generic model results were close to the personalized model (Table 1).

**Table 1:** The regression model accuracy comparison (mean  $\pm$  SD).

	$R^2$ (%)	RMSE (mN.m)
Mismatched feature set	92.0 $\pm$ 3.10	1.32 $\pm$ 1.6
Generic feature set	98.4 $\pm$ 0.97	0.897 $\pm$ 0.89
Personalized feature set	98.9 $\pm$ 0.77	0.654 $\pm$ 0.62

Error reduction and smoother tracking of the moments' profile result of using the generic feature set compared to the mismatched feature set (Fig. 1). The highest similarity to calculated moments via inverse dynamics is a critical characteristic for EMG-based models to provide effortless interaction between human and assistive robots.

**Figure 1:** Ankle moments prediction of personalized, genetic, and mismatched feature set. Target moments from inverse dynamics.

### Conclusions

In this study, we presented a model based on a generic set of features that is capable of accurately predicting ankle joint moments up to 30 msec into the future. This model does not require calibration to new participants, and its performance was comparable to personalized models.

### Summary

Comparing bone and cartilage meshes of different types is a significant challenge. We established a method to register and compare bone and cartilage meshes agnostic to mesh type and nodal density, by looking at bone mesh-to-mesh distance, subchondral bone area and cartilage thickness.

### Introduction

Accurately capturing the bone and cartilage morphology and generating a mesh remains a critical step in the workflow of computational knee modeling. Currently there is no standardized method to compare meshes of different element types and nodal densities (and therefore underlying geometries). For example, different mesh-to-mesh distances are found when comparing mesh A to B or mesh B to A. This makes comparisons across research teams a significant challenge. To overcome this problem, a method to quantify differences in knee joint bone and cartilages meshes, independent of bone and cartilage mesh topology was established.

### Methods

To calculate bone mesh-to-mesh distances, the meshes were registered and resampled after which a dense point cloud was Radial Basis Function (RBF) fitted [1] to the femur (200.000 points), tibia (100.000 points) and patella (100.000 points) meshes. Cloud-to-cloud distances were obtained using CloudCompare (CloudCompare, version 2.10-alpha).

For cartilage mesh comparisons, a common frame of reference was created by RBF fitting parametric templates to resampled bone meshes. The subchondral bone boundaries and cartilage thicknesses were then calculated and visualized in a common frame of reference.

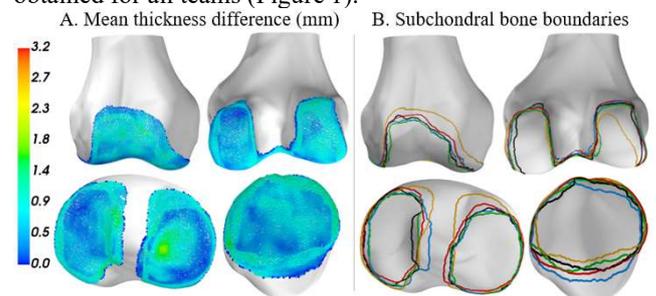

Cartilage thickness was calculated for each subchondral point in the fitted common frame of reference. Cartilage thickness was calculated as the distance along the normal of the subchondral bone point from the bone to the articular cartilage layer. The subchondral bone boundaries were obtained by selecting the bone points closest to the articular cartilage points.

The methods were applied to bone and cartilage meshes generated by five knee modelling teams [2].

### Results and Discussion

Bone mesh-to-mesh distances between all teams' meshes were obtained. The average ( $\pm$ SD) absolute distance difference between the two calculations (mesh A to B vs. mesh B to A) was  $0.0041 \pm 0.0031$  mm for the femur,  $0.0178 \pm 0.0254$  mm for the tibia, and  $0.0091 \pm 0.0085$  mm for the patella.

Cartilage thicknesses and subchondral bone areas were obtained for all teams (Figure 1).

**Figure 1:** Mean absolute thickness difference (n=5) (A) and subchondral bone area (B), where each color presents one team.

### Conclusions

A new method was established to quantify differences in knee joint bone and cartilage meshes independent of mesh type and nodal density. This method can easily be implemented in any study comparing bone and cartilage meshes with different characteristics. Other potential applications exist in unifying the description of anatomical coordinate systems and in mesh generation independent of segmentation method or software.

## The deep hip stabilisers cannot stabilise

### Summary

This study aimed to understand the contribution of deep hip muscles to hip stability during walking. We defined hip stability as hip stiffness in the sagittal plane, calculated via electromyography (EMG)-assisted neuromusculoskeletal modelling. Hip stiffness was compared between three model configurations: (i) deep hip muscles informed by EMG measurements, (ii) no deep hip muscles, and (iii) deep hip muscles imposed by maximal activation. Hip stiffness was 1-5% less over the gait cycle when the model had no deep hip muscles compared to normally activated deep hip muscles, whereas maximally activated deep hip muscles had no significant effect on hip stiffness. Findings suggest the deep hip muscles have a minimal role in modulating hip stiffness and contest their widely proposed role as hip stabilisers.

### Introduction

The deep hip muscles have long been considered hip stabilisers based on their morphology and lines of action [1]. Irrespective of the nebulous definition of “stability” used in clinical literature, it remains unclear whether the deep hip muscles can generate enough force to stabilise the hip. We defined hip stability as hip stiffness in the sagittal plane, a mechanical quantity that measures the joint angle displacement following force perturbation. This study aimed to understand the contribution of deep hip muscles to hip stability during walking.

### Methods

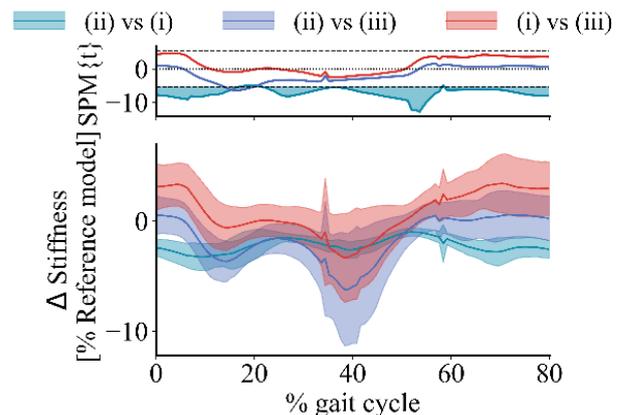

Three-dimensional marker trajectories and ground reaction forces, together with EMG from 12 superficial and 4 deep muscles of the lower limb, were recorded during self-paced walking in nine healthy participants (age: 24±4 yrs). Inverse kinematics, inverse dynamics, and muscle analysis were performed in OpenSim [2] using a linearly scaled modified generic model [3], including all 22 hip spanning muscles. Muscle-tendon parameters were calibrated to the individual using CEINMS [4]. EMG-assisted neuromusculoskeletal modelling was used to calculate muscle-tendon unit stiffness [5] for the hip spanning muscles in the model, followed by hip stiffness in the sagittal plane over the gait cycle.

Hip stiffness was calculated for each participant using three model configurations: (i) deep hip muscles included in the model and informed by

EMG measurements, (ii) no deep hip muscles in the model, and (iii) deep hip muscles included in the model imposed by maximal activation. Hip stiffness was compared between configurations over the gait cycle using within-participant analysis of variance with statistical parametric mapping (SPM) methods [6] ( $p < 0.05$ ). A Bonferroni post-hoc analysis was performed if statistical differences were found.

### Results and Discussion

The model with no deep hip muscles (ii) had 1-5% lower hip stiffness than the model that was informed by EMG measurements (i). Few significant differences were found for the other comparisons.

**Figure 1:** Statistical parametric mapping post-hoc results for within-participant comparison (top). Mean difference in hip stiffness between configurations ( $\pm 1$  standard deviation) in sagittal plane (bottom).

### Conclusion

The deep hip muscles have limited potential to modulate hip stiffness, with no increase in hip stiffness when the deep hip muscles are maximally activated. The merit of targeting these muscles in the management of hip conditions associated with hip instability is unclear.

## Summary

Biomechanical behavior of meniscus can be modeled using different constitutive material models. An isotropic elastic (IE) model offers the simplest approximation, while a fibril reinforced poroelastic (FRPE) model is capable to separate contributions of fluid, and fibrillar and nonfibrillar parts. However, the FRPE material is complex to implement and computationally demanding in 3D geometries. Here, we aimed to quantify the most suitable and efficient constitutive model of meniscus for simulation of cartilage responses in the knee joint during walking. We demonstrated that simpler models can reproduce identical cartilage responses compared with the knee model with the FRPE meniscus. However, the material anisotropy should be considered, if internal responses are of interest.

## Introduction

Meniscus is a poroelastic connective tissue in the knee joint, which distributes joint loads efficiently on cartilage surfaces [1]. The FRPE material model has been used in many studies to characterize anisotropy in meniscus and other soft tissues [2]. However, implementation of such a model in 3D geometries and model simulation are time-consuming processes. The application of a simpler material model for meniscus would accelerate the generation and simulation of biomechanical knee joint models. Hence, we aimed to evaluate how complex material model is required for meniscus so that the cartilage mechanical responses in the knee joint are the same when meniscus is modeled using the FRPE material. We hypothesize that the mechanical function of the FRPE meniscus in the knee can be captured using a simpler material model.

## Methods

A finite element (FE) knee joint model geometry and material properties for the FRPE cartilage and meniscus were obtained from a previous study [2]. In addition to the FRPE meniscus, the following formulations were considered: isotropic elastic (IE), orthotropic elastic (OTE), and orthotropic poroelastic (OTPE). First, the IE, OTE, OTPE material parameters were obtained by fitting the force, stress, and strain responses to those obtained from the FRPE meniscus under 10% deformation (compression and shear) in a simple cubic geometry (Table 1). Then, the fitted material properties of different meniscus models were implemented in the knee joint level models under gait loading (stance phase) [2]. Finally, reaction forces through tibial cartilage and meniscus, and tissue stresses and strains, were compared to the knee model with the FRPE meniscus.

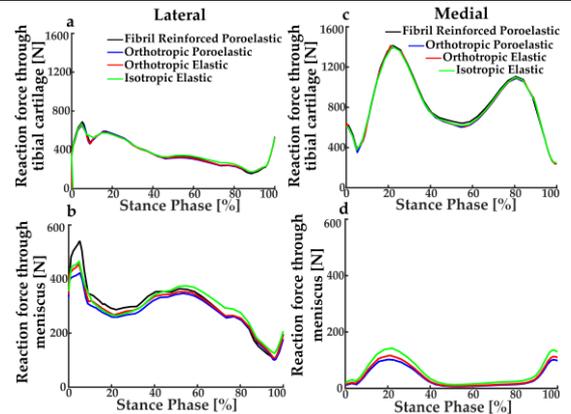

## Results and Discussion

The simulated reaction forces through the tibial cartilages were identical for all meniscus models (Figure 1a, c). This suggests that a properly calibrated and simple meniscus material model can reproduce the same knee joint contact

forces compared to knee model with more complex meniscus. Likewise, the simulated reaction forces through the IE, OTE, OTPE, and FRPE menisci were similar (Figure 1b, d). However, we observed that only OTE and OTPE meniscus models were able to replicate the internal material responses (stresses and strains) of the FRPE meniscus (data not shown), indicating that meniscus anisotropy must be considered to adequately simulate internal tissue responses of the FRPE material.

**Table 1:** Material parameters for the meniscus material models.

Models	Material parameters	Meniscus	Parameter description
Fibril-reinforced poroelastic	$E_f$ (MPa)	184	Fibril network modulus
	$E_m$ (MPa)	0.08	Non-fibrillar matrix modulus
	$\nu_m$ (-)	0.3	Poisson's ratio of the non-fibrillar matrix
	$M$ (-)	12.1	Strain dependent permeability coefficient
	$k_0$ ( $\times 10^{-15} \text{m}^4 \text{N}^{-1} \text{s}^{-1}$ )	0.08	Initial permeability
Orthotropic poroelastic	$E_x$ (MPa)	6	Young's modulus (radial)
	$E_y$ (MPa)	0.08	Young's modulus (axial)
	$E_z$ (MPa)	184	Young's modulus (circumferential)
	$\nu_{xy}$ (-)	0.4	Poisson's ratio
	$\nu_{yz}$ (-)	0.02	
	$\nu_{zx}$ (-)	0.0001	
	$G_{xy}$ (MPa)	0.62	Shear modulus
	$G_{xz}$ (MPa)	1.99	
	$G_{yz}$ (MPa)	1.99	
	$k$ ( $\times 10^{-15} \text{m}^4 \text{N}^{-1} \text{s}^{-1}$ )	0.08	Permeability
Orthotropic elastic	$E_x$ (MPa)	6.2	Young's modulus (radial)
	$E_y$ (MPa)	6.2	Young's modulus (axial)
	$E_z$ (MPa)	184	Young's modulus (circumferential)
	$\nu_{xy}$ (-)	0.91	Poisson's ratio
	$\nu_{yz}$ (-)	0.02	
	$\nu_{zx}$ (-)	0.03	
	$G_{xy}$ (MPa)	1.41	Shear modulus
	$G_{xz}$ (MPa)	2.6	
	$G_{yz}$ (MPa)	2.6	
	Isotropic elastic	$E$ (MPa)	40
$\nu$ (-)		0.49	Poisson's ratio

**Figure 1:** Reaction forces through tibial cartilage and meniscus in (a,c) lateral and (b,d) medial compartment.

## Conclusions

The OTE and OTPE menisci are feasible to be used in knee joint models as they are capable of producing similar joint contact forces and internal tissue responses of meniscus as simulated with the FRPE meniscus.

### Summary

We used a personalized electromyogram-informed neuromusculoskeletal model to assess Achilles tendon strain during dynamic motor tasks. Our model estimates of Achilles tendon force agreed with direct measures reported in the literature. Peak free Achilles tendon strain was highest during running at 5 m/sec, and the average free Achilles tendon was highest during maximal hop landing.

### Introduction

*In vivo* studies have shown that Achilles tendon (AT) geometry and mechanical properties adapt based on the magnitude and duration of tissue strain [1]. 2D ultrasound has been commonly used to measure AT-aponeurosis strain during dynamic tasks, but this method is susceptible to motion artefacts and cannot be used to estimate free AT strain. The primary aim of this study was to estimate free AT strain during locomotor and rehabilitation tasks using neuromusculoskeletal models informed by 3D medical imaging data and surface electromyography (EMG). Our model was validated using direct measurements of AT force reported in literature.

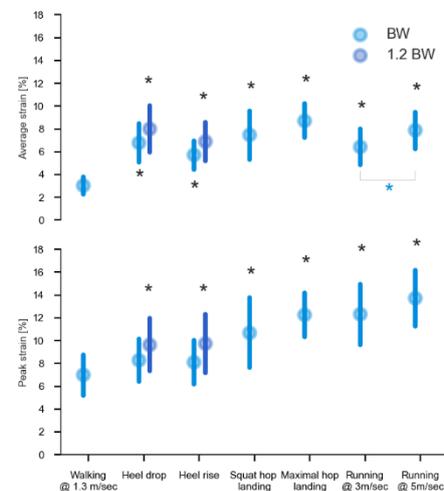

### Methods

Sixteen trained runners (run > 80 km/wk) (10 male, 6 female, age: 25.2±5 yrs, BMI: 20.9±1.8 kg.m<sup>-2</sup>) with no prior history of AT injury completed a range of locomotor and rehabilitation tasks: single leg heel drops and rise, single leg heel drops and rise with added mass (20% BW), walking at 1.3 m/s, running (3 m/s, 5 m/s), counter movement jump, squat hop landing, and maximal hop landing. Motion capture, ground reaction force, and surface electromyography data were synchronously recorded during all tasks. Calibrated EMG-informed neuromusculoskeletal model [2] with tuned muscle-tendon parameters was used to estimate triceps surae muscle forces and tendon strain across all tasks. Personalised models were generated by: 1) linear scaling of the OpenSim model [3], 2) recalculating muscle maximal isometric forces based on linear regression, 3) adjusting triceps surae insertion point to match model moment arm data with experimental data, 4) optimising optimal fibre length and tendon slack length using morphological scaling methods, and 5) modifying normalised force-strain curves of tendons of triceps surae muscles based on experimental data [4]. Differences in average and peak free AT strain across all tasks were assessed using ANOVA (Greenhouse-Geisser corrected), and planned contrast tests. Model estimates of free AT force were compared with direct measures of AT force

reported in the literature as part of the model validation process.

### Results and Discussion

Average strain during walking was significantly lower than the other tasks (Figure 1). Average and peak free AT strains were significantly higher in added mass (20% BW) condition during heel rise and heel drop (Figure 1). Average free AT strain during running at 5 m/sec was significantly higher when compared to running at 3 m/sec (Figure 1).

**Figure 1:** Average and peak strain during locomotor and rehabilitation tasks. Data are mean and standard deviation. \* indicates significant difference between walking and the given task

Our measures of free AT force were close to direct measures of AT force during walking ( $R^2$ : 0.94), counter movement jump ( $R^2$ : 0.86), and running ( $R^2$ : 0.92 – 0.94).

### Conclusions

Average and peak free AT strain were not different between heel drop and heel rise tasks. During locomotor tasks, average and peak free AT strain increased as the average speed of the task increased. Neuromusculoskeletal models can be used to better inform AT rehabilitation programs.

## Morphological Variation in Paediatric Lower Limb Bones

Laura Carman<sup>1</sup>, Thor Besier<sup>1</sup>, Julie Choisne<sup>1</sup>

<sup>1</sup>Auckland Bioengineering Institute, The University of Auckland, Auckland, New Zealand

Email: [icar475@aucklanduni.ac.nz](mailto:icar475@aucklanduni.ac.nz)

### Summary

Here we present a statistical shape model (SSM) from a population of 333 children (aged 4-18 years) to characterise the morphological variation and prediction of new skeletal geometry. Shape and size variation were captured using principal component analysis (PCA) and Procrustes analysis. This model captures morphological variations in growth and can predict bone geometry with errors of  $3.6 \pm 1.3$  mm using demographic information and five linear bone dimensions.

### Introduction

The skeletal anatomy of children differs significantly from adults, yet we often scale down musculoskeletal models that have been developed from adult datasets. Subject-specific models can be built using medical imaging [1], but this is costly and time-consuming. Ideally, we would scale musculoskeletal models using a population of paediatric bones that capture morphological variation of the growing skeleton. The aims of this study were to: 1) characterise bone shape variation in a typically developed paediatric population and 2) evaluate bone shape prediction error using a SSM.

### Methods

Post-mortem CT scans of 333 children (137 F, Age:  $12 \pm 5$  Y, H:  $148 \pm 24$ cm, M:  $49 \pm 22$ kg) were obtained from the Victorian Institute of Forensic Medicine (VIFM, Melbourne, Australia). The pelvis (P), sacrum, femurs (F), tibiae, and fibulae were segmented using Mimics (Materialise, Leuven, BE) and a convolutional neural network. Bones were aligned according to the ISB coordinate system [2]. Right bones for the femur, tibia, and fibula were mirrored to the left side and the tibia and fibula (TF) were considered as a single bone. Each bone was non-rigidly registered and fitted to a template mesh, using radial basis functions to achieve nodal correspondence, and then rigidly aligned. The shape model was characterized using PCA [3]. A Procrustes analysis was performed to characterize the shape variation within the dataset by performing PCA on bones scaled to the size of the mean bone. The accuracy of the shape model was assessed using fitting error, compactness, specificity, and generality. The predictive power of the shape model was assessed with a leave one out (LOO) analysis using demographic (age, height, mass, sex) and bone measurements (thigh and shank length, hip, knee, and ankle width).

### Results and Discussion

The first PC of the general shape model captured most of the variation in the dataset (F: 98%, TF: 97%, P: 91%). This was reduced using the Procrustes analysis (first 9 PC's F: 66%, TF: 74%, P: 74%), where the first PC shows the changes in bone shape within the dataset (Figure 1). The results from the LOO analysis gave average RMSE of 5.6mm (F:  $6.1 \pm 3.3$ mm, TF:  $5.5 \pm 2.8$ , P:  $5.1 \pm 2.1$ mm) using demographic

measurements, which was reduced to 4.32mm (F:  $4.5 \pm 2.1$ mm, TF:  $4 \pm 1.8$ mm, P:  $4.4 \pm 1.6$ mm) when linear bone measurements were included. Results from the femur show that first scaling the bones by length reduces this error to  $3.6 \pm 1.3$ mm.

### Conclusions

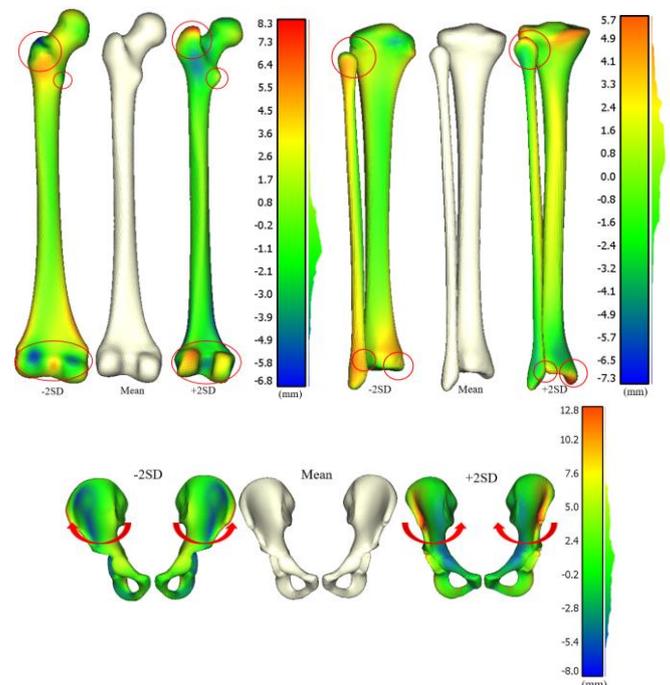

This unique dataset characterises morphological variation in paediatric bone and allows for prediction of new bone shapes with low errors for use in clinical settings and musculoskeletal modelling. Future work will assess the best method of bone prediction for the remaining bones (tibfib, pelvis, and sacrum) by calculating errors in LOO analyses.

**Summary:** Periprosthetic osteolysis remains a serious complication of joint replacement surgery and can lead to revision surgery. Accurate assessment of bone loss after total hip arthroplasty (THA) has the potential to assist with surgical planning and decision making. However, it is difficult due to the complex morphology of the hip joint and the presence of a metallic implants decreasing CT image clarity. This study describes a semi-automated method to extract this from pelvic computed tomography (CT) scans. Ex vivo accuracy and reliability tests of lesion volume measurement were performed. Accuracy and reliability were found to be sufficient (all mean absolute relative error (MARE) below 10% and all coefficient of variation (CoV) below 10% for accuracy and reliability respectively). This new method is accurate and reliable and may be of use when studying acetabular periprosthetic bone loss.

**Introduction:** Implant loosening and periprosthetic fracture are two of the most common causes of THA failure and are associated with acetabular bone loss [1]. High sensitivity and specificity when identifying and monitoring such defects from CT scans are of diagnostic and surgical importance [2]. It is also necessary to measure bone loss within specific three-dimensional (3D) acetabular regions of interest (ROI) [3]. However, there is no established method to achieve this. The primary aim of this study was to develop a semi-automated method for measuring lesion volume and the BMD distribution in the acetabulum. Our secondary aim was to test the accuracy of lesion volume measurements and to test the reliability of the method.

**Methods:** CT scans (0.8 mm pixel size, 1 mm slice thickness) were taken of cadavers with varying numbers of implants *in situ* (as metal implants reduce CT clarity) for the accuracy and reliability tests (four cadavers with one and then two implants and one cadaver with the native anatomy, one implant and two implants respectively). For each cadaver, a physical lesion was created prior to insertion of the first implant. For the accuracy tests, large-volume micro-CT scans were employed as a reference.

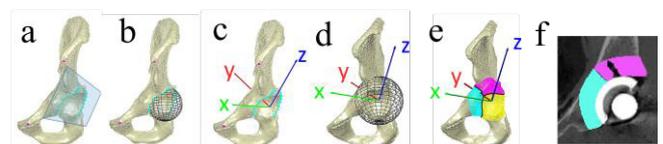

Points around the acetabular rim and the Anterior Superior Iliac Crest and the Pubic Tubercle anterior landmarks were located manually on the 3D reconstruction of the CT and exported as coordinates (nms Builder). The 3D model and landmarks were inputted into custom written code (MATLAB), which applied an acetabular sphere fit via the Pratt method using the acetabular rim coordinates and a local patient-specific coordinate system based on the center of the sphere and the anterior landmark coordinates. The sphere radius was increased by 40%, then the sphere was split into

thirds and the containing areas exported. Regions were overlaid over the original CT image and segmented to determine lesion volume in mm<sup>3</sup> and BMD in Hounsfield units (HU), (Fig. 1).

To test accuracy, lesion volume was measured five times per CT scan (two per cadaver, ten in total) and the MARE between the CT measurements and reference values was calculated. The intra- and inter- operator reliability (three repeats and two repeats respectively) was tested for lesion volume, HU and ROI volume and reported as the CoV.

**Results and Discussion:** For the accuracy tests, all MARE values were less than 10% for lesion volume measurement. For the intra- and inter-operator reliability tests, all CoV values were less than 10%.

Accuracy and reliability of quantifying lesion volume decreased with increasing number of implants by 0.6% - 3.6% MARE and 1.6% - 2.6% CoV respectively, as did the reliability of BMD measurements in the region most disrupted by metal artefacts (2% - 2.9% decrease in CoV).

**Figure 1:** Splitting the acetabulum into three ROI to measure bone loss: a. Acetabular plane b. Acetabular sphere c. Acetabular coordinate system d. Increasing sphere radius by 40% e-f. Acetabulum split into ROI and overlaid over CT with lesion.

**Conclusions:** This study presents a new accurate and reliable semi-automated method to quantify BMD (HU) and lesion volume within 3D anatomical ROI of the human acetabulum from CT scans, which may assist towards developing of a standardized approach.

**Acknowledgments:** This study was supported by National Health and Medical Research Council (ID: 1126229), a research grant from Zimmer Biomet Pty Ltd (Warsaw, IN), the Royal Adelaide Hospital Research Fund and the Australian Research Council (LE180100136)

## Prediction of ACL tunnels: a comparison between model and surgeon.

### Summary

The outcome of ACL reconstruction is strongly related to the placement of the femoral and tibial tunnels. Patient specific anatomy affects tunnel positioning and is a challenge for low-volume surgeons. We developed a computational model that characterised the ACL attachment site in a population of 51 knees and evaluated the model with a leave-one-out (LOO) analysis. We compared the accuracy and variance of the predictions with those of an experienced orthopaedic surgeon.

### Introduction

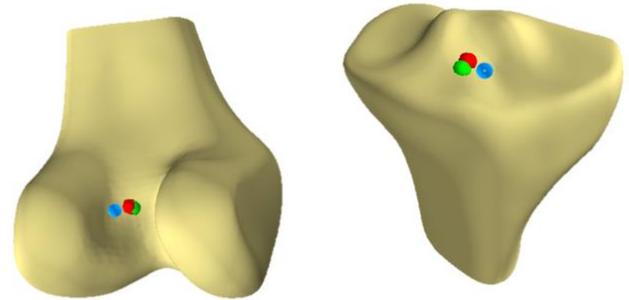

Anterior cruciate ligament (ACL) ruptures are one of the most common sport injuries in the world, with ~ 350,000 reconstructions performed annually in the US alone and 1 million performed globally [1]. Orthopaedic dogma maintains that the outcome of anterior cruciate ligament (ACL) reconstruction is dependent on accurate surgical placement of the graft. However, the procedure is technically challenging and approximately 40% of ACL grafts are misplaced as a result [2]. Patient-specific anatomy is believed to affect tunnel positioning, and improper graft tunnel placement can lead to costly premature degeneration of knee structures, eventually leading to total knee joint replacement.

This study has three aims: 1) quantify ACL attachment sites in a cohort of knees (n=51) with in-tact ACL; 2) develop a computational model to characterise the natural variation of the ACL attachment site across the cohort; 3) compare the model predictions to those of an experienced surgeon.

### Methods

MR images of 51 healthy adult knees ( $28.4 \pm 4.1$  years) were obtained from a previous study [3]. The bones, including the femur and tibia, and the ACL were manually segmented to generate triangulated models. The footprints of the ACL on the femur and tibia were obtained by finding the surface of the bone that overlapped with the ACL. The centroid of each footprint was then quantified. A published method [4] was adapted to characterise the natural variation of the ACL centroids. A machine learning model was developed to predict ACL centroids. The predictive performance of the model was evaluated in a LOO analysis. An experienced surgeon

performed virtual ACL reconstructions and the distance to the ACL centroids were calculated. The accuracy was compared between model and surgeon.

**Figure 1.** Model prediction (green) and surgeon's prediction (blue) compared with anatomical site (red) in one subject.

### Results and Discussion

ACL attachments were quantified in our cohort of knees (n=51) and a computational model that characterised the natural variation of ACL attachment sites was developed.

Mean LOO prediction accuracy for femoral attachments was  $1.89 \pm 1.41$  mm and  $2.21 \pm 1.32$  mm for tibial attachments. The experienced surgeon had an accuracy of  $6.69 \pm 1.38$  mm for the femoral attachments and  $4.96 \pm 2.74$  mm for the tibial attachments (Table 1).

### Conclusions

ACL attachment sites are dependent on bone morphology. Our computational model was more accurate and consistent at predicting the ACL tunnels than an experienced orthopaedic surgeon.

### Summary

Achilles tendon structure and function are intimately coupled. We show that free Achilles tendons in trained runners were stiffer when compared to healthy controls. This was due to shorter length and larger cross-sectional area, but not increased Young's modulus, the latter having no relationship with T2\* relaxation time from MRI's. Achilles tendon T2\* relaxation time was significantly longer in trained runners compared to healthy controls.

### Introduction

The relationship between tissue structure (i.e., geometry and mechanical properties) and function is complex, dynamic, and affected by aging, disease, and, possibly, physical activity levels. For instance, free Achilles tendon (AT) average cross-sectional area (CSA) is larger, and the Young's modulus is lower, in tendinopathic tendons when compared to healthy controls [1]. But how does AT structure vary between low and high physical activity levels? This study compared free AT geometry, mechanical properties, and T2\* relaxation time between trained runners and healthy controls, and determined the relationship between T2\* relaxation times and Young's moduli.

### Methods

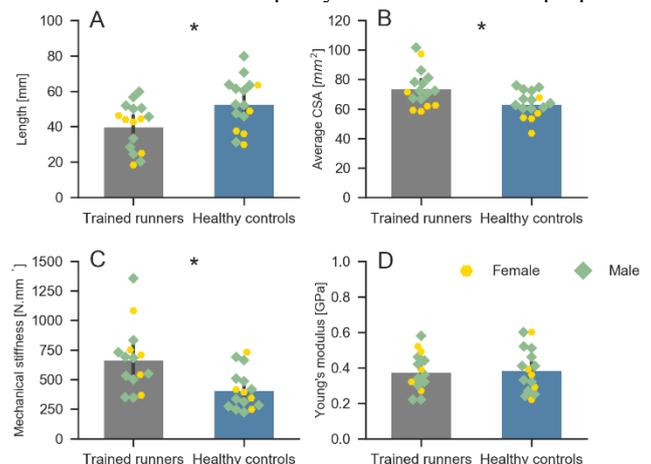

Sixteen trained runners (run > 80 km/week) (10 male, 6 female, age: 25.2±5 yrs, BMI: 20.9±1.8 kg.m<sup>-2</sup>) and healthy controls (11 male, 5 female, age: 30.3±4.9 yrs, BMI: 23.8±4.5 kg.m<sup>-2</sup>) with no prior AT injuries participated in this study. Participants refrained from strenuous physical activity prior testing. Following AT preconditioning, participants underwent magnetic resonance imaging (MRI) of their free AT using a Philips Ingenia 3.0T (T1W 3D FFE, TR/TE 8.0/4.1 ms; slice thickness 0.6 mm, slice gap 0.3 mm) [2,3]. Ultrashort echo time (UTE) T2\* sequence data was acquired using a 16-channel knee coil to estimate T2\* relaxation time of the free AT [3]. The free AT was then imaged using an established 3DUS method (transducer: Canon PLT-805, motion capture: Vicon). All 3DUS data were acquired with the participant lying prone and ankle locked in a neutral position during rest and three isometric loading levels (25%, 50%, and 70% maximum voluntary contraction) [3]. Ankle torque data were synchronously recorded using isometric dynamometer (Humac Norm, FUTEK).

Free AT volume, CSA, length, and moment arm were obtained from MRI data. Mechanical stiffness and Young's modulus were obtained from 3DUS and dynamometer data. ANOVA was used to compare differences in free AT

geometry (discrete measures) and mechanical properties between trained runners and controls. Kruskal-Wallis test was used to compare T2\* relaxation time between the two groups. Relationship between T2\* relaxation time and Young's modulus were determined using Pearson product moment correlation.

### Results and Discussion

Average CSA of the free AT was significantly larger in trained runners when compared to healthy controls (p=0.009) (Figure 1). Length of the free AT was significantly shorter in trained runners when compared to healthy controls (p=0.01) (Figure 1). Trained runners had a stiffer free Achilles tendon when compared to healthy controls (p=0.003) (Figure 1). Free AT T2\* relaxation time was significantly longer in trained runners compared to healthy controls. There was no significant relationship (p>0.15) between T2\* relaxation time and Young's modulus indicating that T2\* relaxation time cannot be used as a valid proxy for tissue material properties.

**Figure 1:** Length, average CSA, mechanical stiffness, and Young's modulus of trained runners and healthy controls.

### Conclusions

Trained runners have a shorter, thicker, and stiffer free AT when compared to healthy controls. T2\* relaxation time is not a valid proxy to assess AT material properties.

## The effects of decellularisation and sterilisation processing on kangaroo tendon strength

### Summary

Escalating incidences of primary and secondary ACL injuries has created substantial demand for a superior graft option for human ACL reconstruction. Kangaroo tendon, processed into an acellular tissue, has potential as a new xenograft tissue source for ACL reconstruction. The present study screened four proprietary decellularisation protocols and two doses of gamma sterilisation, assessing their effect on kangaroo tendon strength. All combinations of decellularisation and sterilisation protocols provided xenografts with higher strength compared to published values for native human ACL.

### Introduction

Rupture of the anterior cruciate ligament (ACL) is one of the most common musculoskeletal injuries in humans. Surgical reconstruction requires the use of either tendon autograft (harvested from the patient), allograft (sourced from a deceased tissue donor), or synthetic construct; each with inherent limitations. These challenges are further exacerbated by increasing incidences of both primary and secondary (re-injury) ACL injury, especially in younger patients. Kangaroo tendon, processed into an acellular tissue, has potential as a new xenograft source for ACL reconstruction. A major challenge faced by loadbearing xenografts is retaining sufficient mechanical strength following necessary decellularisation and sterilisation processing. The present study screened four candidate decellularisation protocols and two doses of gamma irradiation, assessing their effect on kangaroo tendon strength.

### Methods

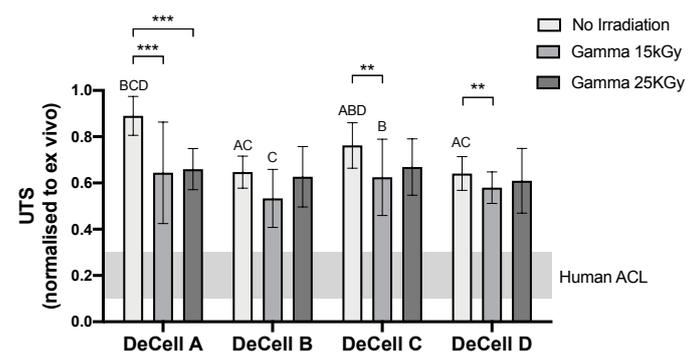

Kangaroo tendons were processed using one of four proprietary decellularisation protocols (A-D), followed by gamma irradiation with either low (15kGy) or standard (25kGy) dose (n=8/group). Unprocessed (“*ex vivo*”), and non-irradiated (decellularised only) controls were also prepared. Biomechanical evaluation was performed by tensile loading to failure at 5% strain/s, with ultimate tensile strength normalised (%) to *ex vivo* controls. Results were analysed using mixed model regression, followed by pairwise comparisons between groups, adjusting for multiple comparisons using the Benjamini Hochberg procedure with false discovery rate of 0.05.

### Results and Discussion

All four decellularisation protocols significantly reduced non-irradiated tendon strength compared to *ex vivo* controls (p<0.007). Decellularisation protocol A retained the highest

tendon strength (89.0% of *ex vivo*) compared to protocol B (64.7%, p<0.001), protocol C (76.2%, p<0.001) and protocol D (64.1%, p<0.001) in nonirradiated groups (Figure 1). Gamma irradiation further reduced tendon strength when compared to nonirradiated controls (p<0.001 both doses), however there was no main effect of irradiation dose (p=0.351 between doses).

Pairwise comparisons between, and within, decellularisation groups showed no consistent effect of decellularisation or sterilization protocol on the reduction in tendon strength (Figure 1). Significant differences observed between non-irradiated decellularisation groups were not maintained after sterilisation; with the singular exception of protocol C (62.5%) retaining significantly higher strength than protocol B (53.3%) in the low irradiation dose group only (p<0.001).

**Figure 1.** Effects of Decellularisation and Sterilisation Protocols on Kangaroo Xenograft Strength.

Despite processing-induced reductions, all combinations of decellularisation and sterilization protocols retained a higher strength when compared to published values for native human ACL [1,2].

### Conclusions

All four decellularisation protocols and both irradiation doses provide grafts with sufficient mechanical strength and remain as viable candidate methods for future development of this novel ACL xenograft. Sufficient mechanical strength only represents one facet of a successful graft, and ongoing biocompatibility studies may highlight more imperative differences between processing protocols to direct future xenograft development.

## Ankle kinematics during walking with a soft exoskeleton in people with dropfoot – a case series

Eveline S. Graf, Markus Wirz, Carole Pauli, Christoph M. Bauer

Institute of Physiotherapy, School of Health Professions, Zurich University of Applied Sciences, Winterthur, Switzerland

Email: [eveline.graf@zhaw.ch](mailto:eveline.graf@zhaw.ch)

### Summary

The effect of XoSoft, a soft exoskeleton providing support during dorsiflexion at the ankle, was analyzed in people with drop foot. This study identifies areas of future research in order to achieve the goal of a support system at the ankle that results in high adherence.

### Introduction

Dropfoot, caused by neurological conditions, is characterized by weakness of the dorsiflexor muscles at the ankle. It results in altered walking mechanics and increased risk of falling due to reduced foot-ground clearance [1]. While there are orthotic solutions available, limited comfort and wearability as well as their limited mobility result in a low adherence of patients. Consequently, a novel comfortable and dynamic solution has great potential, but its functionality must be demonstrated. The aim of this study was to assess the influence of a prototype soft exoskeleton on ankle kinematics in individuals with dropfoot during walking.

### Methods

Three participants with dropfoot (2 female, 2 incomplete spinal cord injury/1 stroke, 2 with unilateral impairment) walked without support (none) and with the XoSoft prototype. A minimum of four trials were recorded and averaged. Ankle kinematics was recorded with a camera system (240 Hz, Vicon Vantage, Vicon Motion Systems Ltd.) and a cluster marker approach [2]. In agreement with the case study characteristics, data were analyzed descriptively.

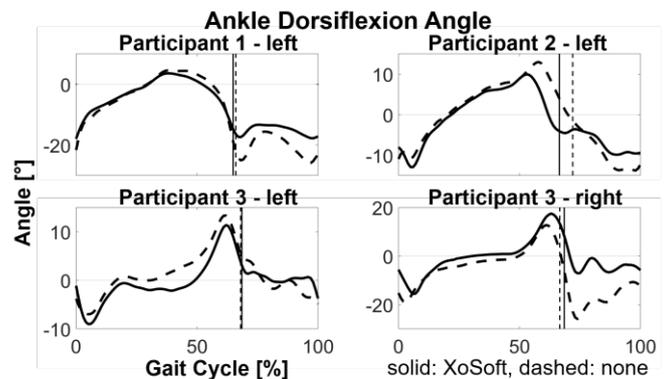

The XoSoft prototype consisted of a soft, pneumatic clutch in series with an elastic band [3]. The two ends were anchored at the shoe and the shin. The clutch was active from 50 to 0 % of gait cycle. The elongation of the distance of the anchor points during push-off (clutch activated) was thought to result in elongation of the elastic band which released its energy during the swing phase, keeping the foot in a dorsiflexed position.

### Results and Discussion

For all three participants, XoSoft was able to increase dorsiflexion during the swing phase; the effect was, however, small with less than 10° difference between conditions (Figure 1). Participant 2 reaches a plateau with XoSoft between 60-80% of gait cycle. It is assumed that the participant may not be able to push-off actively and, therefore, cannot elongate the dorsiflexion clutch enough. When the foot is lifted off the ground, the elastic band can maintain the foot at this position but not actively pull it up. The inertia of the foot during the swing phase may cause the

decrease in dorsiflexion in later swing. Consequently, the participant would benefit from a stiffer dorsiflexion elastic band in combination with active support of the plantarflexion during the push-off movement.

All participants (except participant 1) had a plantarflexion movement at the beginning of the gait cycle that was enabled or increased with XoSoft. Having an initial plantarflexion movement represents a more physiological pattern with heel-strike, followed by flattening of the foot. Participant 1 had a reduced active and passive range of motion in dorsiflexion. It is concluded that the elastic band was not stiff enough to maintain the ankle in dorsiflexion while landing.

**Figure 1:** Ankle dorsiflexion angle [in degrees] during walking with XoSoft (solid line) and no support (dashed line) for each participant (participant 3 had bilateral actuation). Please note the difference in scale of the y-axis between figures.

### Conclusions

Overall, these results indicate that XoSoft can alter gait pattern of the ankle and allow a more natural gait despite an inability of the participants to perform this movement actively. Additional research looking into actuation of the plantarflexion during push-off in combination with a fine tuning of the elastic band is necessary.

### Acknowledgments

The authors would like to acknowledge the entire XoSoft consortium for their contribution during the project. This work has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 688175 (XoSoft).

## Summary

In this paper, we used a semi-passive clutched spring ankle-foot exoskeleton (Figure 1) that enables us to study different assistance onset timings on healthy individuals' gait biomechanics. The results obtained from this study suggest that controlling timing of assistance in clutched elastic ankle exoskeletons can influence the assistive performance and further improve gait efficiency.

## Introduction

Previous studies have shown that incorporating clutches and elastic elements in parallel with the ankle muscles can offload substantial muscle force and therefore reduce the metabolic cost of walking [1]. However, optimal assistance timing with clutched elastic exoskeletons remains unclear. The purpose of this study was to evaluate the effect of different assistance onset timings on human gait mechanics and energetics by regulating the activation of a controllable clutch in an elastic ankle exoskeleton. This mechanism uses the principle of controlled energy storage and release and has been designed to optimize the functionality of a passive elastic exoskeleton.

## Methods

A healthy adult (male; mass = 83.7 kg; height = 1.81 m) participated in the study and completed a series of walking trials at 1.5 m s<sup>-1</sup> on a force-instrumented treadmill. The participant read and signed a written consent prior to participation. The participant walked for 28 min (4 blocks of 7 minutes) with the device unpowered ( $k_{Exo}=0$ ) and then with the moderate exoskeleton stiffness ( $k_{Exo}=105$  N m rad<sup>-1</sup>) with the clutch engaging at three angle points during early stance (P0: heel-strike, P1: foot-flat, and P2: single-support) and disengaged at the same angle during the late stance. In all trials, lower limb joint kinematics, muscle activation, and whole-body metabolic rate were measured.

## Results and Discussion

We found that using a controllable clutched elastic ankle exoskeleton can improve walking economy by an average of 11.7% as compared to the unassisted walking ( $k_{Exo}=0$ ) at 1.5 m s<sup>-1</sup> (Table 1). This suggests that the assistance provided by our semi-passive ankle exoskeleton can compensate for the

distally added mass of the device and reduce plantarflexion muscle activity (Table 1).

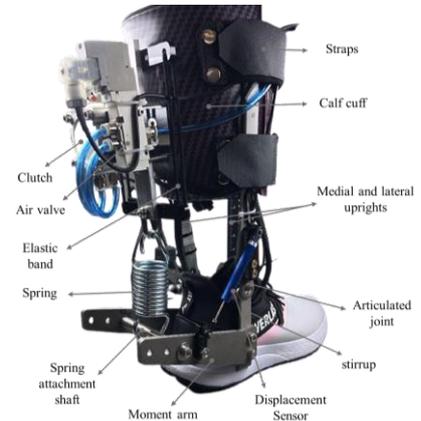

Figure 1: Semi-passive clutched spring ankle exoskeleton.

Additionally, we found that among the tested onset times, the heel-strike timing (P0) led to higher reduction (13.5%) in the metabolic rate. Further reduction in the metabolic cost and soleus muscle activation might be achieved by adjusting the spring stiffness and mass of the exoskeleton. However, since stiffness, timing and walking speed mutually influence the effect of powered walking with ankle exoskeletons, metabolically “optimal” assistance timing needs to be adjusted on a subject-by-subject basis for different walking speeds [2]. This emphasizes the importance of using a controllable clutch along with a passive elastic ankle exoskeleton to optimize assistance during human gait.

## Conclusions

This study presents a first attempt to illustrate that controlling the timing of assistance in passive elastic ankle exoskeletons can influence the assistive performance of a compliant ankle exoskeleton on human gait biomechanics.

# Does maintenance of whole-body balance take primacy over synchronization of footfalls to auditory beats during rhythm perturbed walking?

Deepak K Ravi, William R Taylor, Navrag B Singh

Laboratory for Movement Biomechanics, Institute for Biomechanics, ETH Zürich, Switzerland

Email: [deepak.ravi@hest.ethz.ch](mailto:deepak.ravi@hest.ethz.ch)

## Summary

Towards understanding resilience in walking behavior, this study aimed to investigate the relationships between footfall rhythmicity, auditory perturbations, and dynamic stability. To achieve this, novel techniques for the quantification of resilience were applied after young adults were subjected to a beat delayed perturbation in a metronome sequence.

## Introduction

Impaired regulation of rhythmic walking patterns results in either random or stereotypical behavior that limits one's ability to adapt to perturbations, as observed in individuals with an increased risk of falling. To investigate and identify subtle impairments in rhythmicity, one proposed approach has been to exploit the sensorimotor synchronization paradigm, which evaluates a subject's ability to match the rhythmic oscillations of a limb with an external (often auditory) stimulus, including infrequent temporal perturbations (where beats are presented earlier or later than expected). In synchronizing to rhythm-perturbed metronome beats, the maintenance of stable whole-body (center of mass, CoM) movement patterns can directly influence the timing of footfall correction response to the perturbation [1]. Importantly, the inverse effect of footfall perturbations on the dynamic stability of walking remains unaddressed, hence overlooking the critical aspect inherent in this paradigm for understanding an individual's resilience to falling.

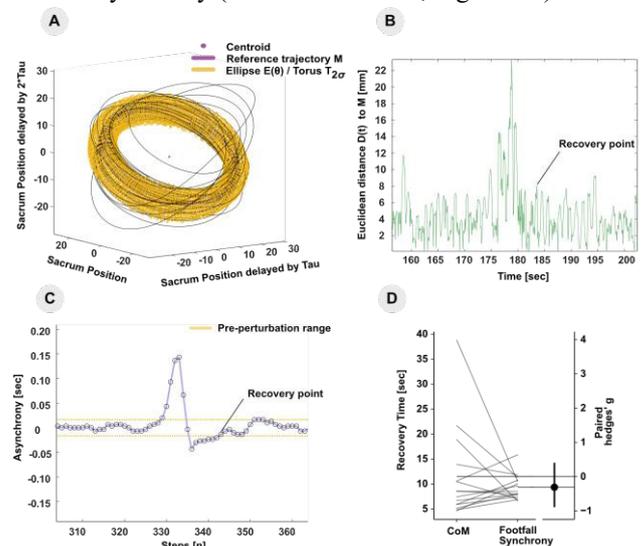

## Methods

Twenty healthy young adults (13 males and 7 females; with mean age: 24.90 (standard deviation: 2.29) years; height: 1.76 (0.07) m; mass: 72.66 (6.33) kg) participated in this study. Participants performed three walking trials: baseline walking 1 (BW1), paced walking (PW) and baseline walking 2 (BW2), each 6 minutes in duration, at self-selected walking speed. The inter beat intervals (IBIs) of an auditory metronome (0.1s of the note A, sine wave with frequency 440Hz) were matched to the mean step time evaluated from BW1. The created track was adjusted by embedding 5 perturbation intervals, increased by 20x the standard deviation of the step time, introduced around 3 minutes of the track (Figure 1A). Participants completed PW listening to the metronome track at their previously selected walking speed. They were explicitly instructed to step in time to the metronome beats while maintaining a natural walking pattern. The vertical displacement time series of the sacrum marker (used as a simple approximation of the body CoM) was used to assess the recovery of whole-body balance to steady-state patterns after a perturbation (Figure 1B and 1C, [2]). Recovery of footfall synchrony to pre-perturbation limits was evaluated

using the approach presented by Bank, Roerdink [3] and compared to the former.

## Results and Discussion

Of the 20 participants recruited for the study, 5 did not show qualitative evidence of effects of perturbation to sacrum kinematics. For the remaining 15 participants, average time between start of the perturbed cues and recovery of CoM kinematics was 11.45 (8.80) sec and similarly to recovery of footfall synchrony was 9.34 (2.39) sec. Here, 8 participants recovered the CoM kinematics ahead of the recovery of footfall synchrony (effect size = -0.31, Figure 1D).

**Figure 1:** A. Resilience Quantification; B. Recovery of CoM to steady-state patterns; C. Recovery of footfall synchrony; D. Comparison of recovery times

## Conclusions

The ability to reliably measure recovery of movement behavior thus clearly provided an improved understanding of the relationships between task level synchronization outcomes (i.e. number of walking steps to return to footfall synchrony) and dynamic stability of walking (i.e. number of walking steps to return to steady state COM kinematics). Future research could attempt to delineate such relationships in balance impaired older adults subjected to rhythmic auditory stimulation.

### Summary

Telerehabilitation can promote innovation in the definition of optimal rehabilitation pathway by treating chronic patients at home. In this perspective, DoMoMEA project aimed at developing a tele-rehabilitation system based on multiple inertial sensors specifically designed for neuro-muscular rehabilitation for stroke patients. In this specific study, the algorithms for real-time joint kinematics estimates and evaluation are presented. For each task, and each joint, a quantitative assessment of the movement quality is obtained and relevant feedbacks are provided to the patients for guide and correction.

### Introduction

Rehabilitation is fundamental for stroke survivors to relearn motor skills and to compensate for residual abilities. In this context, home-based telerehabilitation adopting low-cost wearable technology can be used to provide rehabilitation services, overcoming geographical barriers, and allowing to implement personalized rehabilitation pathways. The aim of this work is to present, within the framework of the research project DoMoMEA, the methods developed for real-time multi-joint kinematic estimation based on the use of seven miniaturized inertial sensors (IMUs).

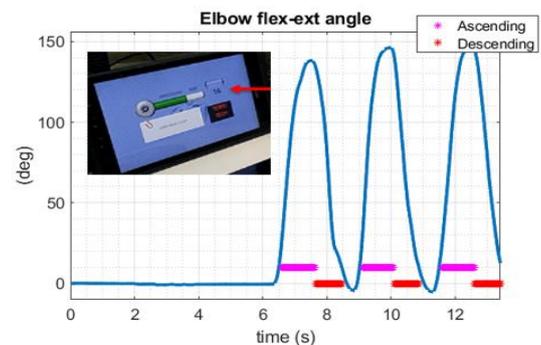

### Methods

The protocol consists of 14 planar exercises involving the main joints of upper and lower limbs aimed at recovering joint angular excursions, stability, and muscle strength. Each body segment of interest is equipped with a IMU aligned along the longitudinal axis thereby avoiding the need for functional movements [1], thus minimizing the patient's effort. The accelerometer and gyroscope data are fused to estimate the IMU orientation by using the filter described in [2], [3]. The orientation is estimated without the magnetometer to prevent any corruptions due to ferromagnetic disturbances (very likely in a domestic environment). The orientation computed by each IMU is then transmitted to an Android device at 50 Hz. At the beginning, the patient is asked to maintain the neutral standing posture for 10 s to allow the skeleton calibration by exploiting gravity direction. This ensures the kinematics to be less dependent on IMU positioning. The resulting joint kinematics is then decomposed into the triplet of Euler angles according to the ISB conventions, one of which represents the joint angle of interest. The amplitude of the secondary rotations is used to quantify undesired compensatory movements. A visual real-time feedback is provided to the

patient to support the correct execution of the rehabilitation protocol (e.g., during elbow flexion-extension the forearm pronation-supination is monitored). The joint kinematics is used to animate the exergaming and to quantitatively evaluate the execution performance by counting the repetitions and computing the range of motion and the repetition time in both ascending and descending parts (identified through the derivative of the joint angle).

### Results and Discussion

Figure 1 shows, as example, the elbow angle and the feedback. Table 1 shows the range of motion (ROM) and the repetition time averaged over 10 repetitions during a shoulder ab-adduction exercise executed at three different amplitudes.

**Figure 1:** elbow flexion-extension angle from which it is possible to compute the ascending/descending parts.

**Table 1:** ROM and execution time for a shoulder ab-adduction exercise repeated at three increasing amplitudes (columns).

## Summary

In order to better understand the influence of fatigue measured on a muscular level on the development of shoulder pain in paraplegic wheelchair users, this study investigated changes in the root mean square (RMS) of the electromyography (EMG) signal of five shoulder muscles during a wheelchair propulsion fatigue protocol. Fatigue was demonstrated in the pectoralis major pars sternalis and upper trapezius with a significant increase in the RMS after the demanding sections of the protocol and a decrease after the recovery times.

## Introduction

Shoulder pain is common in persons with spinal cord injury (SCI) [1] and has been associated with wheelchair use. Previous studies investigated fatiguing propulsion with an overground protocol and identified compensation strategies that could impact the development of shoulder injury and pain [2]. In addition, neuromuscular fatigue was identified as a possible cause for shoulder injury in overhead athletes [3]. To further investigate fatigue's contribution to shoulder pain in wheelchair users with SCI, the aim of this study was to determine changes in neuromuscular activation during the fatiguing task itself and thereby validate the previously used figure 8 fatigue protocol [4].

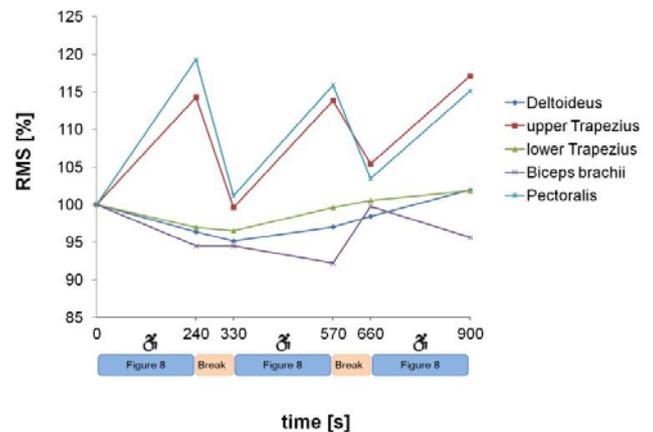

## Methods

Wheelchair users with paraplegia (n = 43, age = 50.2±10.1 years, body weight = 72.1±13.3 kg, time since injury = 27.1±11.6 years) completed a fatigue protocol introduced by Collinger et al. [4]. The fatigue protocol consists of 3 repetitions of 4 minutes maximum voluntary propulsion along an 8-shaped course with 90 seconds of rest between the repetitions. Every lap includes a right and left turn and two full stops at the crossing point. The surface EMG signal (Telemyo 2400T DTS, 305 Noraxon, Inc. USA) of the biceps brachii, pectoralis major pars sternalis, deltoideus pars acromialis, lower and upper trapezius of the non-dominant shoulder was recorded, offset corrected, rectified, filtered with a high pass (20Hz) and low pass (3Hz) 3<sup>rd</sup> order Butterworth filter. The generated linear envelope was used to calculate the RMS. RMS means were normalised to the starting RMS value. A one-way repeated measure ANOVA was used to analyse changes in the dependent variable RMS over time ( $\alpha=0.05$ ).

## Results and Discussion

The results demonstrated a significant increase in %RMS of the pectoralis major and the upper trapezius throughout the fatigue protocol (resp.  $p < .01$ , partial  $\eta^2 = .18$ ;  $p < .001$ , partial  $\eta^2 = .19$ ) (Figure 1).

The RMS of these two muscles showed the expected increases at the end of the demanding parts of the protocol (240s, 570s and 900s) demonstrating a shift in the power of the EMG signal indicating fatigue. Exercise programs targeting the trapezius and pectoralis major may have a role in preventing fatigue related injury [5, 6].

**Figure 1:** Mean of root mean square (RMS) in percentage of the start RMS of the EMG signal of all five muscles measured during the figure 8 fatigue protocol.

## Conclusions

The detected changes in RMS of the upper trapezius and pectoralis major support the protocol introduced by Collinger et al. [4] as an adequate choice to evaluate the effect of wheelchair propulsion induced fatigue in wheelchair users with paraplegia. Furthermore, these findings support strategies to prevent shoulder pain and injury in wheelchair users with paraplegia including strengthening of these muscles.

### Summary

Squatting is a closed chain kinetic exercise frequently performed in activities of daily living and sporting tasks. The decomposition of EMG signals can give specific information on motor unit behaviour during muscle contractions. In this study we analysed the motor unit firing rates from vastus medialis and vastus lateralis using dEMG sensors during a double limb squat at 15 and 25 repetitions per minute (RPM). Twenty-two healthy adults were tested. The faster speed produced an increase in the firing rate during the eccentric phase. These results indicate the importance of movement speed and contraction phase on motor unit recruitment.

### Introduction

Squats are often recommended for strength training [1] or rehabilitation exercises [2], however the influence of the speed that the task is performed at on muscle recruitment is still unknown. The use of surface EMG decomposition (dEMG) to describe motor unit behaviour within muscles has previously been restricted to isometric tasks [3], however this has been recently reported during cyclic dynamic contractions [4]. The aim of this study was to explore the motor unit firing rates in the vastus lateralis (VL) and medialis (VM) in the concentric and eccentric phases during a double limb squat at 15 and 25 RPM to gain more insights into the motor control demands.

### Methods

Twenty-two healthy adults (10 females and 12 males) volunteered and participated in this study. The average (standard deviation) age was 31.2 (6) years, height 1.78 (0.10) m and weight 78.4 (14.6) kg. Surface EMG signals were recorded at a frequency of 2222 Hz using two four-channel dEMG Trigno Galileo wireless sensors (Delsys Inc., Boston, USA). The dEMG sensors were attached to the skin using hypoallergenic double-sided tape over the VM and VL of the dominant leg of each participant. An additional two IMUs sensors (Trigno Avanti, Delsys Inc., Boston, USA) were attached to the skin on the thigh to record angular velocity sampling at 148Hz.

From an upright standing position, participants completed double leg squats flexing their knees to 90° at two different speed conditions, 15 and 25 RPM, for 45 seconds per trial. NeuroMap software v.1.1.0 (Delsys Inc., Boston, USA) was

used to decompose the EMG signals from VM and VL into their constitute motor units. Motor units over an 80% accuracy threshold were then combined with the segment angular velocity data and imported into Visual 3D. The mean, maximum, and tertiles (upper, middle and lower) of the firing rates were then calculated for the different speeds during the eccentric and concentric phases. A 2-factor repeated measures ANOVA was used to examine differences in the two squat speeds and contraction phases. Any interactions between speed and phase were further explored using post hoc paired t-tests. The statistical significance level was set to  $p < 0.05$ .

### Results and Discussion

The repeated measures ANOVA showed significantly higher firing rates during the concentric phase, with VM having higher firing rates than VL (Figure 1). However, significant interactions were seen between speed and phase (see Figure 1). Post hoc tests revealed significant differences between speeds in VM for the maximum firing rate ( $p=0.01$ ), upper and mid tertials all in the eccentric phase only. For VL significant differences were seen between speeds in the maximum ( $p=0.02$ ) and lower tertial ( $p=0.04$ ) firing rates, and a trend towards significance was seen in the mid tertial ( $p=0.05$ ) firing rates, again these differences were only seen in the eccentric phase, Table 1.

### Conclusions

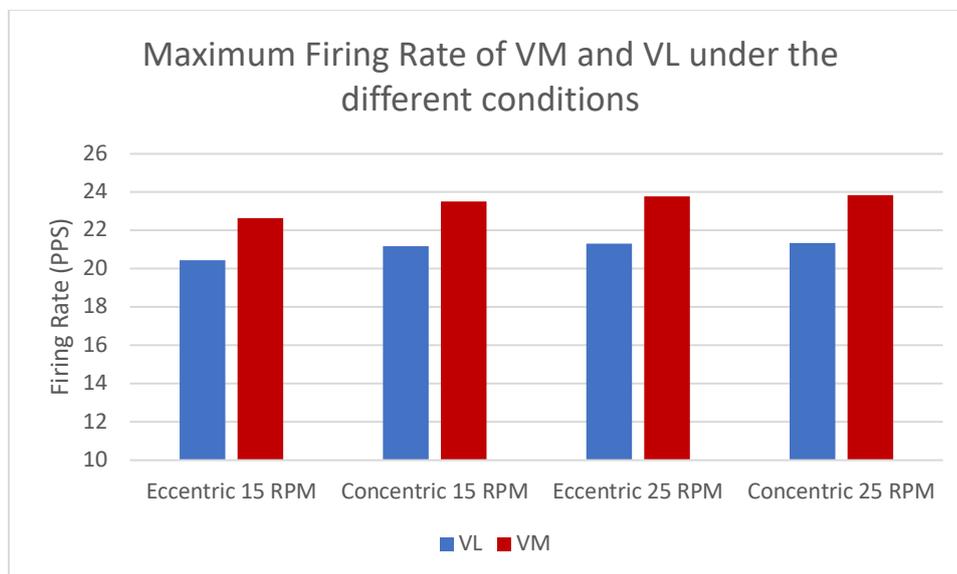

This study showed that faster speeds produce an increase in the motor unit firing rates in the VM and VL during the eccentric phase only. This highlights the previously unreported effects of movement speed and phase during squatting in healthy adults, and provides insights into the differences in motor unit behaviour when performing closed chain kinetic exercises.

## Summary

We evaluated trunk and lower limb kinematics and kinetics in athletes treated with unilateral anterior cruciate ligament reconstruction (ACLR). These individuals were divided into three groups according to time post-ACLR, and compared to asymptomatic athletes and between legs within groups (asymmetry) during weight acceptance in stair descent. We found adaptations independent of time post-ACLR, with greater knee flexion angle and moment for both the injured and non-injured legs. This could presumably be attributed to a change of strategy needed to maintain knee control, since asymmetries were observed only at an early time post-ACLR.

## Introduction

Injury of the ACL is a common and serious knee injury with both short-term and long-term physical and psychological consequences, irrespective of treatment with ACLR or only physiotherapy. The loss of mechanically sensitive receptors originally found in the ruptured ACL is believed to result in poorer knee proprioception, and a functional reorganisation of the cortex for movement compensation [1-2]. This in turn might lead to chronically adapted compensational movement strategies to increase knee control.

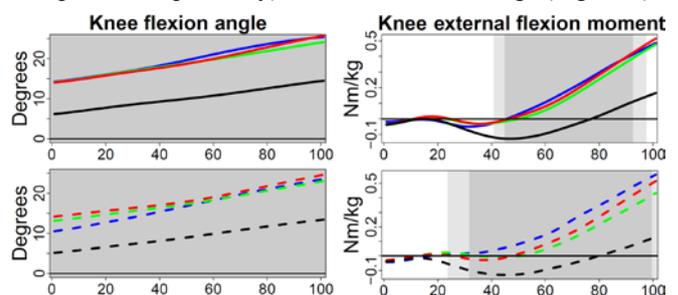

**The current aim** was to evaluate trunk and lower limb kinematics and kinetics for athletes with unilateral ACLR, in relation to time post-ACLR, compared to asymptomatic athletes and between legs within groups during the weight acceptance phase of stair descent.

## Methods

Forty-nine athletes with ACLR (24.4±4.7 years) were classified into three groups according to time post-ACLR (EARLY <6 months, n=17; MID 6-18 months, n=16; LATE ≥18 months, n=16) and compared to 18 asymptomatic athletes (ATH). Data from an eight-camera motion capture system (Qualisys, 240Hz) and a force plate (Kistler, 1200Hz) installed on the first step were used to calculate sagittal plane trunk, hip, knee and ankle kinematics (angle curves) and kinetics (body-mass normalised curves of moments, powers, and vertical ground reaction force [vGRF]). Five stair descent trials per leg were collected to calculate individual mean curves used for analysis. The injured leg was compared to the non-dominant leg of ATH, and the non-injured leg was compared to the dominant leg. The weight acceptance phase was defined from initial contact on the first step of the leading leg, to toe-off of the lagging leg, and time-normalised to 101 data points. Inferential methods for curve (time-series) data were used. In detail, a linear model was used to compare each ACLR-group to ATH, while paired t-tests were used for within-group analyses. Statistical significance was evaluated with adjusted p-values, set *a priori* at 0.05. The statistical analyses were performed using R (v.3.6.1).

## Results and Discussion

**Between-group comparisons:** For the injured leg, EARLY showed different kinematics and/or kinetics compared to ATH at the trunk, hip, knee, and ankle, while MID and LATE displayed differences primarily at the knee. Similar findings between groups were also observed for the non-injured leg. Notably, all ACL groups had greater knee flexion angles and external moments (0-100% and ~final 60-80% of weight acceptance, respectively) than ATH for both legs (Figure 1).

**Figure 1:** Group mean curves of knee angles and external moments for the injured (solid lines) and non-injured legs (dashed lines). Light and dark grey areas indicate p-values <0.05 and <0.01, respectively. Blue = EARLY, Green = MID, Red = LATE, Black = ATH.

**Between-leg comparisons within groups:** Asymmetry was found for EARLY, where the injured leg had greater external hip flexion moment, the ankle had greater dorsiflexion angle while the external dorsiflexion moment and negative power (absorption) were lower, accompanied by lower vGRF. For the other groups only MID displayed significant asymmetry restricted to lower negative ankle power for the injured leg.

Our results with greater knee flexion angle and moment (independent of time post-ACLR) might be an expression of a strategy to maintain knee control. This may be explained by a poorer generation of appropriate motor responses [3], resulting in a sensation of knee instability in the sagittal plane when loading a relatively extended knee at weight acceptance. The differences observed between groups, despite the lack of asymmetry, highlight the importance of including a control group when analysing movement patterns.

## Conclusions

Individuals with unilateral ACLR independent of time post-ACLR (<6 months, 6-18 months, ≥18 months) show compensatory movement strategies to load the knee for both the injured and non-injured legs with greater flexion angle and moment, which may presumably be a strategy to maintain knee control, during weight acceptance in stair descent.

### Summary

Muscle synergies are used to increase our insights in the motor control of the central nervous system. We compared synergies across skateboard tricks with different levels of complexity. The number of synergies were similar between the different tricks. The synergies from the least complex trick, however, were not capable to reconstruct the electromyography data of the more complex tricks in a sufficient way. Based on the findings of our study, it seems that different motor modules are required for different tricks, which might explain why it takes several years of practice before skateboarders are able to perform complex tricks.

### Introduction

Muscle synergy can be used to model how the central nervous system solves the redundancy problem of the musculoskeletal system [1]. It is assumed that each synergy controls several muscles with a single activation command. Previous studies found shared synergies (muscle weightings) across different movements, e.g. walking and cycling [2], overground and beam walking [3] or pedaling with different constraints [4]. So far, no studies, evaluated if more complex movements also share the same synergies.

From a motor control perspective skateboarding is a very complex sport, which has barely been studied. It usually takes beginners weeks to months to be able to do a simple jump, the so called ‘ollie’, with the skateboard. More experienced skateboarders are able to do very complex tricks such as kickflips and 360-flips (Figure 1A).

Our aims were to (i) investigate if the number of synergies differ between skateboard tricks and (ii) evaluate if muscle synergies from a simple skateboard trick, i.e. ollie, can be used to reconstruct the muscle activation pattern from more complex tricks, i.e. kickflip and 360-flip. Considering that it usually takes many months and several years before skateboarders can do a kickflip and 360-flip, respectively, we hypothesized that (i) the number of synergies increases with the complexity of the trick and (ii) synergies from a simple ollie are insufficient to reconstruct muscle activation patterns from more complex tricks.

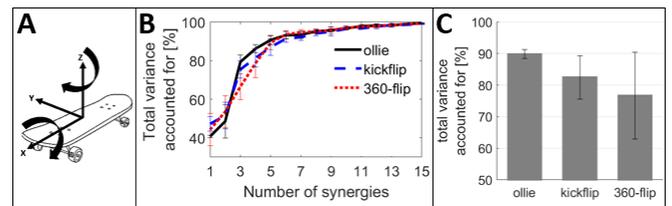

### Methods

Three-dimensional motion capture data (Plug-in-Gait marker set, 12-camera Vicon system, Oxford, UK) and electromyography (EMG) data (Menios, Ratingen, Germany) of 16 lower limb muscles (eight on each leg) were collected from 8 healthy participants with several years of skateboarding experience. EMG data of six successful trials per trick (ollie, kickflip and 360-flip) were filtered, demeaned, time- and amplitude-normalized, and used to calculate muscle synergies using non-negative-matrix-factorization. We

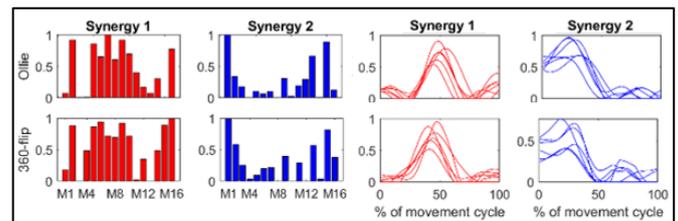

calculated the total variance accounted for (tVAF) for all synergies and tricks. We chose a threshold of 90% for the tVAF to quantify the necessary synergies for each trick. To address our second hypothesis, we used an optimization in which we kept the synergy weightings from the ollie fixed and allowed the activation profile to change to optimize the fit with the EMG data of the kickflip and 360-flip [5]. Afterwards, we calculated the tVAF based on the optimized activation profile and ollie synergies and compared the results with the tVAF based on the synergies and activation profile of each trick.

### Results and Discussion

In all except of one participant five or six synergies were enough to get a tVAF above 90% for all tricks. Surprisingly, the number of synergies was not significant different between tricks (Figure 1B). Synergies from the simplest trick, i.e. ollie, were not capable to reconstruct the majority of EMG signals (Figure 1C).

**Figure 1:** A: Skateboard with rotation axes. Ollie=jump without any rotation; kickflip=jump with a 360° rotation around the x-axis; 360-flip= jump with a 360° rotation around the x- and z-axis. B: tVAF (mean+/-SD over all participants) for all tricks. C: tVAF (mean+/-SD) obtained with synergy weightings from the ollie.

**Figure 2:** Example for muscle synergies (only two synergies are shown) and activation pattern for two tricks from one participant.

### Conclusions

Different tricks require different motor modules, which might explain why it is so difficult and time-consuming to learn new complex movements.

## Corticospinal excitability during the preparatory phase of preloaded concentric and eccentric contractions

Daniel Hahn<sup>1,2</sup>, Rica Gerdesmeyer<sup>1</sup>, Brent J. Raiteri<sup>1</sup>

<sup>1</sup>Human Movement Science, Faculty of Sport Science, Ruhr University Bochum, Bochum, Germany

<sup>2</sup>School of Human Movement and Nutrition Sciences, University of Queensland, Brisbane, Australia

Email: [daniel.hahn@rub.de](mailto:daniel.hahn@rub.de)

### Summary

The control of eccentric contractions has been linked with neural inhibition that might already be evident prior to movement onset. Therefore, this study investigated whether corticospinal excitability as measured by motor evoked potentials differs during the preparatory phase of preloaded concentric and eccentric contractions. Our results indicate that corticospinal excitability 150-ms before movement onset is not significantly different between contraction types.

### Introduction

When an active muscle is stretched during an eccentric contraction, its force capacity is enhanced (i.e., force enhancement, FE) compared with a fixed-end reference contraction at the same muscle length and activation level. As FE is commonly observed in isolated muscle preparations, but not during human voluntary eccentric contractions, absent FE *in vivo* has been suggested to arise from neural inhibition [1]. Evidence suggests that neural inhibition can exist even prior to movement onset [2], which indicates that neural inhibition might be based on movement planning rather than sensory feedback during the contraction. As the evidence for neural inhibition prior to movement onset is based on EMG and EEG activity only, the aim of this study was to investigate corticospinal excitability via transcranial magnetic stimulation (TMS) of the motor cortex. Based on the neural inhibition reported in the literature, we predicted that corticospinal excitability would be reduced in the preparatory phase of voluntary eccentric contractions.

### Methods

Ten healthy participants (4 females) performed fixed-end, concentric and eccentric knee extension contractions with their right leg, while torque and EMG of the vastus lateralis (VL), vastus medialis (VM) and rectus femoris (RF) muscles were recorded. All contractions started at 60° knee flexion and were performed up until 50% of maximum voluntary torque with a 2-s ramp and 3-s hold phase. At the end of the hold phase, the crank arm of a dynamometer either remained at 60° knee flexion (fixed-end contraction) or was triggered to rotate the knee at an angular velocity of 60°·s<sup>-1</sup> either into further extension (concentric contraction) or further flexion (eccentric contraction). During the rotations, participants were asked to maintain the same level of effort as during the preceding hold phase. 150-ms prior to movement onset, participants received an electrical femoral nerve stimulation (ENS) or a TMS of their left motor cortex. The time of movement onset was marked with a cursor on a screen in front of the participants. Overall, participants performed 13 contractions of each type, with three of them involving ENS

and ten of them involving TMS. Contraction types were performed in a randomized order.

Net knee joint torque and crank arm angle were measured by an isokinetic dynamometer (IsoMed2000, D&R Ferstl GmbH, GER) and sampled at 1000 Hz. Muscle activity and neural responses to ENS and TMS were recorded from VL, VM and RF using bipolar surface EMG (AnEMG12, OT Bioelettronica, IT) and sampled at 5 kHz. ENS over the femoral nerve was delivered by 1-ms single pulses with a supramaximal stimulation intensity (DS7AH, Digitimer, UK) to evoke maximal M-waves ( $M_{max}$ ). TMS (MagPro Compact, MagVenture, DK) over the left motor cortex was done using a double-cone coil (D-B80, MagVenture, DK) delivering 280- $\mu$ s single pulses with a stimulation intensity that resulted in motor evoked potentials (MEPs) of 30-50%  $M_{max}$ .

The sizes of M-waves and MEPs were determined as peak-to-peak amplitudes and responses were averaged. MEPs were normalized to  $M_{max}$  of the same contraction type. The duration of the silent period (SP) after MEPs was determined as the time from stimulation onset to the instance of time when the EMG signal reappeared. All data were checked for normality using Shapiro-Wilk tests. One-way repeated measures ANOVAs were used to compare dependent variables between different contraction types. The alpha level was set to 5%.

### Results and Discussion

Torque ( $p = 0.374$ ) and background EMG ( $p > 0.305$ ) did not differ between contractions types during the hold phase 1-s prior to the onset of stimulation. Average normalized MEPs ranged between 36% and 49%  $M_{max}$  and MEP amplitudes were not significantly different prior to eccentric contractions compared with fixed-end and concentric contractions ( $p > 0.67$ ). The mean durations of SPs ranged between 112-ms and 121-ms and SP durations were not significantly different between contractions types ( $p > 0.397$ ).

### Conclusions

Our results suggest that corticospinal excitability is not specifically modulated 150-ms prior to the execution of eccentric contractions in comparison with fixed-end and concentric contractions. This is in line with earlier research that found no signs of neural inhibition during voluntary eccentric contractions [3].

# Muscle shortening velocities and joint-specific powers at different external power and cadence requirements during cycling

<sup>1</sup>Cristian Riveros-Matthey, <sup>1</sup> Timothy J. Carroll, <sup>1</sup> Glen A. Lichtwark, <sup>1</sup> Mark J. Connick

<sup>1</sup> The University of Queensland, School of Human Movement & Nutrition Sciences, Centre for Sensorimotor Performance, Brisbane, Australia

Email: [c.riverosmatthey@uq.net.au](mailto:c.riverosmatthey@uq.net.au)

## Summary

This study aimed to quantify the effect of cadence and external power requirements on vastus lateralis (VL) fascicle shortening velocities and joint-specific powers during cycling. VL fascicle shortening velocities and joint-specific powers were measured between 60 and 120rpm along with the self-selected cadence (SSC) at 10%, 30% and 50% of peak maximal power (Pmax). The VL shortening velocity showed a tendency to increase as cadence increase. Contrarily, joint-specific powers may be affected by the external requirement increase.

## Introduction

Humans tend to locomote in ways that minimize energy consumption (1). For example, people tend to select a step frequency near that which minimizes the metabolic energy cost during submaximal walking (2). However, people do not show the same behavior in cycling tasks, where riders tend to use higher cadences than the metabolically optimal one (3). Apparently, other criteria besides energetic economy are at play in the SSC during cycling. Alternative factors that influence cadence selection might be related to mechanical advantage (4-5). Based on intrinsic contractile properties of the VL muscle, empirical measurements have demonstrated that cadences close to the SSC provide an optimal shortening velocity condition for producing knee extensor muscle power during submaximal cycling (5). However, it is still questionable whether maximization of power generation capacity remains a priority in external power requirement near to the maximal conditions. This study, therefore, aimed to quantify the effect of cadence and external power requirements on VL fascicle shortening velocities and joint-specific powers during cycling.

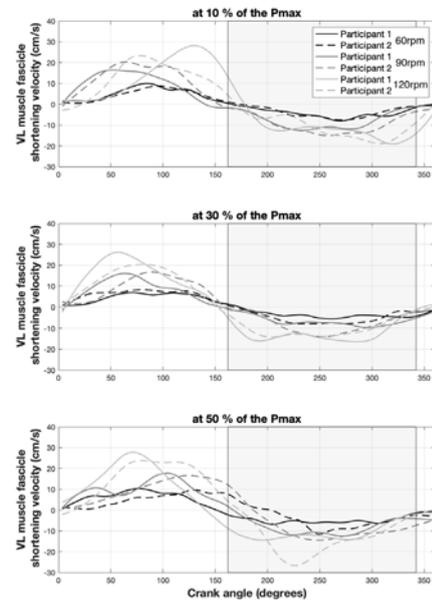

## Methods

Ten level 3-4 cyclists were recruited for this study. Each rider used a bike ergometer (Excalibur Sport, Lode BV, Groningen, The Netherlands) adjusted according to individual anthropometric characteristics. The experimental design was conducted in two days-assessments. The first day comprised a force-velocity test, which aims to obtain the Pmax that the participant can exert during pedalling. Secondly, the self-selected cadence test will be applied aiming to establish the preferences in cadence of each participant. During the second-day assessment, cyclists pedaled at eight different cadences (ranging from 60 to 120rpm plus the SSC) at 10%, 20% and 50% of the Pmax. During the experimental protocol, the VL muscle shortening velocities were measured using double ultrasound transducers in series (LV7.5/60/96Z, TELEMED, Vilnius, Lithuania). An inverse dynamic (OpenSim) approach was run from kinematic and kinetic data to calculate joint-specific powers. Two-way ANOVA was used to test the main effects of cadences and external power requirements on muscle shortening velocities, and joint powers with an alpha of  $p =$

0.05. The local ethics committee approved this study (2020000111). Also, a written informed consent was obtained from the participants.

## Results and discussion

Preliminary results of two participants, indicate that VL muscle fascicle shortening velocities increase as cadence increases per intensity condition, reaching an approximate peak value between 20 and 30cm/s in both participants (see Fig. 1). Knee and hip extension powers show a tendency to increase as the external power requirements increase (Table 1).

**Figure 1:** VL fascicle shortening velocity waveforms at 60rpm, 90rpm and 120rpm across 10%, 30% and 50% of the Pmax. The shaded area represents the knee flexion phase that was not included in the analysis. The crank angle is 0 at top-dead-center. The 70, 80, 100, 110rpm and SSC cadences are omitted for each intensity conditions for clarity.

**Table 1:** Mean of joint extension powers of hip and knee at 60, 90 and 120rpm at different external power requirements.

Cadence (rpm)	10% of the Pmax		30% of the Pmax		50% of the Pmax	
	Hip ext. power (W)	Knee ext. power (W)	Hip ext. power (W)	Knee ext. power (W)	Hip ext. power (W)	Knee ext. power (W)
60	9.9	32.3	12.48	69.5	49.34	91.8
90	5.6	30.7	15.23	68.8	32.96	107.7
120	16.3	29.0	28.66	68.2	45.28	99.5

## Conclusions

Although the analysis is restricted to two participants, preliminary results showed that VL shortening velocity responses may be affected by cadence. Conversely, joint-specific powers would be affected by the increase of external powers requirements. The data analysis continues and the complete data set will be prepared for presentation.

## Summary

**Objective:** To analyze six-degrees-of-freedom (6-DOF) knee kinematics before, at, and after heel strike during walking and running using high-speed fluoroscopy and magnetic resonance imaging (MRI) technique. **Methods:** Knee models were constructed from MRI scans of 10 healthy male participants. Participants walked and ran on a treadmill while fluoroscopic images were acquired. **Results:** During walking, knee extension and internal femoral rotation were higher at heel strike than before and after heel strike. At heel strike, the proximal-distal distance decreased by 0.32 mm as the knee loaded. During running, the knee flexion was higher before and after heel strike than at heel strike, and knee flexion before heel strike was higher than after heel strike, whereas the proximal-distal distance decreased by 0.22 mm as the knee loaded at heel strike. **Conclusion:** Revealed differences in 6-DOF knee kinematics during gait, providing insight into knee function and normal reference data for sports injury research.

## Introduction

Walking and running are popular fitness activities with many associated health benefits [1]. However, running-related injuries, especially involving the knees, are prevalent [2]. The aim of this study was to evaluate in-vivo knee kinematic data with 6-DOF during treadmill walking and running using a combined high-speed fluoroscopic and MRI technique to reveal the differential effects of these gaits on the knee joint kinematics.

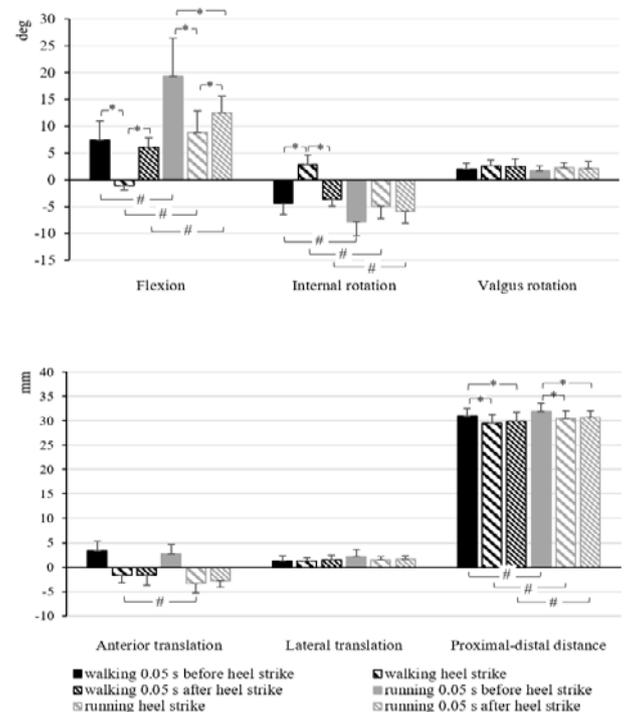

## Methods

Three-dimensional (3D) knee models were constructed from MRI scans of 10 healthy adult male participants. Participants walked and ran on a treadmill while fluoroscopic images were acquired at 200 Hz; 3D knee bone models were then related to the fluoroscopic images to capture the 3D motion of the joint. Instantaneous knee kinematic characteristics were calculated at three time points: 0.05 s before heel strike, at 0.00 s relative to impact (heel strike), and 0.05 s after heel strike.

## Results and Discussion

During walking, knee extension and internal femoral rotation were higher at heel strike than before and after heel strike. At heel strike, the proximal-distal distance decreased by 0.32 mm as the knee loaded. During running, the knee flexion was higher before and after heel strike than at heel strike, and knee flexion before heel strike was higher than after heel strike, whereas the proximal-distal distance decreased by 0.22 mm as the knee loaded at heel strike. Compared with walking, the knee before heel strike during running was 11.97° more flexed,

3.42° more externally rotated, and 1.00 mm more distracted. Similar differences between running and walking were observed at heel strike (9.95°, 7.85°, and 0.95 mm, respectively) and after heel strike (6.45°, 2.24°, and 0.85 mm, respectively). Posterior femoral translation at heel strike was also increased during running relative to walking.

**Figure 1:** Kinematics changes of the knee seen 0.05 s before heel strike, at heel strike, and 0.05 s after heel strike during walking and running; \* $p < 0.05$  among time points; # $p < 0.05$  walking vs. running.

## Conclusions

Combined fluoroscopy-MRI derived 3D-image analysis revealed differences in 6-DOF knee kinematics between walking and running in healthy participants, providing insight into knee function and normal reference data for sports injury research.

### Summary

Segment coordination variability (CV) indicates the degrees of fluctuations in a movement pattern and relates to injury incidence. We observed the changes in lower limb segment CVs and vertical loading rates in fifteen runners accomplishing a half marathon. Synchronized kinematic/kinetic data were collected every 2 km (from 2 km to 20 km) and processed with musculoskeletal modeling to report the outcomes. We found no alterations in loading rates across the running mileages. At early stance, the CV of pelvis frontal vs. thigh frontal was higher at 20 km than at 8 km ( $p = 0.022$ ). The CV of shank transverse vs. rearfoot frontal increased from 2 km to 18 km and 20 km, respectively ( $p < 0.001$ ). The unchanged loading rates could be attributed to stable CVs on the sagittal plane. The increased CVs on the frontal/transverse plane may be an early sign of fatigue and possible injury risks.

### Introduction

Two adjacent body segments coordinate to produce specific movements that fulfill a locomotion task. Segment CVs measure the degrees of fluctuations in a coordination pattern. Maintaining a consistent coordination pattern, or namely a stable CV, is considered one of the knacks to avoid injuries during a prolonged run [1]. Increased CVs could be seen in fatigued runners with decreased neuromuscular control of the body and contribute to pathologies [2], despite the lack of supporting evidence.

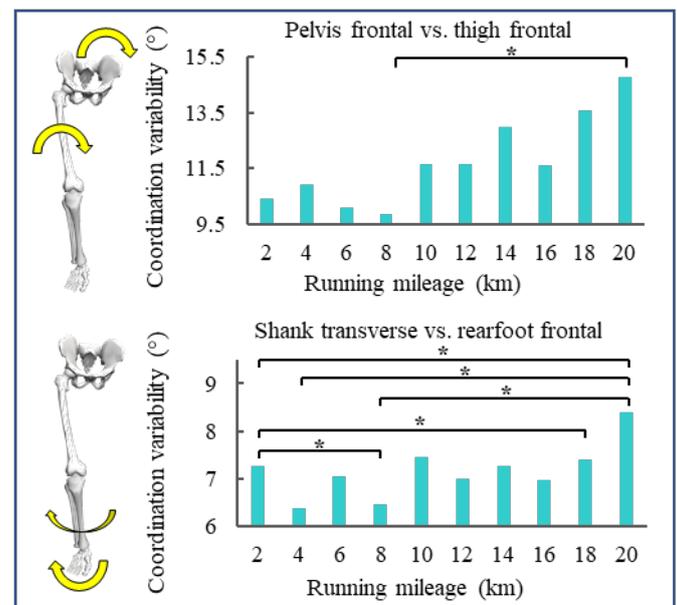

In the study, we assessed the runners' lower limb segment CVs and vertical loading rates at different distance checkpoints of a half marathon. We hypothesized that both variables would increase as running mileage accumulated.

### Methods

Fifteen experienced runners were recruited to finish a half marathon on an instrumented treadmill. The kinematic and kinetic data were collected every 2 km (from 2 km to 20 km) and processed by a musculoskeletal model. Segment CVs were computed from the angle-angle plots of selected pelvis-thigh, thigh-shank, and shank-rearfoot couplings using a modified vector coding technique. Segment CVs and vertical loading rates were averaged across ten running steps using circular and linear statistics respectively.

### Results and Discussion

MANOVA reported no changes in vertical loading rates across the distance checkpoints ( $p = 0.881$ ). CVs of the pelvis frontal vs. femur frontal during the early stance (Figure 1) were significantly increased at 20 km compared to that at 8 km ( $g = 0.59$ ,  $p = 0.022$ ). CVs of shank transverse vs. rearfoot frontal during early stance were higher at 18 km than at 2 km ( $g = 0.05$ ,  $p < 0.001$ ) and higher at 20 km than at 2 km, 4 km, and 8 km, respectively ( $g = 0.36-0.66$ ,  $p < 0.036$ ). The results showed that segment CVs increased on the frontal/transverse planes but not on the sagittal plane. CVs on the frontal/transverse planes were driven by small muscles and therefore possessed lower stability under fatigue [3]. Conversely, large muscle groups regulate coordination on the sagittal plane and are more robust in attenuating landing impacts during a prolonged run.

**Figure 1:** CVs of selected segment couplings over the course of a half marathon. \* significant difference in pairwise comparisons.

### Conclusions

The runners' coordination patterns were more variable on the frontal/transverse plane as the half marathon progressed, which may be related to fatigue onset and injury risks.

### Summary

The recovery of mechanical energy during running is important for evaluations of bouncing steps performed by spring-like leg behaviors, but little is known about energy transduction in unilateral transfemoral amputees (UTFAs) with running-specific prostheses (RSPs). Since, energy transduction can be expressed as the recovery  $R$  (%), we investigated the  $R$  at different running speeds in UTFAs. On an instrumented split-belt treadmill, 14 UTFAs ran at incremental speeds (30%, 40%, 50%, 60%, and 70% of the average speed of their 100-m personal records). At all running speeds, the  $R$  of the unaffected limb was significantly greater than that of the affected limb. These results suggest that UTFAs with RSPs perform bouncing steps using limb-specific elastic behavior.

### Introduction

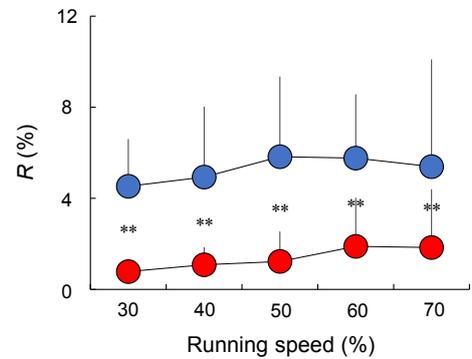

Running-specific prostheses (RSPs) have enabled unilateral transfemoral amputees (UTFAs) to run by partly providing a spring-like leg function in their affected limbs. When non-amputees run at a constant speed on level ground, the gravitational-potential and kinetic energy curves of the body center of mass (COM) are in phase for each step because of the elastic behavior of their lower limbs [1]. The energy transduction can be expressed as the recovery  $R$  (%);  $R = 0\%$  indicates that the curves are perfectly in phase. Although the  $R$  is important for evaluating bouncing steps performed by spring-like leg behaviors, little is known about the energy transduction in UTFAs during running. This study aimed to investigate the  $R$  at different running speeds in UTFAs with RSPs.

### Methods

14 UTFAs with RSPs participated in this study (age:  $29 \pm 10$  years, height:  $1.63 \pm 0.08$  m, mass:  $59.8 \pm 9.3$  kg, 100-m personal records:  $17.70 \pm 2.83$  s, mean  $\pm$  SD). Each participant ran on an instrumented split-belt treadmill (FTMH-1244WA, Tec Gihan, Kyoto, Japan) at incremental speeds of 30%, 40%, 50%, 60%, and 70% of the average speed of their 100-m personal records. The anteroposterior and vertical ground reaction forces were used to calculate the mechanical energy of the COM ( $E_{ap}$  and  $E_v$ ), respectively. The total mechanical energy of the COM ( $E_{tot}$ ) was the sum of  $E_{ap}$  and  $E_v$ . The negative ( $W_{ap}^-$ ,  $W_v^-$ , and  $W_{ext}^-$ ) and positive work ( $W_{ap}^+$ ,  $W_v^+$ , and  $W_{ext}^+$ ) per step were computed as the negative and positive increments of the  $E_{ap}$ ,  $E_v$ , and  $E_{tot}$  curves, respectively [1]. Consequently, the recovery  $R$  (%) was computed as follows [2]:

$$R = 100 \frac{W_{ap}^+ + |W_{ap}^-| + W_v^+ + |W_v^-| - (W_{ext}^+ + |W_{ext}^-|)}{W_{ap}^+ + |W_{ap}^-| + W_v^+ + |W_v^-|} \quad (1)$$

We analyzed 10 consecutive steps and averaged 5 steps for the affected and unaffected limbs to determine  $R$  at all speeds.

**Figure 1:** The recovery  $R$  of unaffected (blue) and affected (red) limbs across five running speeds. Error bars represent 1 standard deviation. The asterisks (\*\*) indicate there are statistically significant differences ( $P < 0.01$ ) between both limbs at each speed. Statistical significance was set to  $P < 0.05$ .

### Results and Discussion

As shown in Figure 1, no significant main effect of speed was observed ( $P = 0.70$ ) on the recovery  $R$ . However, there was a significant main effect of limb ( $P < 0.01$ ), where the  $R$  of the unaffected limb was significantly greater than that of the affected limb for all running speeds ( $P < 0.01$ ). In non-amputees,  $R$  is known to be less than 5% across a range of speeds because of the elastic behavior of the musculoskeletal system in the lower limbs during running [1]. The unaffected limb in UTFAs wearing RSPs would work similarly to non-amputee limbs because both types of limbs have the same biological structures. In contrast, the  $R$  in the affected limb was significantly smaller than that in the unaffected limb at all speeds. These results suggest that affected limbs would behave as a springy leg compared to unaffected limbs using the energy storing and restoring capabilities of RSPs [3].

### Conclusions

As the recovery  $R$  shows the energy transduction for each step during running, the difference of the  $R$  in both limbs indicates that UTFAs wearing RSPs performed bouncing steps using limb-specific elastic behavior across different running speeds.

## The “spring-like” function of the subtalar joint in maintaining stability during running

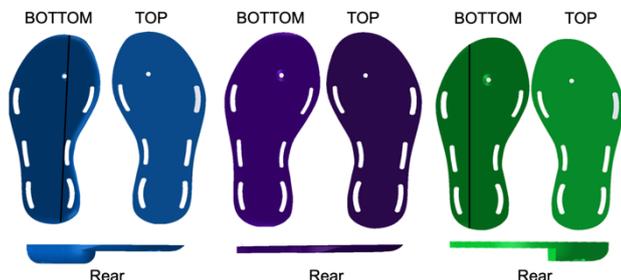

Michael J. Asmussen<sup>1</sup>, Glen Lichtwark<sup>2</sup>, Jayishni Maharaj<sup>3</sup>

<sup>1</sup>Mount Royal University, Calgary, Alberta, Canada, <sup>2</sup>University of Queensland, Brisbane, Queensland, Australia. <sup>3</sup>Griffith University, Gold Coast, Queensland, Australia. Email: [masmussen@mtroyal.ca](mailto:masmussen@mtroyal.ca)

**Summary:** We studied the mechanical and energetic function of the subtalar joint during running and how it responds to custom-made footwear that perturbs frontal plane kinematics. We found that in all footwear conditions the tissues at the subtalar joint absorbed energy in early stance and released this energy in late stance in a “spring-like” manner. We believe that this behaviour is largely attributed to the tibialis posterior (TP) tendon and may be important for maintaining mediolateral (ML) stability during gait.

**Introduction:** Muscles contribute to joint stabilization and are important for maintaining ML stability during locomotion. The subtalar joint allows for rotation in the frontal plane and given its proximity to the ground, excessive rotation at this joint would create instabilities during locomotion. The TP muscle has the largest moment generating capacity to control rotation of the subtalar joint [1, 2]. In fact, during walking, it has been shown that the TP stores and releases energy about the subtalar joint through stance in a “spring-like” manner by utilizing its tendon [3]. During running, when large forces are produced at high rates, it is unknown if the subtalar joint can maintain this “spring-like” function or whether it may absorb more energy than it returns, which could ultimately make a person unstable in the frontal plane (i.e., ML stability). The purpose of this study was to determine the mechanical and energetic function of the subtalar joint during running while wearing footwear that would induce kinematic perturbations in the frontal plane.

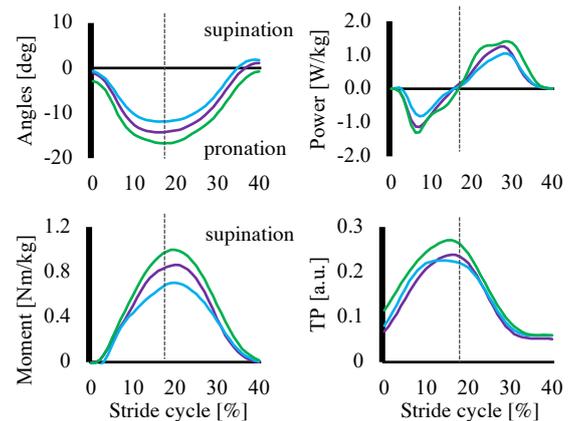

**Methods:** Ten participants ran on an instrumented treadmill in three footwear conditions (**Figure 1**) that were designed and 3D printed to perturb stability of the subtalar joint: **1.** supination perturbation (blue), **2.** no ML perturbation (purple), **3.** pronation perturbation (green). Motion capture (Qualisys: 29 reflective markers) were used to capture kinematics of each participant’s right leg. Intramuscular EMG was inserted into the TP muscle to determine relative muscle activation. A validated multi-segment musculoskeletal foot model was used to model joint moments and powers using inverse kinematics and dynamics, with *OpenSim*.

**Figure 1:** Shows supination 1 (blue), no ML (purple), and pronation (green) perturbation conditions. Top, bottom, and rear views of the footwear conditions are displayed. The foot is placed on the “Top”.

**Results and Discussion:** In the no ML perturbation condition, soft tissue structures at the subtalar joint absorbed mechanical

energy during early stance, as TP muscle activation increased. In late stance, positive power was generated about the subtalar joint, which was coupled to decreasing TP activation. Energy absorption and power generation decreased in the supination perturbation condition (condition 1, blue) and increased in the pronation perturbation condition (condition 3, green) relative to the no ML condition (see **Figure 2**). Peak subtalar joint moments, summed negative and summed positive power, and TP EMG were different across the conditions ( $p < 0.05$ ).

**Figure 2:** Shows the mean (n=10) time-series data of subtalar joint angles, moments and powers and TP EMG across Footwear conditions 1 (blue), 2 (purple), 3 (green). The dashed line marks the periods of negative (left) and positive power (right).

The negative followed by positive power phases suggest that the subtalar joint functioned in a “spring-like” manner during running. We speculate that the TP muscle and tendon contribute to the “spring-like” function of the subtalar joint, storing energy with increasing muscle activation during subtalar pronation, and releasing this energy during subtalar supination when the muscle deactivated. This resembles the function during walking [2], although energy return seems to immediately follow absorption in running. Given that the subtalar joint continued to absorb and return more energy in the pronation perturbation condition compared to absorbing more energy than it returns suggests that this “spring-like” function of the subtalar joint is important for maintaining ML stability during gait. We speculate that the TP muscle and tendon is the main source of this function, but further investigation will confirm these speculations.

**Conclusions:** The subtalar joint functions in a “spring-like” manner during running even in response to footwear conditions that perturbs an individual’s ML stability. We suspect that this function is driven by TP muscle and tendon.

### Summary

Repeated sprinting is a common activity in team and court sports that has been linked to team performance. Here we demonstrate, for the first time, the changes in the work done by the hip, knee, and ankle joint moments during a 10-metre sprint, following a repeated-sprint protocol. In summary, the main reductions in joint work were observed at the hip and knee during the swing phase while no changes were observed during the stance phase for any of the three joints..

### Introduction

To succeed in their respective sports, athletes often depend on repeated sprint ability. A better understanding of lower limb mechanical adaptations to repeated sprinting can inform strategies to improve performance and reduce injury in running-based sports. Point mass mechanics have received much attention in the past [1] but do not resolve the mechanical work done by muscles. Joint work can be used as a surrogate for mechanical energy transferred by muscles [2]. The aim of this study was to quantify changes in work done by lower limb joint moments during maximal running accelerations following a sports-specific repeated running protocol.

### Methods

Recreational athletes (n=18, 9 female, age=25±8 years) performed a repeated running protocol consisting of 12 maximal 30-metre sprints on a self-paced treadmill with 60 seconds of physical testing and active rest between sprints. Three-dimensional kinematics (200 Hz) and ground reaction forces (2000 Hz) were recorded during a maximal 10-metre overground sprint before and immediately after the repeated running protocol. Data collected during overground sprints were used to calculate normalised sagittal plane joint power

(J/kg) for the hip, knee, and ankle. Individual power bursts were identified for each joint based on direction of net joint moment (i.e., flexion or extension), direction of angular velocity (i.e., flexing or extending), and sign of power (i.e., + or -) [3]. Work done by net hip, knee, and ankle moments (J/kg) was calculated using a trapezoidal numerical integration of power-time curves for each power burst (Figure 1). Work done by net joint moments before and after the repeated running protocol was compared using univariate analyses of variance ( $p < 0.05$ ). Pearson product-moment correlation coefficient ( $r$ ) was used to assess the correlation between maximum running speed and joint work.

### Results and Discussion

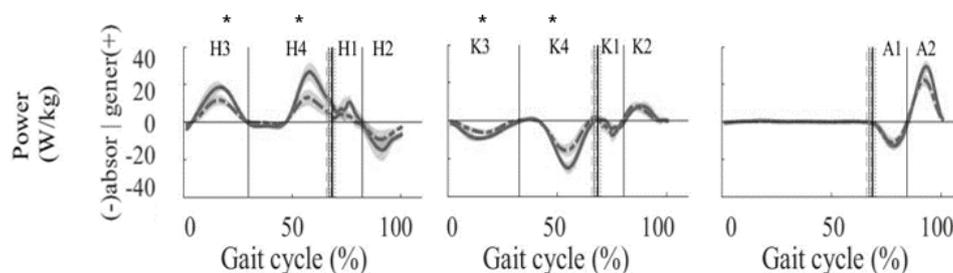

Maximal running speed decreased 19% after the repeated running protocol and was accompanied by significant reductions in work done by hip (H3= -29%, H4= -45%,  $p=0.002$ ) and knee (K3= -31%; K4= -24%,  $p=0.005$ ) moments during swing (Figure 1). No changes in work done by the ankle were observed (A1= -1%; A2= -8%,  $p > 0.05$ ). Reductions in work done by hip and knee moments during swing were significantly correlated with reductions in maximum running speed ( $r=0.61-0.89$ ).

### Conclusions

Our results suggest strategies to maintain sprint performance should focus on maintaining positive work done by hip extensors and negative work done by knee flexors during the swing phase of running.

## Summary

We analyzed the distribution of negative work performed during the first half stance among the major lower extremity joints and within all three motion planes. Further, we investigated the effects of running speed and footwear use on these distributions. Since step frequencies differed between speeds and footwear conditions, we found different directions and effect size of changes when performing the analysis over a single stance phase compared to performing the analysis over a fixed running distance (1000 m). Depending on the purpose of the analysis, studies on running mechanics should consider the effects of spatiotemporal parameters when determining work or load magnitudes.

## Introduction

During ground contact, runners' legs typically show a spring-like behavior, overall performing negative work in the first and positive work in the second half of stance. Researchers frequently analyze joint work patterns in human locomotion by lumping together the contributions from different planes of movement, limiting the ability to locate sources of energy absorption/generation in greater anatomical detail. Further, when analyzing running interventions, work analyses are often performed for individual gait cycles or stance phases, ignoring that these phases' duration might change with the intervention. Therefore, a runner might perform a different number of gait cycles and different work quantities when considering the entire running distance.

Therefore, the purpose of this study was to analyze changes in 3D negative work patterns within the initial half of the stance phase in running when changing running speed and when using cushioned footwear compared to barefoot running.

## Methods

We recruited three female and ten male participants (age:  $25.5 \pm 2.76$  years; height:  $1.82 \pm 0.08$ m; body mass:  $73.3 \pm 9.71$  kg; leg length:  $0.93 \pm 0.05$ m) and captured the 3D running kinematics and kinetics of their right lower extremity joints on a force-instrumented treadmill using previously described methods [1]. The participants ran in a barefoot and neutral cushioned running shoe condition at five different leg-length (l) normalized speeds (0.7, 1.375, 2.05, 2.725, and 3.4 Froude Number;  $N_F \tau = v^2/g$ ) in randomized order. Joint power was calculated as the product of the resultant internal joint moment and joint angular velocity. We determined negative work during the first half of stance by integrating joint power over time. We quantified the number of steps needed to run 1000 m and calculated the cumulated negative work for each joint in each plane of motion for each running speed. We then performed a two-factor (speed, footwear) repeated measures

ANOVA to identify their effects on joint work-related parameters ( $\alpha=0.05$ ).

## Results and Discussion

Analyzing the effects of speed on negative work patterns over just the first half of the stance phase resulted in a different direction of change compared to analyzing them per running distance (Fig. 1). Most negative work was performed by ankle plantarflexion, knee extension, and hip abduction moments. We found several speed\*footwear interaction effects, highlighting the differential response to speed changes in initial stance energy absorption patterns between barefoot and shod running.

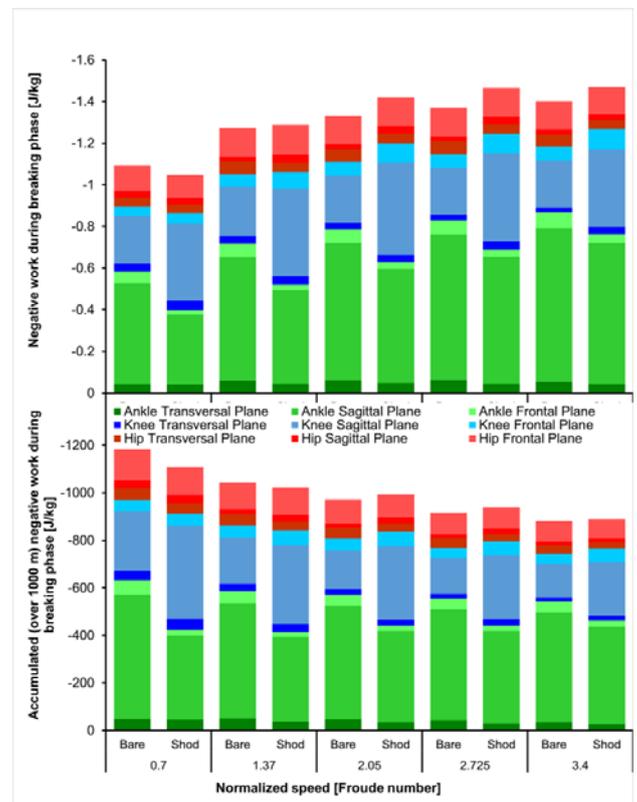

Figure 1: 3D-negative work patterns during the braking phase of stance per stance phase (top) and per 1000 m distance (bottom).

## Conclusions

Intervention studies analyzing work-related parameters should consider potential changes in step frequency due to the intervention.

## Summary

This study investigated whether muscle fiber conduction velocity (MFCV) of lower limb muscles is sensitive to different degrees of diabetic polyneuropathy (DPN). Ten control subjects and 36 diabetic patients with different neuropathy degrees were evaluated. Multichannel Surface EMG (64 electrodes matrix: 16 x 4) was acquired during 10%, 20% and 30% of maximum isometric voluntary contractions (MIVC) of tibialis anterior (TA) and vastus lateralis (VL) muscles. MFCV was determined using a modified, beamforming algorithm, that estimate the delay of motor unit action potentials across the 2-D grid. Correlation analysis between MFCV and neuropathy degree, and ANOVAs analysis followed by Bonferroni post-hoc test comparing control, non- DPN and DPN groups were performed ( $P < 0.05$ ). MFCV decreased progressively with neuropathy progression. The TA muscle showed a more consistent pattern of changes across all the studied force levels. These results suggest that DPN causes changes in the muscle fiber contractile properties with disease progression.

## Introduction

DPN is one of the most prevalent complications of diabetes mellitus, affecting both sensory and motor nerve fibers and leading to pronounced motor dysfunction. Neuromuscular impairment is related not only to nerve integrity but to factors like the state of motor end plates and skeletal muscle fibers as well. The DPN is a progressive phenomenon and related alterations could be different for earlier and more advanced stages of the disease. The MFCV is a parameter that represents the mechanisms underlying the muscle functional status and can be a sensitive tool to detect signs of motor axonal dysfunction with DPN progression. Therefore, the aim of this study is to investigate whether MFCV is sensitive to different degrees of DPN, during isometric contractions at low level forces for one proximal and one distal lower limb muscle.

## Methods

Ten control subjects (49.4±9.6yrs) and 36 diabetic patients (58.6±4.8yrs, 14.8±13.1yrs of diabetes diagnosis, 196.9±79.1 mg/dL blood glucose) were evaluated. Participants were assessed for (i) vibratory perception, (ii) tactile sensitivity (10g monofilament) and (iii) presence of typical neuropathy symptoms. These three groups of variables were used as linguistic inputs in a fuzzy system to determine the DPN degree (score 0-10). Diabetic subjects with the score > 2.5 were considered neuropathic. Multichannel Surface EMG (64 electrodes matrix: 16 x 4, OT Bioelettronica, Torino, Italy) was acquired during 10%, 20% and 30% MVC of TA and VL

muscles. MFCV was determined using a modified, beamforming algorithm, that estimate the delay of motor unit action potentials across the 2-D grid, as moving high-potential regions across the skin's surface [1]. Correlation analysis were performed in order to analyze the association between MFCV and DPN degree. Control, non-DPN and DPN groups were compared using ANOVAs, followed by Bonferroni post-hoc tests ( $P < 0.05$ ).

## Results and Discussion

MFCV decreased significantly for TA muscle in all studied force levels and for VL muscle at 20% MVC with DPN progression (Table 1). DPN subjects showed lower MFCV values for TA at 30% MVC and VL at 10% MVIC regardless the DPN degree (Table 2).

**Table 1:** Correlation analysis results.

Muscle	Force level	Person's correlation analysis	
		r	P
TA MFVC	10 % MVC	-0.362	0.016*
	20 % MVC	-0.306	0.041*
	30 % MVC	-0.338	0.023*
VL MFVC	10 % MVC	-0.209	0.155
	20 % MVC	-0.340	0.018*
	30 % MVC	-0.269	0.068

**Table 2:** MFCV values (m/s) for tibialis anterior and vastus lateralis muscles for the studied groups and ANOVA results.

Muscle	Force level	Control (n=10)	Non-DPN (n=12)	DPN (n=24)	P
TA	10 %	5.1±0.4	4.9±0.6	4.7±0.6	0.18
	20 %	5.1±0.3	4.9±0.5	4.8±0.5	0.20
	30 %	5.1±0.5 <sup>a</sup>	4.9±0.5	4.7±0.4 <sup>a</sup>	0.04*
VL	10 %	5.9±0.3 <sup>b</sup>	5.4±0.6	5.1±0.8 <sup>b</sup>	0.01*
	20 %	5.5±0.6	5.2±0.5	4.9±0.7	0.08
	30 %	5.3±0.5	4.9±0.6	4.8±0.7	0.08

\*Statistically differences. <sup>a, b</sup> Differences between groups.

## Conclusions

MFCV decreases progressively with DPN progression in TA and VL muscles. MFCV presented lower values in later stages of DPN, presumably related to changes in muscle fiber contractile properties. The greater proportion of type I fibers lost in the course of the disease in TA may explain the differences observed in a more consistent way for TA muscle.

## Summary

During steady-state walking, active control is exerted to maintain mediolateral gait stability. To this end, the center of pressure (CoP) location relative to the center of mass (CoM) can be modulated to control CoM acceleration. During steady-state treadmill walking, muscle driven foot placement control largely determines the CoP location relative to the CoM. As a compensation for errors in foot placement, muscle driven mediolateral ankle moments caused corrections of CoP location by shifting it underneath the stance foot. We tested whether constraining ankle moments would acutely cause tighter foot placement control, but instead participants walked with wider steps and increased their stride frequency. Training with constrained ankle moments did enhance foot placement control, which may be a more energetically efficient strategy for stability control.

## Introduction

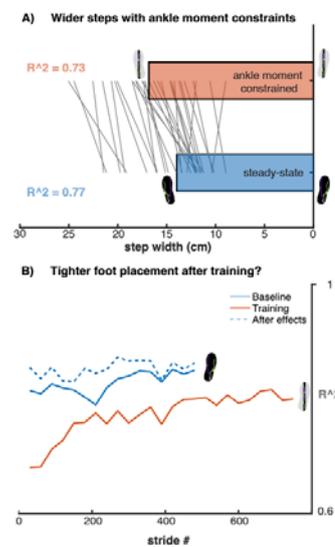

Understanding the mechanisms underlying mediolateral gait stability can help in designing training interventions for those with impaired stability control. Earlier studies have shown active stability control in response to perturbations and during steady-state walking. We focused on step-by-step muscle driven foot placement control during steady-state walking, replicating [2, 3] and providing support for active control of foot placement. Here we hypothesized that active ankle moment control would compensate for foot placement errors. Concurrently, we expected tighter foot placement control when walking with ankle moment constraints.

## Methods

Healthy adults walked on a treadmill at normal walking speed. Participants walked normally, or while wearing a shoe with a narrow ridge attached to the sole. This flexible ridge constrained mediolateral CoP shifts, yet retained push-off. A constant stride frequency was dictated by a metronome. We used linear regression models to analyse the measured full body kinematics and EMG data. Foot placement control was defined as the relationship between foot placement and CoM kinematic state in preceding swing. The  $R^2$  of this model quantified how tight foot placement was controlled. Ankle moment control was defined as the relationship between errors in foot placement and the subsequent CoP shift. We correlated gluteus medius and adductor longus activity with foot placement to test for active control. We correlated peroneus longus, tibialis anterior and soleus activity with the CoP shift due to ankle moment control.

## Results and Discussion

Bayesian statistics revealed evidence for active foot placement control ( $BF_{10} > 100$ ) and active ankle moment control partially accounting for errors in foot placement ( $BF_{10} > 100$ ). Yet, constraining ankle moment control did not lead to tighter foot placement control (Figure 1A). Instead, participants increased their step width and stride frequency.

**Figure 1:** Effects of ankle moment constraints. **A:** Wider steps ( $BF_{10} > 100$ ) and decreased mean  $R^2$  (less tight foot placement control). **B:** Tighter foot placement control after longer exposure and as an after effect (no statistics).

Thus, ankle moment constraints perturbed foot placement, and participants resorted to general compensatory strategies [1, 4]. This emphasizes the interdependence of stability control mechanisms and suggests that ankle moment constraints can be used for training, similar to e.g. [5], to enhance foot placement control. Longer exposure to ankle moment constraints indeed showed a potential training effect (Figure 1B). Tighter foot placement control may allow for narrower steps, associated with lower metabolic cost [6].

## Conclusions

Foot placement and ankle moment control are interdependent in coordinating the center of pressure with the center of mass. Constraining ankle moment control holds potential as a training tool to enhance foot placement control.

### Summary

Unilateral swing leg resistance (SwR) may be used in rehabilitation post stroke. When walking with SwR, more power is required to progress the trunk and the loaded leg through swing. Arguably, this will stimulate propulsion. This study assessed the bilateral effects of SwR on propulsion, braking and muscle activity. The results show that propulsion increased in duration and magnitude while braking decreased in duration and magnitude, in both legs with SwR. In addition, activity of muscles related to propulsion was altered bilaterally. Activity of Rectus Femoris in the loaded leg increased during swing when SwR was applied. Simultaneously, activity of Biceps Femoris in the unloaded leg increased. The Medial Gastrocnemius increased in activity during stance in the loaded leg while a small decrease could be observed in the unloaded leg. The stimulation of propulsion and muscles related to propulsion can be promising for the training of walking ability post stroke.

### Introduction

The ability to generate propulsive force on the affected side is often severely affected after stroke [1]. Propulsion can be defined as the impulse of the positive anterior component of the ground reaction force (GRF) [2] and is essential for forward progression. A decreased propulsive capacity is associated with a diminished walking ability [1]. Therefore, improving propulsion should be an important focus in rehabilitation post stroke. When walking with SwR, more power is required to actively progress the body and the loaded leg through swing. Arguably, the increased demand for propulsion may stimulate propulsive behavior after stroke. Before resistance forces can be applied in rehabilitation settings, the precise effects on propulsion, braking and muscle activity related to propulsion need to be assessed.

### Methods

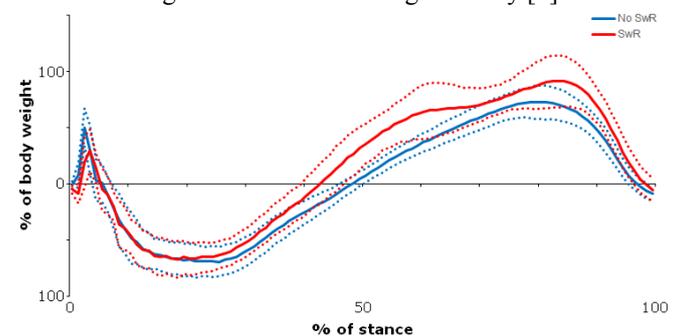

To assess the effects of SwR on propulsion, braking and muscle activity independent of gait pathology, 14 able-bodied participants walked on a treadmill with and without unilateral SwR at 0.56m/s. SwR was applied by attaching a weight of 1.25kg to a rope that was carried by pulley wheels and horizontally attached to the subject's right ankle. The effect of SwR was assessed on (1) propulsive force in terms of peak, impulse and duration, (2) braking force in terms of peak, impulse and duration and (3) muscle activity of Biceps Femoris (BF), Rectus Femoris (RF) and Medial Gastrocnemius (MG).

### Results and Discussion

SwR alters the demand for propulsion, braking and muscle activity bilaterally. When SwR was applied:

- (1) Propulsive impulse, peak force and the relative duration of the propulsive phase increased in both legs (Figure 1).
- (2) Braking impulse, peak force and the relative duration of the braking phase decreased in both legs (Figure 1).
- (3) RF activity in the loaded leg increased during swing to progress the leg. Since the demand for deceleration of the swing leg decreased, BF activity in the loaded leg decreased during late swing. In contrast, BF activity in the unloaded leg increased during its single stance phase to generate propulsion. To maintain stability and to progress the loaded leg through swing, MG activity increased during stance in the loaded leg. A small decrease of MG activity during stance was found in the unloaded leg.

Stimulation of propulsion and muscle activity can be relevant for training settings as these gait features are often considered to be a limiting factor for functional gait ability [3].

**Figure 1:** Group-averaged profiles (solid lines) and standard deviations (dashed lines) of the anterior-posterior ground reaction force in the loaded leg during walking with (blue line) and without (red line) unilateral swing leg resistance (SwR).

### Conclusions

Unilateral SwR increases propulsion and muscle activity bilaterally in able-bodied participants. The provision of unilateral SwR may stimulate propulsive capacity after stroke.

## Tactical Vest Loading Alters Head-Torso Coordination in Operational Police Officers During Running

M.A. Ellison<sup>1</sup>, F. Mulloy<sup>1</sup>, A.J. Gorman<sup>1</sup>, O. Brown<sup>1</sup>, D.R. Mullineaux<sup>1</sup>

<sup>1</sup>School of Sport and Exercise Science, University of Lincoln, Lincoln, United Kingdom

### Summary

Loaded carriage has been associated with injury, with police populations showing a high prevalence of neck and shoulder pain. Kinematic data was collected during running with typical police tactical vest loads. Peak torso lean, head-torso displacement and the coupling angle between head and torso were assessed. Findings indicate that there is a delayed torso motion when loaded with no corresponding changes in head motion to accommodate. This suggests a possible mechanism for the prevalence of shoulder and neck pain amongst police officers.

### Introduction

The modern police force is required to carry operational equipment, but to date there has been little consideration of an officers' capacity to effectively carry this load. Loaded carriage is associated with an increased risk of injury [1] and police populations display high injury rates when compared to other occupations, specifically with neck and shoulder injuries shown to be problematic [2]. Loaded carriage effects on lower limb joint kinematics [3] and ground reaction and joint forces [1] have been assessed in military populations, however there is little understanding of the mechanisms that may cause injury to the neck and shoulders, with only limited research investigating the effects of typical police load carriage systems. Vector coding is a method by which the coordination of interacting segments can be investigated [4] and may provide more information than a comparison of discrete variables or individual segments alone. This study aimed to assess the effects of police equipment carriage on head-torso co-ordination, during running, using three different loading distributions.

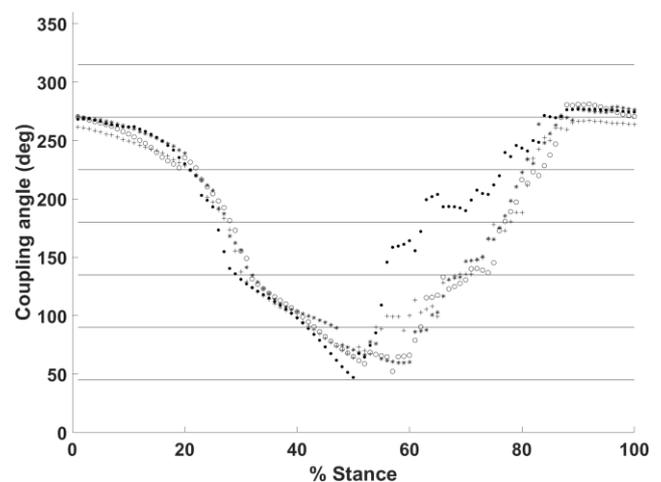

### Methods

Following ethical approval, 29 police officers from a UK police force participated in this study (14 females; age 42±8 years; mass 85.9±15.2 kg; height 1.74±0.08 m). Participants wore a commercially available tactical vest used globally by international police forces (P9MPS, Arktis Endurance Textiles, Exeter, UK). Customised sandbags were used to replicate equipment masses of items typically carried (total 2.54 kg). These were positioned in Low, High and Distributed configurations on the torso. Participants ran at a self-selected pace with each load and an unloaded control condition, on a treadmill for 60s. 15 Raptor cameras and Cortex software (Motion Analysis, CA) recorded kinematic data at 150 Hz for the final 30s. Peak forward torso lean, and peak head-torso displacement were calculated across the stance phase, along with the head-torso coupling angles using vector coding [4] and the torso and head angle time-series. Configurations were compared using one-way repeated

measures ANOVA (SPSS v25, IBM, NY) (discrete variables) and statistical parametric mapping (SPM) in MATLAB R2020a (Mathworks, MA) (time-series variables).

### Results and Discussion

Analysis indicated no differences in peak torso lean ( $F = 1.603$ ,  $p = 0.196$ ) or peak head-torso displacement ( $F = 0.190$ ,  $p = 0.903$ ). All loading conditions altered the head-torso coupling angle compared to the control (Figure 1). SPM indicated torso orientation was significantly different between control and all loaded conditions at 37 to 53% stance ( $p < 0.001$ ), but no differences existed between loaded conditions ( $p > 0.05$ ). No differences were found in head angle orientations between conditions ( $p > 0.05$ ), but the torso reached peak forward lean later in stance when loaded compared to the control conditions. The head and torso move out of phase during this time, with the head effectively tilting back as the torso tilts forwards. The smaller postural neck muscles are likely stretched more in the loaded conditions, and eccentrically loaded during weight acceptance presenting a possible mechanism for neck pain in these populations.

**Figure 1:** Coupling angle of head tilt and torso lean for control (.) and Low (\*), High (o), Distributed (+).

### Conclusions

Typical police load carriage alters head-torso coordination during running. Specifically, torso orientation is altered during weight acceptance, while the head does not move, which may contribute to the incidence of neck and shoulder pain in police officers.

## Predictive Simulations of Fixed-Speed Treadmill Gait

Kayla M. Pariser, Jill S. Higginson

Department of Mechanical Engineering, University of Delaware, Newark, DE USA

Email: [pariserk@udel.edu](mailto:pariserk@udel.edu)

### Summary

Fixed-speed treadmill gait training is a common gait rehabilitation method, but it can be challenging to experimentally determine the optimal training speed for an individual. This study develops and validates the first predictive simulation framework to estimate user response to various treadmill belt speeds. Overall, the framework captured many experimental kinematic, kinetic, and spatiotemporal trends of gait with increasing speed. This is the first step to establishing a workflow to effectively and efficiently design treadmill-based rehabilitation protocols to target specific therapeutic goals.

### Introduction

Treadmill gait training is a commonly used rehabilitation strategy to improve walking function for individuals with diseases or injuries impacting the neuromusculoskeletal system [1]. Musculoskeletal models and simulations generated from experimental treadmill gait data have shown that training at faster speeds can be used to promote increased soleus positive work, resulting in increased propulsion and gait speed [2]. However, simulations generated from experimental data cannot answer what-if questions about the ideal training speed for an individual or to estimate user response to a novel speed.

An emerging approach to addressing these questions is predictive simulations that estimate movement via trajectory optimization of high-level task goals without relying on experimental data [3]. The objective of this study is to develop and validate a predictive simulation framework for fixed-speed treadmill gait at three treadmill speeds.

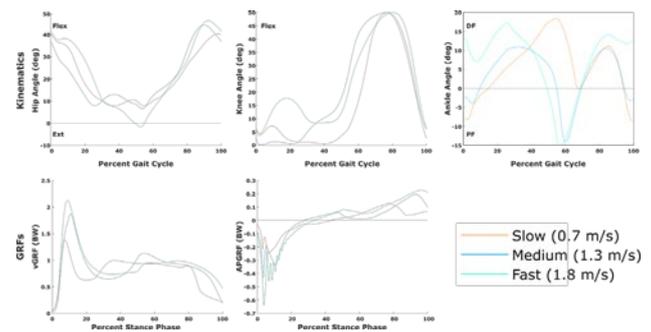

### Methods

A 2D lower limb gait model with 10 degrees of freedom, 18 musculotendon actuators, two contact spheres on each foot, and a mass of 63 kg was modified to include a treadmill body with prescribed linear motion. The ground contact was defined between the contact spheres and the top plane of the treadmill. The slope of the linear function defining the treadmill motion was set to -0.7, -1.3, and -1.8, to represent the speed and posterior movement of the treadmill belt at slow, medium, and fast speeds.

To predict the model's motion at the three belt speeds, a two-step framework was established: (1) motion tracking and (2) motion prediction, using direct collocation optimal control in OpenSim Moco [4]. The tracking simulation minimized the control effort and the error between reference and simulated states and ground reaction force data. The tracked motion was set as the initial guess to the predictive problem. The predictive problem calculated the motion that minimized the sum of muscle activations cubed while enforcing the boundary constraints of bilateral periodicity and zero average speed of the center of mass relative to the ground.

### Results and Discussion

The treadmill simulation framework successfully predicted many trends, values, and trajectory curves observed in experimental data [5]. Peak hip extension and ankle plantarflexion increased with increasing speeds. The peak anterior and vertical ground reaction forces also increased with increasing belt speed (Figure 1). In addition, predicted spatiotemporal parameters, cadence and step length, increased with increasing belt speed, matching well-established experimental trends [6].

**Figure 1:** Predicted kinematics and GRFs at 3 treadmill speeds.

Our predictions did not capture increasing swing phase knee flexion with increasing speeds [5]. This is most likely due to bounding the knee flexion at  $50^\circ$  for all three simulations thereby not enabling the flexion angle to increase at faster speeds. Also, predicted hip extension angle values are small and likely due to the small hip extension angles in the reference coordinates applied to the tracking simulation.

### Conclusions

The simulation framework correctly predicted several kinematic, kinetic, and spatiotemporal trends with increasing treadmill belt speed. Future work should seek to predict increasing knee flexion with increasing speed and improve the match of hip extension angle values with experimental data using subject-specific scaling and reference data. In addition, we will explore whether this framework will predict gait adaptations on a fixed-speed treadmill when modeling impairments such as unilateral muscle weakness.

# Voluntary control of a lower limb exoskeleton during walking using an EMG-driven biomechanical model

Guillaume Durandau<sup>1</sup>, Herman van der Kooij<sup>2,1</sup>, Massimo Sartori<sup>1</sup>

<sup>1</sup>Department of Biomechanical Engineering, Technical Medicine, University of Twente, The Netherlands

<sup>2</sup>Department of BioMechanical Engineering, Delft University of Technology, Delft, The Netherlands

Email: g.v.durandau@utwente.nl

## Summary

Assisting walking via an exoskeleton is still challenging. Even more challenging is the task to give complete voluntary control of the exoskeleton over to the user, giving him the freedom to move as desired. Here, we present a controller based on biomechanical modelling of the human body controlled by the user's EMG signals. We tested the developed controller on four healthy subjects and on one uninterrupted recording containing a mix of two different walking speeds and three different elevations as well as the change between them. Results showed that for all conditions and between the transition of those conditions, reduction of EMG and joint torque levels were observed. These results open new avenues for biomechanical based control informed by bio-electrical signals for wearables robotics.

## Introduction

Current commercial exoskeleton controllers are position-based and state of the art research controllers are based on predefined torques patterns. Those have shown remarkable results in controlled sessions aimed at rehabilitation but are still limited for assisting in everyday life in unknown and rough terrain. To circumvent current limitations, internal biomechanics variables and user's intention knowledge is desired. For this purpose, we developed a real-time neuromusculoskeletal framework that can inform in real-time on the user muscle forces and joint torques [1]. Later, this framework was used to control an ankle-knee exoskeleton during sited exercises with strokes and spinal cord injury patients [2].

## Methods

The developed method is based on real-time Hill-type muscle modeling driven by recorded EMG and joint position. To obtain subject-specific results the model is first calibrated using experimental data. More information about the developed real-time framework can be found in [1]. The framework was adapted to work with the ankle modules of the WR2 exoskeleton presented in [3]. Experiments were done on four subjects (30±4 years, 177±6 cm, 71±6 Kg) and consisted on one long walking recording on a treadmill comprising a mix of two different speeds (1.8 km/h and 2.8 km/h) and three elevations (-5%, 0%, and 12%). This was repeated two times for each tested conditions, I) minimal impedance where the exoskeleton try to be as transparent as possible to the user and II) assistance where a percentage of the computed joint torques by the framework is given back to the user as assistance.

## Results and Discussion

Results showed that EMG levels for each tested walking conditions were reduced when assistance was provided compared with minimal impedance (Figure 1). Reductions were also observed in the transition between walking conditions. At the muscle level, the Soleus muscle showed the biggest reductions contrary to the tibialis anterior that showed slight increases. The developed framework showed the possibility to reduce EMG levels for all tested conditions as well as in the transition between them. Importantly, these reductions were achieved without having to change any parameters in the exoskeleton controller or in the biomechanical model use. This is possible because the user's intention is known through the EMG signal, which allows for voluntary control of the exoskeleton by the user. Future works will make use of the rich level of internal information given by the biomechanical model such as muscle forces, joint stiffness, and joint loading to design wearables controller that offers personalized assistance to reduce effects of affliction.

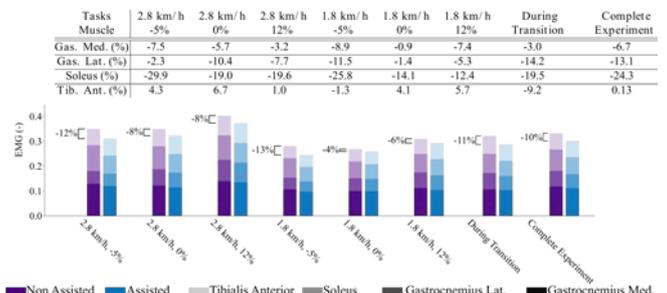

Figure 1: EMG results for all tested conditions. The table shows results at the muscle levels.

## Conclusions

Real-time biomechanics combined with wearables robotics open new opportunities to develop controllers that can offer biomechanical benefits (EMG reduction) on a broad range of walking conditions. This method also offers the unique opportunity to observe changes in the neuromusculoskeletal system user as they happen.

# Large-scale multi-channel electromyography and musculoskeletal modeling via wearable smart garments to support clinical decision-making

D. Simonetti<sup>1</sup>, B. F. J. M. Koopman<sup>1</sup>, M. Sartori<sup>1</sup>

<sup>1</sup>Department of Biomechanical Engineering, University of Twente, Enschede, The Netherlands

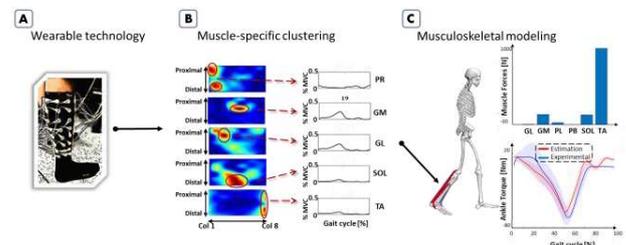

Email: [d.simonetti@utwente.nl](mailto:d.simonetti@utwente.nl)

## Summary

Clinical decision-making requires above all rapidity. Currently, motor deficit evaluation is based on a simplistic and subjective assessment, i.e. a simple 10m walk. It fulfills the main requirement, but it is not accurate, and it is just based on the evaluator's knowledge and experience. Greater accuracy is achieved in biomechanical laboratories where advanced technology together with neuro-musculoskeletal modeling allows to quantify the subject impairment. However, this is made at the expense of rapidity. The lengthy set-up and time-consuming post-processing do not allow the translation of this technology in the clinical environment. Our work aims to blend the two worlds, clinical rapidity and biomechanical accuracy, through an advanced technology quick to set up like a sock. The integration of advanced signal processing and real-time musculoskeletal modeling integrated into a smart wearable garment could become a promising asset helping clinicians to better and quickly characterize stroke patients.

## Introduction

The key aspect in clinical environments is rapidity. A large number of people with motor deficit forces clinicians to rely on a simplistic but rapid tool to assess the motor function. It is common to use functional ambulatory categories (FAC)[1], i.e. 10m walk. The evaluation is rather subjective based on the knowledge and experience of clinicians. On the other hand, in biomechanical laboratories, the availability of advanced technology combined with musculoskeletal modeling techniques can give more accurate insights into the actual patients' state. However, the accuracy is achieved at the expense of rapidity so that the lengthy setup, data acquisition, and the time-consuming post-processing prohibit the translation of this advanced technology in the clinics. Our work is aimed to balance clinical rapidity and biomechanical accuracy. We propose to use advanced signal processing techniques and real-time neuro-musculoskeletal modeling integrated into a smart wearable garment. The garment is a simple lower leg sock instrumented with a large-scale multi-electromyography (EMG, 64 channels) grid and inertial sensors (IMUs) allowing to get over the lengthy setup and to prevent human error in the manual electrodes' placement. The smart clothing together with advanced signal processing techniques provides muscle activation and muscle-tendon unit (MTU) kinematics necessary to finally model the subject-specific musculoskeletal properties. In the following paragraphs, we show the results on (1) the automatic extraction of 5 muscle activations and (2) the torque estimation at ankle joint during different locomotion speeds using EMG-driven musculoskeletal modeling.

**Figure 1:** Schematics of the proposed technology: (A) fully wearable soft sensorized garment, (B) signal processing techniques to extract MTU activations (C) framework for patient-specific musculoskeletal modeling.

## Methods

Seven healthy subjects were equipped with 33 reflective markers and a lower leg flexible garment instrumented with 64 equally distributed EMG monopolar electrodes. The 64-electrode space is reduced in 5 muscle-specific clusters applying iterative non-negative matrix factorization (NNMF) [2] during slow locomotion at 1km/h. Afterward, 5 average muscle activations were extracted during locomotion at different speeds 1, 3, and 5 km/h, and used as input to EMG-driven musculoskeletal model to estimate ankle torque.

## Results

The NNMF-approach seems to be able to locate the muscle location and to extract averaged activations during each locomotion speed that resembled with good accuracy the activation recorded with bipolar EMG. Afterward, the musculoskeletal model driven by the automatically extracted muscle-specific activation reproduced experimental ankle torques during gait at different speeds.

## Discussion and Conclusions

The combination of a soft sensorized garment and the automatic procedure for the extraction of muscle activations added to the framework for neuromuscular modeling has a good potential to become a resource for fast and more accurate clinical decision-making.

## Acknowledgment

This work was funded by EFRO Op Oost GUTs (20913301). The garment is developed in collaboration with TMSi.

## Summary

Modelling muscle stiffness-generating capacity under different types of dynamic contractions and history-dependencies is an open challenge. We present an experimental dataset that captures history-dependent phenomena *in vivo* as well as an initial resulting *in silico* model that also takes muscle architecture-contribution to stiffness generation into account. We compare the proposed model against joint stiffness reference values obtained via system identification during dynamic plantar-dorsi flexion joint rotations and show preliminary results.

## Introduction

Quantifying human joint stiffness *in vivo* during movement remains a challenge. Here we propose a data-driven musculoskeletal model-based approach to estimate multi-muscle stiffness as well as resulting joint stiffness. Importantly, the proposed model-based approach does not require joint perturbations, in contrast to well established system identification methods. Musculoskeletal models often use a standard Hill-type muscle model that does not capture history-dependent properties, *e.g.* stretch-induced force enhancement (FE) and shortening-induced force depression (FD). Moreover, muscle architecture features, specifically pennation angles, are often neglected when estimating equivalent muscle-tendon stiffness. Our goals are: 1) to experimentally capture history-dependent muscle contraction mechanisms to further implement them in the model; 2) to include pennation angles into the current muscle-tendon unit stiffness model; and 3) validate the joint stiffness profiles predicted by our extended muscle model against an ensemble-based system identification method during ankle rotations.

## Methods

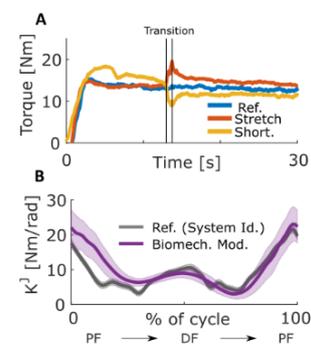

A young healthy voluntary participant was instructed to keep the tibialis anterior muscle's (TA) activation level between 15% and 20% of maximum voluntary contraction while the resulting ankle torque was recorded by a dynamometer. The subject performed a) isometric contractions, b) an active stretch followed by an isometric contraction, and c) an active shortening followed by an isometric contraction.

Additionally, the subject was instructed to follow a sinusoidal plantar-dorsi flexion angle target (amplitude: 0.15 rad, frequency: 0.6 Hz). Electromyography (EMG) and kinematic data were used to estimate joint stiffness using an extended EMG-driven musculoskeletal model that considers the muscle fiber's pennation angle in the equivalent muscle stiffness computation:  $K_{eq}^m = dF^m/dl^m \cos^2\alpha + F^m/l^m \sin^2\alpha$ , where  $F^m$  and  $l^m$  are the force and length, respectively, of the

muscle fiber, and  $\alpha$  represents the muscle fiber's pennation angle [1]. Joint stiffness predictions were compared to an ensemble-based system identification method [2].

## Results

Preliminary results (Figure 1) show that we were able to elicit FE (19% torque increase compared to the reference) and FD (14% torque decrease compared to the reference) on the TA. The aforementioned values were computed by averaging the relative torque change in a one-second window one second after the joint angle transition was completed. Our extended model's joint stiffness prediction was comparable to the system identification reference profile ( $R^2 = 0.69$  and root mean squared error, RMSE, = 3.33 Nm/rad).

**Figure 1:** A) Measured ankle isometric DF torque in three conditions: reference (blue), and after muscle lengthening (red) and shortening (yellow). The vertical lines indicate the transition from the initial to the reference joint angle. B) Ankle joint stiffness during a plantar-dorsi flexion task estimated by the reference system identification method (grey) and predicted by our proposed model-based approach (purple).

## Discussion and Conclusions

We captured history dependent muscle properties *in vivo* and we extended our joint stiffness formulation to consider the muscle's pennation angle. The inclusion of physiological features in musculoskeletal models may be beneficial for joint stiffness estimation. Next steps include the implementation of FE and FD models, as well as a short-range stiffness module, in the Hill-type muscle model to improve its capabilities of force and stiffness estimation during complex tasks involving eccentric, concentric and isometric contractions.

### Summary

Human motor function is highly variable across motor tasks, pathology, and training, within the same person and between individuals. This is a major problem for devising neurorehabilitation strategies to restore natural movement. Although current signal-driven neuromusculoskeletal models can predict accurate joint moments, there is room for improvement in reproducing neuro-mechanical processes across different conditions. For this, we propose an motoneuron-based approach to extract relevant alpha-motor unit (a-MU) properties, and to employ their statistical distributions for generating a-MU-specific muscle activation dynamics. We expect that this will enable better torque predictions across multiple conditions, as well as a better understanding of how alpha motor neurons interact with muscles, and how they modulate in response to neurorehabilitation devices (e.g. spinal electrical stimulators).

### Introduction

The development of closed-loop neuro-modulative techniques is currently hampered by the inability of interfacing with neural targets responsible for motor function. State of the art electromyography (EMG)-driven models [1] aim to provide a deeper insight into force-generation processes of movement, however, they do not offer detailed information on individual a-MU behavior. The ability of decomposing several MUs from high density-EMG opens up new avenues to extend current generalized neuromusculoskeletal models into MU-specific formulations. This work presents a technique for sampling a-MU distributions, and creating more detailed models that account for MU-specific twitch properties.

### Methods

Four healthy men performed a series of isometric plantar-dorsi flexion tasks as described in [2]. We recorded high density-EMGs from the lower leg muscles, and decomposed them into constituent MU spike trains using a convolutive blind source separation technique [3]. The non-physiological spike trains were eliminated using quantitative accuracy indices [4]. We then calculated the mean discharge rate (normalized to 40 Hz) and recruitment threshold of each MU across all trials for each subject. We obtained a linear combination from these features through principal component analysis, and projected the data onto the first eigenvector (Figure 1). Moreover, we designed a piecewise parametric function that models a critically damped system where shape parameters (amplitude, time-to-peak and half-relaxation time) can be fine-tuned based on the MU distribution (Figure 2).

### Results and Discussion

The probability density functions of the first eigenvector showed an overlapping mixture of two gaussians (Figure 1).

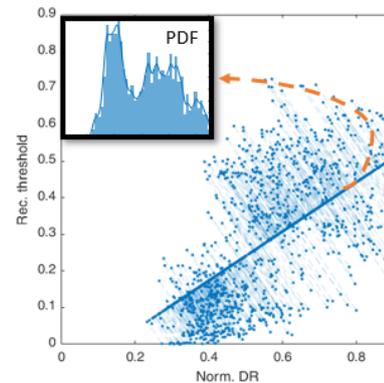

Figure 1: Scatter plot of norm. discharge rate and rec. threshold.

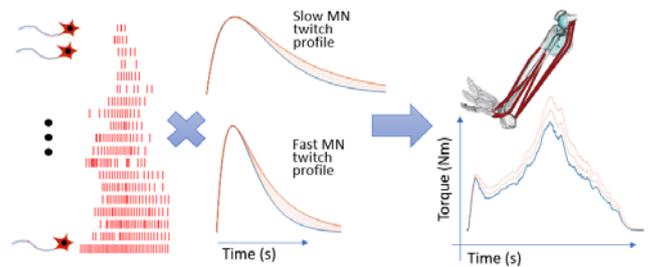

Figure 2: The convolution between decode spike trains and their specific twitch response will allow a better torque estimation.

These may correspond to slow and fast MU populations. The slow MU population had the ranges (95% confidence interval): 0.091-0.104 for rec. threshold, and 0.41-0.43 for norm. discharge rate; whereas the ranges for the fast MUs were: 0.38-0.45 for rec. threshold, and 0.61-0.71 for norm. discharge rate. Future work aims at coupling this sampling technique with our proposed twitch model to generate a MU-specific formulation of activation dynamics.

### Conclusions

We proposed a technique to sample MU distributions and to model specific twitch responses based on their properties. This enables MU-specific activation dynamics which, in turn, may provide better torque predictions in comparison to current EMG-driven models. In a rehabilitation scenario, this would enable developing personalized neurorehabilitation strategies tailored to specific neural targets.

## Is the side-stepping exercise effective on targeting gluteal muscles?

Heron B. O. Medeiros<sup>1</sup>, Géssica A. Silvano<sup>1</sup>, Erik M. Roesler<sup>1</sup>, Marcio O. Nunes<sup>2</sup>, Walter Herzog<sup>3</sup>, Heiliane B. Fontana<sup>1,4</sup>

Email: [heronbomed@gmail.com](mailto:heronbomed@gmail.com)

### Summary

In this study, we tested the commonly made assumption that the side-stepping exercise with an elastic band around the forefeet creates a torque of adduction and medial rotation of the femur around the pelvis resulting in the activation of gluteal muscles in opposition to the external moments created.

### Introduction

Strengthening hip abductor and lateral rotator muscles has been a common goal in lower limb rehabilitation and injury prevention exercise programs, with great emphasis given on maximizing gluteal muscle activation during movement-based exercises [1].

The side-stepping exercise is typically performed in a squatted posture with the individual moving laterally with a looped resistance band around the forefeet. Both, the use of a squatted posture and the forefeet band position were shown to be optimal for enhancing gluteal activity [2,3], which has contributed to the popularity of side-stepping with the band around the forefeet.

It is assumed that **the band** around the forefeet **produces** a hip adduction and medial rotation torque, which is counteracted by gluteal muscles. However, this assumption seems to ignore the mechanics of the exercise [4] and the changes in gluteal muscle action that occurs with hip flexion in the squatted position [5].

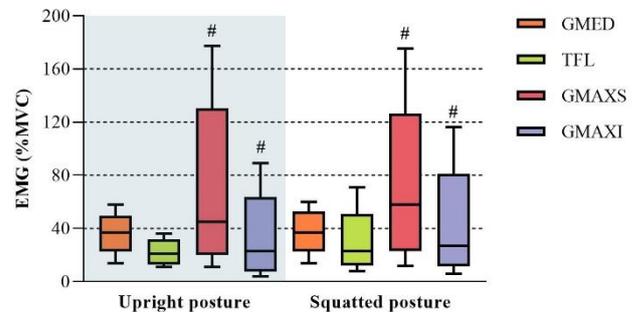

Here, we investigated simultaneously the electromyography (EMG) of gluteal muscles (and tensor fascia lata (TFL)) and hip moments in the sagittal, transverse, and frontal plane during side-stepping and tested the hypotheses that: i) hip muscle torques during side-stepping are of extension, medial (not lateral) rotation and abduction, and ii) the increase in gluteal activation in the squatted posture compared to the upright posture in this exercise is not related to an increase in hip lateral rotator or abductor torque but to an increase in hip extensor torque.

### Methods

Thirty-six adults performed side-stepping with an elastic band around the forefeet in an upright and a squatted posture while 3D kinetic/kinematic and EMG data were collected. An inverse dynamics approach was used to estimate hip joint torques. EMGs of the gluteus medius (GMED), TFL, and superior and inferior fibers of gluteus maximus (GMAXS and GMAXI) were analyzed.

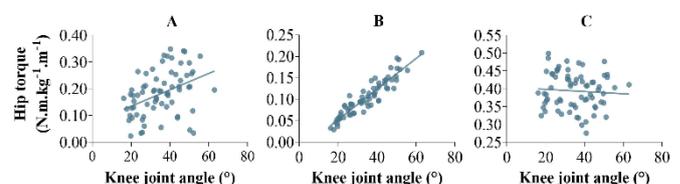

### Results and Discussion

Average EMG of GMAXS and GMAXI was greater in the squatted posture than the upright posture (Figure 1,  $p \leq 0.001$ ), while no differences were observed for the GMED and TFL ( $p > 0.133$ ).

**Figure 1:** Hip muscle activity (median  $\pm$  QI) during side-stepping (#: significant differences between postures with Wilcoxon).

Regardless of posture, a hip muscle torque of extension, medial rotation and abduction was necessary during all phases of side-stepping, challenging the assumption that GMAX activity during side-stepping results from the need to **laterally** rotate the hip during this exercise. Side-stepping in a squatted posture resulted in an increase in hip extensor and **medial** rotator torque but not hip abductor torque (Figure 2).

**Figure 2:** Association between knee joint angle and hip extensor (A), medial rotator (B), and abductor torques (C).

While the role of gluteal muscles in the transverse plane may change with hip flexion [5], transverse hip muscle torque of medial rotation is required in both postures (Figure 2B) and for all phases of the exercise (data not shown).

### Conclusions

The assumption that the side-stepping with the band around the forefeet targets gluteal muscle action towards hip lateral rotation and abduction is not correct. Hip muscle torques required are of abduction, extension and **medial** rotation.

The increase in gluteal muscle activity observed in the squatted posture compared to an upright posture might be related to the increase in hip extensor torque and hip medial rotator torque as GMAXS fibers change their moment arm to medial rotation as the hip is flexed.

### Summary

This study aimed to combine shear wave (SW) elastography for the quantitative assessment of muscle tissue stiffness variations after transfemoral (TF) amputation and used simplified finite element (FE) simulations to map numerical material inputs for different muscles to replicate the biomechanical response of the residual limb at the residual limb-prosthetic socket interface under loading.

### Introduction

The residual limb shape changes in time with muscle atrophy and stiffening of loaded tissue regions; this constantly evolving interface is an important parameter to consider for personalized and comfortable socket development. FE modeling has been used to support prosthetic socket design for many years because of its potential to offer insights into soft tissue load distributions. It has been shown that variation of the muscle stiffness in numerical models caused substantial differences in the predicted strains between liner and skin interface [1]. Here we aimed to determine the differences of elastic modulus in different muscle regions of TF amputee using SW elastography and the effect of muscle material parameter inputs on predicted numerical strains for the residual limb which is ultimately related with socket comfort.

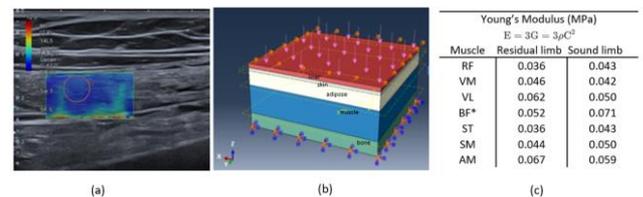

### Methods

SW elastography measurements were performed on muscles of the residual and sound limb in five (2 males and 3 females) TF amputees with mean age of  $38.4 \pm 5$  years. TF amputees' rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), biceps femoris (BF), semitendinosus (ST), semimembranosus (SM), adductor magnus (AM) muscles were measured. Shear wave propagation speeds were captured using ultrasound scanner for shear wave elastography. from the participants' amputated (Figure 1.a) and sound limb. For each muscle, shear modulus was measured three times. All participants were recruited at Hospital Universitario Virgen del Rocío and ethics committee approval was obtained. FE models were developed with ABAQUS software. The shear modulus data was converted to linear elastic modulus (Figure 1.c) and simplified model geometry was developed (Figure 1.b). The contact interface between the skin and liner was modeled as a tied interface to demonstrate if slip not occurred. A rigid interface between bone and muscle was also defined to prevent separation. The load conditions were obtained from

literature and 25mm displacement [2] and 5 kPa distributed pressure [3] was applied to liner surface.

### Results and Discussion

Different elastic moduli values were found in TF amputees' residual limb muscles at relaxed state. The AM had a significantly ( $p < 0.05$ ) higher elastic modulus compared to the other muscles. The FE simulations with corresponding muscle material models resulted in varying biomechanical responses to same levels of load conditions at the residual limb-liner interface. As expected less stiff muscle regions experienced higher levels of compressive strain. Young's moduli of the residual limb tissues were significantly ( $p < 0.05$ ) smaller than those of their sound sides for BF muscle (Figure 1.c).

**Figure 1:** (a) Longitudinal sonogram of RF, color-coded box represent elasticity (stiffer areas were coded in red and softer areas in blue), (b) Simplified geometry of FE model, (c) Measurements of elastic modulus for residual limb and sound limb where C is the SW propagation speed and  $\rho$  is the tissue's density. \*Significant difference between residual limb and sound limb ( $p < 0.05$ )

### Conclusions

Different muscle groups of TF amputee's residual limb had varying elastic modulus stiffness which influences the numerical model outcomes of the simplified FE models. This is an important aspect to take into consideration while modelling bulk soft tissue representations for the entire stump.

**Eccentric training increases the cross-sectional area in different regions of the Achilles tendon after rupture**  
**Emmanuel S da Rocha**, Francesca C Sonda, Klauber D Pompeo, Mariane B Scheeren, Jean M Geremia, Marco A Vaz  
 Biomechanics and Kinesiology Research Group, Federal University of Rio Grande do Sul, Porto Alegre, RS, Brazil  
 Email: emmarocha@gmail.com

**Summary**

Here we verified the effects of 12 weeks of eccentric training on the Achilles tendon (AT) cross-sectional area (CSA) from patients with AT rupture (mean=4.6 years post-surgical repair). We compared the effects of two different training programs (isokinetic and conventional) on the CSA of 10 different regions of the AT. AT rupture leads to morphological adaptations (higher CSA) in the injured tendon after years from the surgery that is different among regions of the tendon. We showed that the tendon adapts after 8 weeks, and that eccentric training hypertrophied the tendon (18% increase in CSA).

**Introduction**

Achilles tendon (AT) rupture is associated with an increase in tendon cross-sectional area (CSA) because the healing process generates a tendon callus that affects the plantar flexor function, with deficits persistent several years post-surgery [1]. AT morphology is an important measure to investigate tendon plasticity in response to training [2] and rehabilitation post-rupture [3]. Mechanical load from exercise stimulates biochemical signals eliciting tissue adaptation. Changes in the extracellular matrix [4], as well as fibre re-alignment, change the AT's CSA [2]. Eccentric contractions are the muscle actions with the highest force production capacity, and, therefore, elicit the highest tendon loading). However, the effects of different types of eccentric training [conventional (CONV) and isokinetic (ISOK)] on AT CSA remain unclear. The purpose of this study was to verify the effects of 12 weeks of these two eccentric training modalities in 10 different regions of the tendon of patients that underwent AT surgical repair.

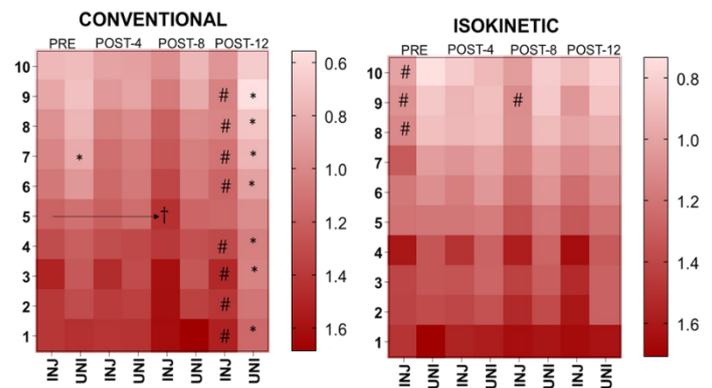

**Methods**

This is a randomized evaluator-blind controlled clinical trial (NCT03861572) that was approved by the university's ethical committee (#96310118.4.0000.5347). AT CSA was obtained from 10 consecutive ultrasound images (1 cm apart) obtained from the calcaneus insertion to the myotendinous junction. An experienced evaluator used B-mode ultrasonography before training (Pre-training), and after 4, 8 and 12 weeks of training. We randomized participants using a computer program to generate random numbers in permuted blocks thereby assigning them into two groups: the ISOK training [n: 14 (13 men), age: 38.4 ± 6.8 years old, body mass: 87.5 ± 14.8 kg, postoperative follow-up: 5.1 ± 5.2 years]; and the CONV training [n: 14 (13 men), age: 37.7 ± 4.3 years old, body mass: 87 ± 10 kg, postoperative follow-up: 4.1 ± 3.5 years]. Volunteers trained twice a week. Two to four series of 8 to 12 repetitions were performed. The load

was increased from 60% to 80% of maximal effort in the three mesocycles (1<sup>st</sup>-2<sup>nd</sup> week: 2x8, 60%; 3<sup>rd</sup>-4<sup>th</sup> week: 3x8, 60%; 5<sup>th</sup> week: 3x8, 70%; 6<sup>th</sup>-8<sup>th</sup> week: 3x10, 70%; 9<sup>th</sup>-10<sup>th</sup> week: 3x12, 80%; 11<sup>th</sup>-12<sup>th</sup> week: 4x10, 80%). Both legs were trained.

**Results and Discussion**

Eccentric training increased (18%) the injured leg's tendon CSA in region 5 (Figure 1) in the CONV group after 8 weeks (p=0.048; 95% CI -0.50, -0,001; d=0.67). The injured tendon in the CONV group had higher CSA at post-12. ISOK showed higher (21-35%) CSA at the uninjured leg than CONV at the end of the training period.

**Figure 1.** Cross-sectional area. Heat map where higher area values are depicted with darker or stronger colour. † means training effect; \* means differences between groups; # differences between legs.

**Conclusions**

CONV eccentric training increased the injured AT CSA by 18%, while the ISOK training increased the uninjured AT CSA by 21-35% at the end of the training program.

### 3D Body Landmark Detection for Markerless Motion Tracking

Alex Spencer<sup>1</sup>, Serge H. Roy<sup>1</sup>, Paola Contessa<sup>1</sup>, Gianluca De Luca<sup>1</sup>, Joshua C. Kline<sup>1</sup>, and Bhawna Shiwani<sup>1</sup>  
<sup>1</sup>Delsys Inc. and Altec Inc., Natick, USA

#### Summary

Rapid advances in depth-sensing and computer vision technologies have provided unique opportunities for the translation of traditional marker-based kinematic tracking into markerless assessments for clinical practice. We evaluated the feasibility of providing clinical outcome measures from depth-based features of the human body detected using a single video and depth (RGB-D) camera. Our 3D Body Landmark Detection algorithm leverages point-cloud processing techniques to localize and track body landmarks. We evaluated this approach by tracking body movement during commonly assessed motor tasks in a neurological exam (finger tapping, toe tapping, heel tapping, and gait) and calculating the resulting landmark position-based outcomes. The mean accuracy of the 3D Body Landmark Detection algorithm with respect to a marker-based motion capture system was 93.1% across tasks, which was 30% higher than a traditional pose estimation algorithm. These findings provide a foundation for using 3D landmark-based localization and tracking techniques for the assessment of clinical outcomes.

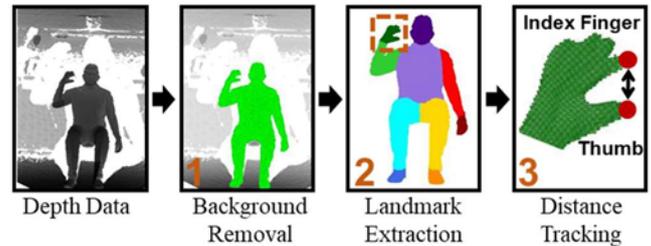

#### Introduction

Motor assessments are an essential part of most clinical examinations. While traditional multi-camera optical motion capture solutions have proven effective in delivering kinematic accuracy during such assessments, they are confined to a research lab and require significant setup. Other single camera efforts to localize features of the body primarily utilize pose estimation algorithms, which have known limitations in computing clinically relevant outcomes (e.g., distance between body segments or locations in space), especially during motor assessments tasks [1, 2]. To overcome these limitations, we designed a 3D Body Landmark Detection algorithm that bypasses the need for pose estimation to obtain clinical outcomes by automatically localizing and tracking body landmarks directly from a single RGB-D camera during standardized motor assessment tasks.

#### Methods

Six healthy participants (3 F, 3 M; 21-30 y.o.) performed the following motor-activities: finger tapping, toe tapping, heel tapping, and gait. All tasks were completed at three different self-selected speeds (>500 cycles per movement). Movements were concurrently recorded with an 8-camera optical motion capture system (Vicon, Oxford, UK) and a single RGB-D camera (Microsoft Kinect Azure). The point-cloud data was processed through a multi-stage algorithm architecture (Figure 1) including: 1) Background Removal using depth-based spatial filters; 2) Landmark Extraction via geodesic path tracking and body segment identification; and 3) Movement Tracking by extrema detection and neighborhood cluster

tracking. Task-relevant clinical outcomes were computed as the peak-to-peak amplitude between relevant landmarks for each activity – index finger and thumb (finger tap); toe/ foot and floor (toe tap and heel tap); and alternate feet (step length and step width during gait). We compared the proposed 3D Body Landmark Detection algorithm with Kinect body tracking software to gauge its outcome accuracy with respect to an established joint estimation-based solution [3].

**Figure 1:** 3D Body Landmark Detection approach for distance tracking, illustrated for a finger tapping task

#### Results and Discussion

The 3D Body Landmark Detection algorithm achieved greater than 90% accuracy (Table 1) across the range of fine-motor and whole-body assessments with respect to gold-standard motion capture recordings. Mean accuracy margins were 30% higher than traditional Kinect pose estimation algorithms.

**Table 1:** Accuracies for the 3D Body Landmark Detection and Kinect pose estimation

Motor Activity	3D Landmark Detection		Kinect Pose Est.	
	Absolute Error (cm)	Relative Accuracy (%)	Absolute Error (cm)	Relative Accuracy (%)
Finger Tap	0.6 ± 0.5	93.1 ± 6.3	6.0 ± 1.4	39.5 ± 15.4
Toe Tap	0.4 ± 0.3	94.3 ± 4.2	3.8 ± 1.6	40.6 ± 14.5
Heel Tap	1.5 ± 1.2	93.1 ± 4.6	6.7 ± 3.0	66.2 ± 15.5
Step Length	3.6 ± 2.9	93.2 ± 5.9	8.5 ± 3.8	84.8 ± 6.4
Step Width	1.7 ± 1.4	91.9 ± 6.1	4.3 ± 3.1	80.9 ± 12.8

#### Conclusions

The 3D Body Landmark Detection algorithm provides a useful alternative to traditional pose estimation methods by directly localizing relevant body landmarks using a single-camera system. This study demonstrates the proof-of-concept feasibility of using markerless movement tracking systems to supplement clinical assessments with quantitative metrics that facilitate objective and evidence-based practice.

### Summary

Femoroacetabular impingement (FAI) is a motion related clinical disorder of the hip represented by symptomatic contact of the hip joint surfaces. Hip mechanics in this population during level walking are inconsistent and question whether more challenged walking is necessary to evaluate the role of mechanics in this disease. The current study examines lower limb neuromuscular activity to better understand hip joint mechanics in individuals with FAI compared to asymptomatic individuals. Effect sizes suggest that individuals with FAI may walk with reduced activation of the knee and hip extensors as well as hip abductors.

### Introduction

FAI is a proliferative musculoskeletal diagnosis in young adults. Although level walking is considered the gold standard for quantifying lower limb muscle activation, reported neuromuscular changes in this population are limited and inconsistent, thus highlighting the need for more challenged walking tasks to better understand hip joint mechanics in individuals with FAI. The purpose of the current study was to investigate neuromuscular activation during challenged walking in individuals with FAI compared to age matched controls.

### Methods

Seven individuals with a clinical diagnosis of FAI (3M/4F) and seven asymptomatic individuals (2M/5F) were recruited to participate. Participants were prepared for surface electromyography (EMG) using a standardized protocol. Surface electrodes were placed bilaterally in a bipolar configuration over the vastus medialis (VM) and lateralis (VL), rectus femoris (RF), medial (MH) and lateral (LH) hamstrings, as well as gluteus maximus (GMax) and medius (GMed). The treadmill walking protocol consisted of level walking and four randomized walking conditions including: 5° and 10° inclines, and 5° and 10° declines. Participants walked for three minutes in each condition, and during the third minute a 20-second data collection was recorded. Maximum voluntary isometric contractions (MVIC) were collected for the knee and hip flexors and extensors, and hip abductors. Surface EMG profiles were amplitude normalized using the maximum amplitude calculated for all corresponding MVIC trials (%MVIC). For asymptomatic participants, the study limb was randomly selected for analysis. Peak activations (%MVIC) during stance and their

mean between group differences were calculated for each condition. Cohen's *d* was calculated using the mean difference between groups for each walking condition divided by the pooled standard deviation and interpreted using cut points including 0.2 (small), 0.5 (moderate), and 0.8 (large).

### Results and Discussion

Moderate to large between group effect sizes for VM ( $d=0.61-1.39$ ) and VL ( $d=0.67-0.88$ ), and small to moderate effect sizes for RF ( $d=0.22-0.52$ ), were observed for all walking conditions. Individuals with FAI consistently walked with lower quadriceps (VM and VL) activation during all conditions (15%-37%MVIC). Between group differences increased two-fold during inclined and declined walking with larger activation increases for asymptomatic individuals. Minimal between group differences were observed for RF (4%-7%MVIC) during all conditions. Small to moderate between group effect sizes were observed for MH ( $d=0.0-0.39$ ) and LH ( $d=0.10-0.57$ ). Although the between group differences for hamstring activation were small (<9%MVIC) for all walking conditions, individuals with FAI consistently walked with higher activation. Their increases in MH and LH activation were larger (12-19%MVIC) during inclined walking conditions compared to asymptomatic individuals (9%MVIC), but both groups had similar decreases in activation (5-7%MVIC) during declined walking. Small to large between group effect sizes were observed for GMax ( $d=0.26-0.73$ ) and GMed ( $d=0.60-0.87$ ) for all walking conditions. Individuals with FAI consistently walked with lower GMax (8%-25%MVIC) and GMed (13%-20%MVIC) activation during all conditions, with larger between group differences observed during inclined walking.

### Conclusions

The present results suggest that neuromuscular activation patterns differ between individuals with FAI and asymptomatic individuals, and between group differences increased during challenged walking. Individuals with FAI may walk with learned strategies to minimize hip joint movement that mirrors hip impingement. Future research to understand these patterns and their relationship with hip joint loading is warranted.

### Summary

Fatigue is a risk factor for musculoskeletal disorders and older adults have been shown to experience more fatigue in everyday life. Motor variability has been shown to mitigate fatigue in repetitive tasks, but the influence of old age is unclear. Young and old adults completed a fatiguing repetitive reaching task while seated. Trunk and upper limb joint angles were computed for the forward reaches of the first (no fatigue: NF) and final (fatigue terminal: FT) minutes. Variability size was quantified by the reach-to-reach standard deviation (SD) of joint angles and variability structure was quantified by uncontrolled manifold outcomes. Old adults had smaller SD in shoulder and wrist angles and less variance parallel to the manifold, but old age did not affect synergy index at NF or FT. Findings suggest that old adults preserved the synergy that stabilized the forward reach motion despite using less motor flexibility.

### Introduction

Fatigue has been identified as a risk factor for musculoskeletal disorders. Fatigue from repetitive movements may be mitigated by motor variability and some studies have shown that older adults have more variable motor patterns in repetitive tasks such as gait [1]. However, how older adults use motor variability to mitigate fatigue in the upper limb is unclear. With fatigue from occupational assembly, old and young adults had different changes in the SD of elbow posture [2], a measurement of the size of variability. Without fatigue, old adults have been reported to have higher [3] or no difference [4] in the synergy amongst the joint elements, a structural component of variability. Investigating the size and structure of motor variability together could provide new insights on control of repetitive reaching. Thus, our purpose was to determine the effects of age and fatigue on the *size* and *structure* of joint angle variability during forward reaching.

### Methods

Healthy young (N = 18, 9 females, 24.4 ± 2.9 years) and old (N = 16, 11 females, 73.5 ± 7.3 years) adults performed a seated repetitive reaching task with the dominant arm between targets placed at 30% and 100% of functional reach, at a frequency of 1 Hz [5]. Perceived exertion (Borg CR-10 scale) was recorded each minute and, after a rating ≥ 8, the participant performed the task for one final minute. Optoelectronic marker data were used to model joint angles across 11 degrees of freedom of the trunk and upper limb for the last 30 seconds of the first and final minutes, defined as the NF and FT conditions. Angles were partitioned into 15 time-normalized (0-100%) forward reaches.

Size of motor variability was measured by the reach-to-reach standard deviation (SD) of individual joint angles. Structure of motor variability was quantified by the uncontrolled manifold that predicted endpoint position from the 11 joint angles.

Measurements were variance not affecting performance ( $V_{UCM}$ , i.e. “good” variability) and variance affecting performance ( $V_{ORT}$ , i.e. “bad” variability), as well as the synergy index ( $\Delta V_z$ ). Means were calculated for the early (0-10%), middle (40-60%), and late (90-100%) phases of the reach for each condition, then compared in Age\*Condition\*Phase general estimating equations that covaried for sex and body mass index.

### Main Results

**Size of reach-to-reach variability:** Generally, SD of trunk, shoulder, and wrist angles increased from NF to FT. SD of shoulder abduction/adduction, shoulder flexion/extension, wrist pronation/supination, and wrist flexion/extension in the early phase were larger in young than in old adults.

**Structure of reach-to-reach variability:** No age effects were seen in  $\Delta V_z$  (young: 0.27-0.54; old: 0.45-0.65).  $V_{UCM}$  increased from NF to FT at the late phase in both age groups, and  $V_{UCM}$  was larger in young than in old adults at the early phase (interaction effect:  $p < 0.001$ ; Figure 1).

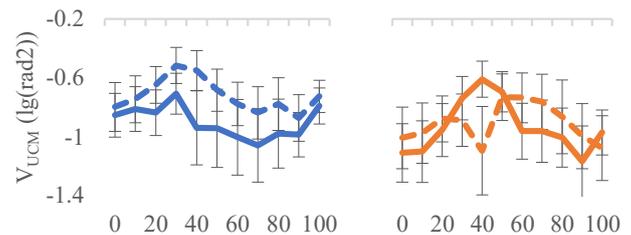

Figure 1. Mean forward reach  $V_{UCM}$  of young (left) and old (right) adults at no fatigue (solid line) and fatigue time (dashed line).

### Conclusions

In seated repetitive forward reaching, fatigue similarly affected the size and structure of variability of young and old adults. While old adults had less motor flexibility in the early phase of reaching than young adults, due to greater variability in shoulder and wrist angle, old adults still produced a similar motor synergy that stabilized endpoint motion.

### Summary

The mirror neuron system integrates sensory stimuli into our own motor control. Initially, mirror behavior is known in human and monkey motor neurons when seeing or hearing another individual's actions. An open question is how this mirror behavior relates to one's own kinaesthetic input. Here we present data showing that motor evoked potentials (MEP) by transcranial magnetic stimulation (TMS) are the same for passive viewing of other's wrist movement and passive movements of one's own wrist. The kinaesthetic influence on the motor threshold was even slightly stronger than the visual stimulation, whereas combined visual and kinaesthetic stimulation further increased the MEPs. We thus provide, for the first time, evidence for the integration of passive kinaesthetic- and visual-sensory stimuli.

### Introduction

Cells of the mirror neuron system have originally been described as motor neurons from the premotor cortex that also respond if motor action is seen while the individual is passive [1], but such mirror activity has later been found for the entire frontal cortex [2]. In humans, mirror neuron activity is typically studied using Motor Evoked Potentials (MEPs) [3]. MEPs can be evoked by placing an electromagnetic coil over the skull which directs a brief, focal electromagnetic pulse into the cortex, known as Transcranial Magnetic Stimulation (TMS). When placed over the motor cortex, such a magnetic pulse may evoke brief, local, involuntary muscle contractions. When a wrist movement is seen by a passive subject, even subthreshold TMS pulses over the hand region of the contralateral motor cortex can evoke an MEP [2].

Since mirror neurons are motor neurons [1], we hypothesized that kinaesthetic sensory information should also affect the mirror neurons. However, it is not known if this is so. Moreover, it is not known if kinaesthetic sensory information from passive movements can activate the motor system in the way that visually perceived motor actions do.

The goal of the present experiment was to find out how the seeing of passive wrist movement and the kinaesthetic sensory information from the passively moved wrist relate, by implementing an MEP paradigm [4].

### Methods

Twenty healthy participants with a mean age of 28.3 years ( $\pm 8.3$ ) with no history of neurological disease or upper limb impairment were included.

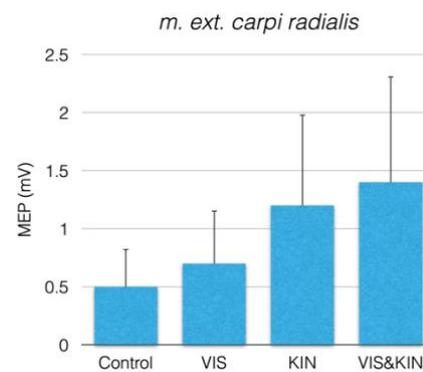

60 stimulations were applied for the three conditions in random order: KIN: the kinaesthetic stimulus was applied by a passive, motor controlled, wrist extension movement, VIS: visual presentation of an animated wrist extension movement, and VIS&KIN: the synchronously applied

visual and kinaesthetic stimuli. For the control condition (CC) 20 Stimulations were applied. Subjects could not see their arm, were requested to keep their wrist relaxed all the time.

For TMS a magnetic stimulator R30 MagPro with MagOption (MagVenture, Skovlunde Denmark) and a parabolic coil type MMC-140 were used. For recording of the EMG, two electrodes (surface area of  $3 \text{ mm}^2$ ) were placed with a distance of 1 cm longitudinally over the belly of the *extensor carpi radialis* muscle.

### Results and Discussion

All differences were statistically significant (Fig. 1). Both VIS and KIN stimulation resulted in stronger MEPs than the control condition. The combined condition VIS&KIN showed an even stronger MEP, but less than the sum of VIS and KIN.

**Figure 1:** Evoked potentials in the wrist extensor muscle.

The kinaesthetic information from passive wrist extension lowers the motor threshold for wrist extension. This result shows, that on a cortical level, the motor system does not oppose passive movement, but rather releases it.

This result is fully consistent with the known mirror neuron mechanism. The low level of summation indicates, that at least some of the VIS and KIN sensorimotor integration depends on a shared pool of motor neurons.

### Conclusions

Our results support the implicit assumption of the mirror neuron theory, that the motor system processes afferent kinaesthetic information and sensory information about others' actions in a coherent manner [4].

### Summary

Our study addresses the control of individual finger movements in humans and the associated brain response. We investigated this by simultaneous recordings of finger kinematics and functional Magnetic Resonance Imaging (fMRI) in 26 asymptomatic individuals. Preliminary results show that finger independence differed between fingers, and that there were associated, overlapping finger movement representations primarily found in the contralateral sensorimotor areas of the brain.

### Introduction

Digits are represented as a fine-grain somatotopy in the primary somatosensory cortex [1] but it is not known to which extent finger movement control can be broken down to the digit specific level. The current study aims to examine the underlying neural correlates of individual finger movements. Specifically, we want to associate kinematic indices of finger movement independence [2], with brain activity estimated with fMRI in healthy individuals.

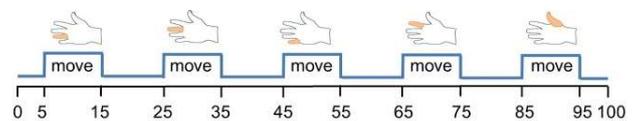

### Methods

Twenty-six right-handed participants (Mean age 62 years) performed cyclic flexion-extension movements of one finger at a time while keeping the other fingers still (Figure 1), lying in a 3T MR scanner. The blood-oxygen-level-dependent imaging technique (fMRI) quantified brain response while four 3D optical special non-magnetic cameras (Qualisys AB, Gothenburg) simultaneously recorded the positions of ten reflective markers affixed to each finger. Test instructions were presented on a screen via a tilted mirror.

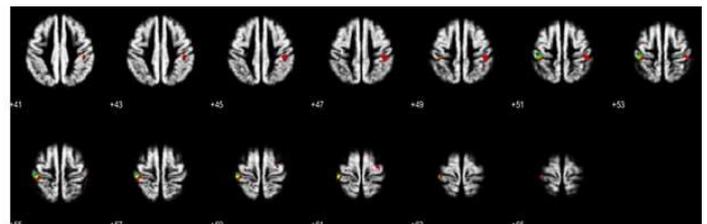

Movements of the dominant hand's fingers were analyzed. Motion capture data were exported to Visual3D software and filtered with a 6 Hz low-pass filter. Automated scripts identified the start and stop of each flexion-extension. An Individuation Index (II) computed each finger's movement independence by the ratio of the finger's normalized movement in relation to the others; "1" represented excellent finger independence and "0" represented no independence [2]. Brain response associated to each finger's movement was analyzed, both in comparison to rest and in comparison to the thumb movement using statistical parametric mapping (SPM12, Wellcome Trust Centre for Neuroimaging).

### Results and Discussion

The thumb had the highest II ( $0.98 \pm 0.01$ ) followed by the index finger ( $0.95 \pm 0.02$ ), the little finger ( $0.91 \pm 0.05$ ), the ring finger ( $0.91 \pm 0.04$ ) and the middle finger ( $0.90 \pm 0.03$ ), in line with previous studies [2]. Preliminary results reveal differences in the associated brain activation (Figure 3), with overlapping regions primarily found in the contralateral sensorimotor areas (Fig 3).

**Figure 1:** A block design was used where the finger either moved or were held still during a period of 10 seconds.

**Figure 3:** Statistical brain maps (familywise corrected,  $p=0.05$ , voxel threshold 15) describing overlapping regions for the fingers when contrasted against the thumb (Index finger: blue, long finger: green, Ring finger: yellow, Little finger: red)

### Conclusions

The movement independence was lower in all fingers compared to the thumb, and the ranking seems to also be corresponding to activation of different but yet overlapping somatosensory areas of the brain. Further analysis is in progress.

## **Synergic control of individual muscles and agonist-antagonist muscle pairs**

Mark L. Latash

(Pennsylvania State University, University Park, PA 16802)

According to the original concept of synergy introduced by Nikolai Bernstein, numerous muscles, which take part in natural movements, are united into stable groups, and the group involvement co-varies to ensure dynamical stability of salient performance variables. Recently, we have extended this concept to within-a-muscle recruitment patterns of motor units (MUs). During accurate cyclical force production, MUs in extrinsic hand muscles (flexor digitorum superficialis, FDS, and extensor digitorum communis, EDC) form stable groups – MU-modes. Within-a-muscle analysis of MU-mode variance across force cycles has shown much larger variance within the space that leads to no force change (uncontrolled manifold, UCM) compared to the orthogonal to the UCM space (ORT). These signatures of force-stabilizing synergies were present in spaces of the MU-modes defined for FDS and for EDC separately. Analysis of MUs combined over FDS and EDC has revealed two MU-modes corresponding to the reciprocal and coactivation commands as introduced within the theory of control with spatial referent coordinates – a major support for the theory. The existence of MU-based synergies suggests an important role of segmental reflex mechanisms in synergic control of movements.

# Automated Analysis of Medial Gastrocnemius Muscle-Tendon Junction Displacements in Healthy Young Adults Using Deep Neural Networks

Rebecca L. Krupenevich, Callum J. Funk, Jason R. Franz

<sup>1</sup>Joint Department of Biomedical Engineering, UNC Chapel Hill and NC State University, Chapel Hill, NC  
Email: rkrup@email.unc.edu

## Summary

We show that deep neural networks (DNNs) created with open-source software are capable of accurately tracking muscle-tendon junction (MTJ) positions in cine B-mode ultrasound images in tasks spanning controlled loading during isolated contractions to physiological loading during treadmill walking.

## Introduction

Direct measurement of MTJ position is important for understanding dynamic tendon behavior and muscle-tendon interaction in healthy and pathological populations [1]. Obtaining MTJ position during functional activities is often accomplished by manually labeling the MTJ in cine B-mode ultrasound images, a laborious and time-consuming process. Advancements in deep learning have facilitated the availability of open-source software for automated video tracking [2]. However, these tools were originally intended for animal pose estimation and have not been widely applied to ultrasound images. The purpose of this paper was to evaluate the efficacy of DNNs to track medial gastrocnemius MTJ position in cine B-mode ultrasound images from isolated contractions and treadmill walking.

## Methods

Cine B-mode ultrasound images of the medial gastrocnemius MTJ were collected from 15 subjects (6M/9F, 23 yr, 71.9 kg, 1.8 m) during treadmill walking at 1.25 m/s and during maximal voluntary isometric plantarflexor contractions (MVCs). Subjects were randomly shuffled into five combinations of 12 training and 3 test subjects - each combination was trained using 480 manually labeled images collected during walking (40 per training subject) - which we used to predict MTJ position in images from test subjects during walking (novel subject) and MVCs (novel condition).

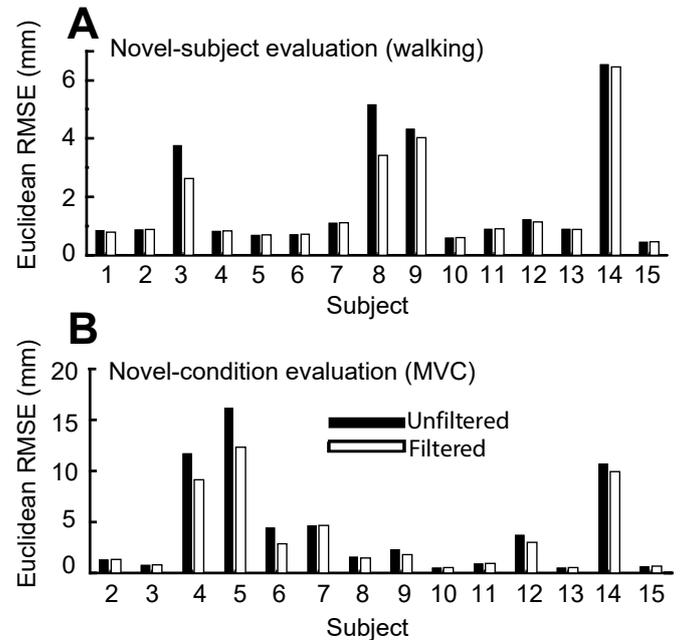

## Results and Discussion

Overall root mean square error (RMSE) was 2.72 mm and 6.24 mm between manually labeled and predicted MTJ position in novel-subject and novel-condition evaluations, respectively – comparable to previous DNNs trained with larger training sets [3]. A modified median filter reduced overall RMSE to 2.37 mm and 5.05 mm in the novel-subject and novel-condition evaluations, respectively.

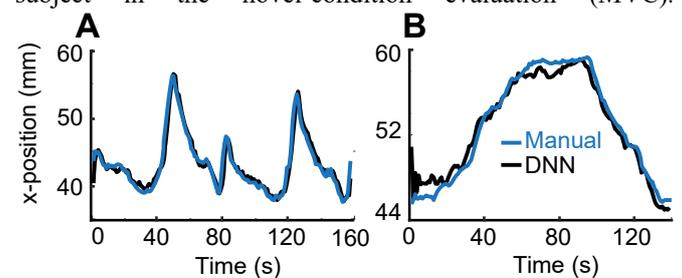

## Conclusions

Our results support the use of open-source software for creating DNNs to reliably track MTJ positions in B-mode ultrasound images. We believe this approach to MTJ

position tracking is an accessible and time-saving solution, with broad applications for many fields, such as rehabilitation or clinical diagnostics.

**Figure 1:** Unfiltered (black) and filtered (white) root mean square error (RMSE) for A) each individual subject in the novel-subject evaluation (walking), and B) each individual subject in the novel-condition evaluation (MVC).

**Figure 2:** Manually labeled (blue) and predicted (black) MTJ positions for one representative subject during A) walking, and B) MVC.

Email: Lydia.willemse@fontys.nl

## Summary

To determine the intra-assessor reliability of ultrasound measurements of intrinsic foot muscles' size in older and younger adults, we used a portable tablet-based device. Measurement errors relative to the mean muscle size did not exceed 6.3% in older adults. The intrinsic foot muscles' size measurements are sufficiently reliable to be used in the assessment of force generating capacity of these muscles in older adults.

## Introduction

Intrinsic foot muscles have an essential role in foot function during walking. The size of the foot's intrinsic muscles serves as a measure of the strength and has been associated with balance [1] and gait biomechanics [2] in healthy younger adults. In order to study foot function in older adults, the reliability of ultrasound measurements of intrinsic foot muscles' size in this specific population needs to be investigated. The purpose of the study was to determine the intra-assessor reliability of ultrasound measurements of intrinsic foot muscles' size in older and younger adults.

## Methods

A single assessor test-retest study was performed in 10 older (5 male, 5 female, 74.5 ± 5.6 years) and 10 younger adults (4 male, 6 female, 21.9 ± 1.8 years) not presented with conditions that compromise gait. Ultrasound images of abductor hallucis (AbH), flexor digitorum brevis (FDB), quadratus plantae (QP), flexor hallucis brevis (FHB) and abductor digiti minimi (AbDM) were captured on two separate occasions (1-7 days apart) using a portable tablet-based Philips Lumify ultrasound device.

The scan protocol [3] was carried out by a single operator. Three longitudinal and transverse (only for AbH and FDB) images per muscle and for each occasion were post-processed using Image J software to obtain the mean thickness and cross-sectional area (CSA). The intraclass correlation coefficient (ICC; 3,3; absolute agreement) and standard error of measurement (SEM) were calculated.

## Results and Discussion

For all, but the FDB thickness, the SEM was smaller for younger adults (Table 1). This may be explained by the increased intramuscular adipose and connective tissue with advancing age that is detrimental for image quality. Even

though this difference, the SEM relative to the mean did not exceed 6.3% for older adults. This SEM is smaller compared to other foot muscle strength measures, such as those obtained with dynamometry [4], and also smaller than the effect that is expected from a strengthening exercise intervention [4].

The SEM of the CSA is slightly smaller than the SEM of the thickness of the same muscles in the older adults. Considering that the CSA is a more representative measure of the force generating capacity of a muscle, we recommend to use the CSA to measure the size of AbH and FDB in this population.

**Table 1:** Measurement properties of muscles' size measures.

Muscle	Size measure	Older		Younger	
		ICC	SEM (%)	ICC	SEM (%)
AbH	CSA	0.97	9.86 (4.8)	0.98	8.04 (4.2)
	thickness	0.95	0.56 (5.4)	0.99	0.18 (1.6)
FDB	CSA	0.98	11.0 (4.4)	0.98	7.57 (3.6)
	thickness	0.96	0.52 (5.0)	0.87	0.81 (7.6)
QP	thickness	0.94	0.34 (3.8)	0.94	0.26 (2.6)
FHB	thickness	0.79	0.84 (6.3)	0.93	0.57 (4.0)
AbDM	thickness	0.89	0.49 (5.3)	0.96	0.41 (3.7)

AbH: abductor hallucis, FDB: flexor digitorum brevis, QP: quadratus plantae, FHB: flexor hallucis brevis, AbDM: abductor digiti minimi, CSA: cross-sectional area, ICC: intraclass correlation coefficient, SEM: standard error of measurement.

## Conclusions

Based on our findings, we conclude that the size of intrinsic foot muscles can be reliably assessed in older adults by the same assessor using a portable ultrasound system and hence can be used to investigate foot function in this population.

### Summary

Hypomimia is one of the clinical hallmarks of Parkinson's disease (PD). Patients experiencing this symptom have a limited facial expression that could lead to a reduction of their social well-being. We conducted a preliminary study on ten PD patients who underwent a specific rehabilitation treatment and quantified its effects exploiting a face tracking algorithm.

### Introduction

PD is a progressive disease that mainly affects the movement. The most frequent symptoms are tremor, rigidity, and bradykinesia, that have been widely investigated in the upper and lower limbs. However, they can also affect facial muscles causing hypomimia: a reduced facial expression both in spontaneous and voluntary facial movements. Hypomimia can lead to a significant reduction of the patient's quality of life who may experience social interaction difficulties. Limited data are available on validated treatments and on the evaluation of their possible effects [1]. The aim of our study is to quantitatively assess the effects of a hypomimia treatment in PD patients comparing the pre- and post-treatment conditions. We exploited a face tracking algorithm based on the Facial Action Coding System (FACS) [2,3].

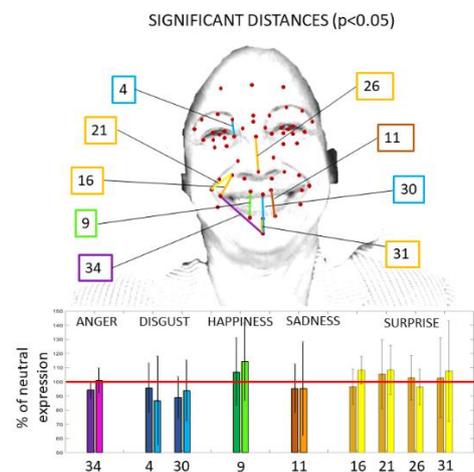

### Methods

Ten PD patients (mean(±SD) age: 68.4(±8.46) years) were analyzed. Patients underwent a hypomimia rehabilitation treatment consisting of 9 sessions of 60 minutes each, in a time window of two months. Data acquisition took place before (T<sub>0</sub>) and after the treatment (T<sub>1</sub>). MDS-UPDRS values were collected (Table 1). Moreover, frontal face videos of the subjects were recorded while they were instructed by an operator to perform the face expressions described in [3]. A GoPro Hero 3 camera (1920x1080 pixels, 30 fps) placed at eye level, at 1.36 m from the patient seated with a white background behind was used. Videos were segmented into 4 frames per each emotion; using an ad-hoc set of 56 features tracked in the 2D-image space (*TrackOnField*, self-developed software, *BBSof S.r.l.*) [4], 35 distances were calculated

(Fig1). Each distance was normalized on the corresponding one in the neutral expression. The two conditions were compared through Wilcoxon signed-rank test (p<0.05).

### Results and Discussion

Along with the improvements in the MDS-UPDRS scale values (Table 1), results showed an enhancement in facial mobility at T<sub>1</sub> (Figure 1).

**Figure 1:** Statistically significant distances per emotion. Darker colors refer to T<sub>0</sub>. The red line represents the neutral expression.

### Conclusions

Preliminary results on the quantification of the treatment outcomes are encouraging. This method can be used in future investigations increasing the dataset and studying different rehabilitation treatments.

Email: williamsd37@cardiff.ac.uk

### Summary

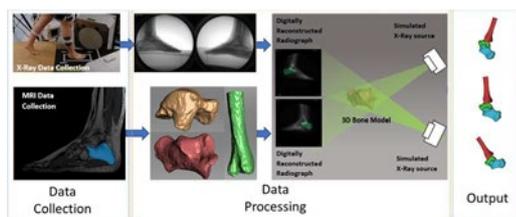

It is an important and technical challenge to measure the in-vivo kinematics to evaluate the biomechanical and functional effects of ankle injury. To fully understand these difference healthy comparator data is needed. This pilot study develops imaging protocols to measure the direct bone movements of the tibia and talus using biplane video X-ray and MRI. The pilot results demonstrated the differences between the activities and provided suggestions on stratification of future healthy cohorts.

### Introduction

To be able to evaluate the biomechanical and functional effects of ankle injury and disease, and the interventions used to treat them, it is first necessary to characterize ankle kinematics in a healthy population. Due to the anatomical complexity of the ankle, it is difficult to accurately measure the Tibiotalar and Subtalar joint angles using traditional marker-based motion capture techniques. Biplane Video X-ray (BVX) is an imaging technique that allows direct measurement of individual bones using high-speed, dynamic X-rays. It has been suggested in a recent review that there is a lack of research on healthy ankle joint kinematics and different activities need to be investigated [1]. This pilot study is focused on developing an in-vivo protocol for the ankle joint looking initially at the tibiotalar joint for two different activities of daily living.

### Methods

A custom-built raised walkway was manufactured to position the foot and ankle inside the field of view of the BVX system.

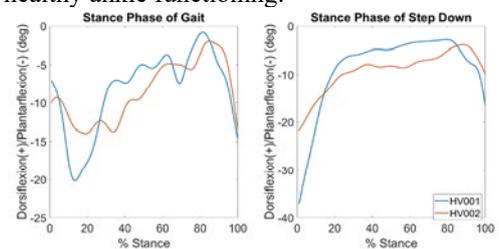

**Figure 1:** Data collection and processing pipeline

Two healthy volunteers performed five gait and step-down trials while capturing Biplane Video X-Ray (125Hz, 1.25ms pulse width, 80kVp and 160 mA). Participants underwent MR imaging (Magnetom 3T Prisma, Siemens) which were manually segmented into 3D bone models (Simpleware Scan IP, Synopsis). Anatomical coordinate systems were applied to the 3D bone models using the centroid and inertial axes of each bone. Bone position and orientation for the Talus and Tibia were calculated by manual matching of 3D Bone models

to X-Rays (DSX Suite, C-Motion, Inc.) (Fig 1). Kinematics were calculated using MATLAB (MathWorks, Inc. USA).

### Results and Discussion

For this pilot study it was found that for the two activities of daily living there was a larger range of motion (ROM) for the sagittal plane rotations (Fig. 2) for step down (26.1°) compared with gait (16.2°) at the tibiotalar joint. For frontal and transverse plane rotations the ROM were found to be larger for gait (frontal: 13.9°, transverse: 9.5°) when compared with step down (frontal: 11.0°, transverse: 6.5°). When comparing the two volunteers it was found that they performed varying movement strategies for the different activities. For gait it was found that HV002 had reduced plantarflexion during heel strike and ROM during stance compared with HV001 (Fig. 2). For step down, HV001 used a forefoot strike during step down whereas HV002 used a midfoot strike strategy to step down. This is shown in Fig. 2 by the reduced plantar flexion at initial contact of step down. These results suggest that for future data collection it may be necessary to stratify by movement strategy for different activities of daily living to fully understand the variation within healthy ankle functioning.

**Figure 2:** Sagittal plane Tibiotalar joint angles during gait and step down

### Conclusions

The developed protocol successfully calculated the in-vivo kinematics of the tibiotalar joint for different dynamic activities of daily living. These pilot results show the varying kinematics between two different activities of daily living and highlight the need for a larger cohort study. Future work would look to expand the analysis to the other joints in the ankle complex and investigate further activities of daily living.

### Summary

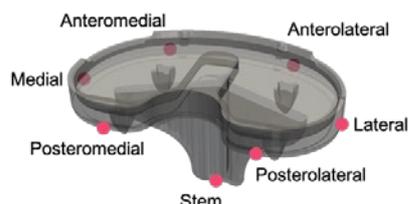

This study aims to investigate cementless total knee replacement (TKR) implant fixation using radiostereometric analysis (RSA), and to study the corresponding bone-implant interfaces for bone ingrowth using modified magnetic resonance imaging (MRI). Early results show a potential relationship between the amount of migration and the type of bone-implant interface.

### Introduction

Modern cementless TKR implants have porous metal surfaces that allow for bone ingrowth to create a biological fixation mechanism. The gold standard for investigating implant fixation is RSA, which has previously been used to study cementless TKR [1]. Modified MRI techniques have been developed to analyze the bone-implant interface and classify an implant as loose if there is poor bone integration. However, there is yet to be a study that uses both modalities to determine if there is a relationship between implant fixation and the type of bone-implant interface. Therefore, the objective of this study is to investigate cementless TKR implant fixation using RSA, and to study the corresponding bone-implant interfaces for bone ingrowth using modified MRI.

### Methods

Thirty patients will be recruited and implanted with cementless titanium tibial components and cobalt-chromium femoral components. Supine RSA and MRI exams will be performed at a baseline of one day after TKR surgery and again at 2-weeks, 6-weeks, 3-months, and 6-months postoperatively. Additional standing weight-bearing RSA exams will be done at all non-baseline timepoints. Supine RSA is used to measure implant migration at different fictive points (Figure 1) on the tibial component relative to bone over time. Standing RSA exams are compared to their supine counterparts to determine inducible displacement, a measure of how much an implant shifts in weight-bearing conditions.

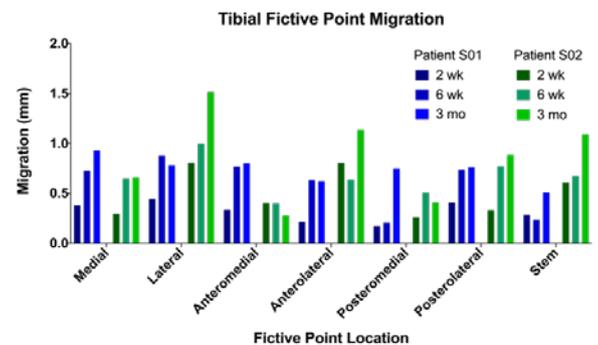

**Figure 1:** Location of fictive points on the tibial component.

MRI is performed using a 3T clinical scanner and the MAVRIC metal artifact suppression sequence, from which the bone-implant interface is classified as: normal, fibrous, fluid, or osteolytic and the percent contact of bone with the porous metal implant surface is assessed. Implants are then scored as either loose or not loose.

### Results and Discussion

Two patients have been recruited at time of submission and data has been collected up to 3-months. Figure 2 displays the fictive point migration of the tibial component for both patients. For Patient S01, the maximum inducible displacement was 0.61 mm at 2-weeks (posteromedial), 0.67 mm at 6-weeks (medial), and 1.06 mm at 3-months (lateral). For Patient S02, the maximum inducible displacement was 0.50 mm at 2-weeks (stem), 1.75 mm at 6-weeks (posteromedial), and 0.93 mm at 3-months (posteromedial). MR images at all timepoints revealed >66% contact of bone with the porous implant surfaces. Patient S01 had normal bone-implant interfaces in all regions of the tibial component. Patient S02 had fibrous tissue in the anteromedial and anterolateral regions at Day 1 and 2-weeks, but these regions scored normal at 6-weeks and 3-months. All other bone-implant interfaces were normal. Both patients' implants were scored as not loose.

**Figure 2:** Migration of each fictive point on the tibial component for Patient S01 and S02 at 2-weeks (2 wk), 6-weeks (6 wk), and 3-months (3 mo).

### Conclusions

Early results show a potential relationship between the amount of migration and the type of bone-implant interface, as a high amount of migration was seen at fictive points in regions where a fibrous membrane interface was located.

## Force transmission via intertendinous linkages of the m. flexor digitorum profundus

G. Geusebroek<sup>1</sup>, G.C. Baan<sup>1</sup>, H.E.J. Veeger<sup>1,2</sup>, H. Maas<sup>1</sup>

<sup>1</sup>Dept. of Human Movement Sciences, Vrije Universiteit, Amsterdam

<sup>2</sup>Dept. of Biomechanical Engineering, TU Delft

Email: [g.m.geusebroek@vu.nl](mailto:g.m.geusebroek@vu.nl)

### Summary

Force transmission via intertendinous linkages of the extrinsic finger flexors has been proposed as one of the factors causing limited independent finger movement. We assessed force transmission via linkages between the tendons of the flexor digitorum profundus (FDP) in fresh frozen cadaver hands by exerting force on the tendon of one finger and measuring the flexion force exerted by the other fingers. Our results show that intertendinous linkages of the FDP transmit force to neighboring fingers and that the extent of such force transmission increases upon flexion of the target finger (TF).

### Introduction

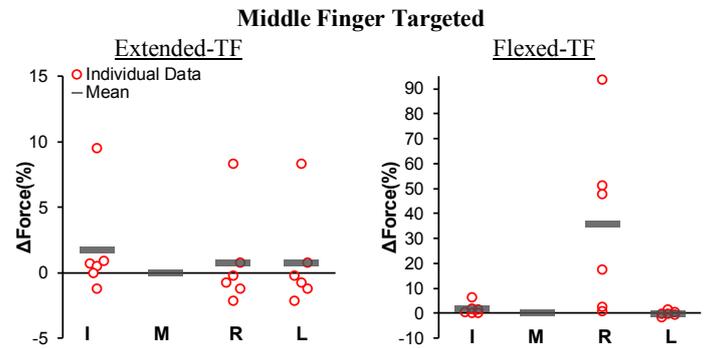

The independent movement of fingers is limited [1]. Unintended movement or force production of fingers is termed enslavement [2]. Besides neural factors, mechanical coupling between finger flexor tendons via intertendinous tissue may cause enslavement [3], but this has not been investigated. We assessed the effects of finger position on force transmission between FDP tendons via mechanical linkages.

### Methods

In six fresh-frozen cadavers, lower arms were amputated, the volar skin was removed until the carpal tunnel, and the myotendinous junctions of the FDP were severed. The arm was secured to a frame with the fingers pointing upward and the wrist fixed at  $\sim 20^\circ$  dorsiflexion. The dorsal aspect of each proximal phalangeal bone of the fingers was connected to force transducers to measure flexion force. Each non-targeted finger (NTF) tendon was loaded with a weight of 3N. Then the TF tendon was loaded with 10N. Flexion force of each finger was measured before and after loading the TF tendon and the difference was calculated ( $\Delta$ Force). Each of the four fingers was tested with the TF extended and flexed in  $\sim 90^\circ$ .  $\Delta$ Force exerted at each NTF was expressed as a percentage of the total flexion force exerted at all fingers.

### Results and Discussion

For all fingers, applying a load on the TF tendon resulted in changes of force exerted at the adjacent NTFs (Table 1).  $\Delta$ Force was higher for fingers adjacent to the TF than for fingers not adjacent to the TF.  $\Delta$ Force of adjacent NTFs increased upon TF flexion, ranging from 18 to 58%, except for the index finger when the middle finger was targeted (Figure 1).

**Figure 1:**  $\Delta$ Force(%) exerted by the NTF of each hand when the middle finger(M) was the TF; tested in extended and flexed position.

Results indicate that the linkages between the FDP tendons do transmit force when pulled on only one of the tendons and that force transmission increases upon TF flexion. Thus, intertendinous linkages of the FDP do contribute to finger enslavement, especially when one finger is moved relative to the other fingers. Intertendinous force transmission should be taken into account in the design of musculoskeletal models of the hand.

## Monitoring Development in Children using Hand function

Vasiliki Vardakastani<sup>1</sup>, Oluwalogbon O. Akinola<sup>1</sup>, Angela E. Kedgley<sup>1</sup>  
<sup>1</sup>Department of Bioengineering, Imperial College London, London, UK

### Summary

This study aims to investigate the effectiveness of different metrics of hand function as a valid and reliable measure of children development. Four tests were used to acquire strength and dexterity measurements of a group of 184 children [range between 5-18 years old]. Our findings show that grip strength and the box and block dexterity tests are appropriate to assess children development.

### Introduction

There are a number of clinical tools and assessment tests used to evaluate development in children. Object manipulation is one of the standard metrics for evaluating mental development. Hand function also can be assessed objectively by measuring strength and dexterity. However, there is currently little evidence of the effectiveness of these tests in monitoring developmental changes in children. The aim of this study is to investigate whether specific metrics of hand function can be better correlated with child development and to show whether age can be expressed as a function of such measurements.

### Methods

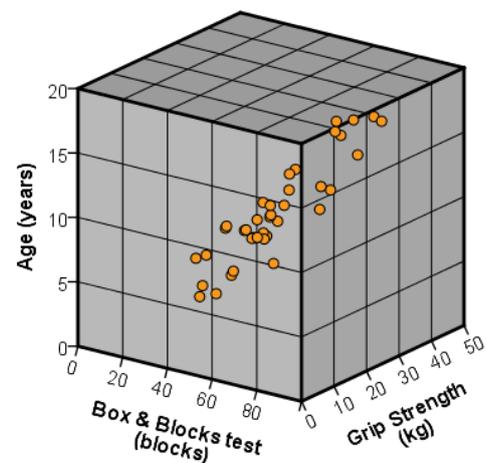

A group of 184 children (100 female, range between [5-18] years old) were recruited for this study. Demographic information about their age, height, weight and hand dominance was collected. Four tests were used to assess the manual strength and dexterity of the participants: the box and block (BBT) and the functional dexterity (FDT) tests and the maximum grip and lateral pinch strength tests. Each participant was randomly assigned to one dexterity and one strength test and they were asked to perform all tests with their dominant hand. For the BBT, the participant was asked to transfer as many blocks as they could in 60 seconds. For the FDT, the participant was asked to turn over all 16 pegs on the board as quickly as possible. Grip and lateral pinch strength were measured using a Jamar dynamometer G200 and a pinch meter P200 (Biometrics Ltd, Newport, UK), respectively. A multiple regression analysis was performed between the test results and the demographic parameters. To avoid overfitting, the models presented below were generated using only parameters with significant effect on the regression.

### Results and Discussion

From the four tests investigated in this cohort, only the results of grip and BBT showed large association (Pearson Correlation Coefficient > 0.5) with development parameters age (0.874 for grip, 0.719 for BBT), height (0.858 for grip,

0.612 for BBT) and weight (0.856 for grip). Grip strength showed significant correlations with both dexterity tests ( $p = 0.001$  for BBT and  $p = 0.002$  for FDT). A linear regression was able to express 63.2% of the variance of the age with respect to grip strength ( $R^2=0.632$ ). However, a second linear regression where both grip and BBT results were used (Figure 1) expressed 78.6% of the age variance within our group ( $R^2=0.786$ ). Both factors had a significant contribution to the regression with a final equation:

$$\text{Age} = 0.175 \cdot \text{Grip strength} + 0.136 \cdot (\text{Box and Block test}) - 0.594$$

**Figure 1:** Linear regression between age and grip strength and box and blocks test results.

Our results show that the grip strength and BBT dexterity tests are appropriate for monitoring development. While grip strength alone was able to express a large proportion of the variance within the group, the regression including both grip and BBT presents a more spherical expression of the functional changes during a child's development. Both tests are non-invasive and standardized and they have been previously used to assess hand function in children with myopathy and cerebral palsy [1,2].

### Conclusions

The application of these findings can be extended further to healthy cohorts as a sufficient and non-invasive metric to evaluate development in children.

## A new radiographic index for early diagnosis of perilunate injuries

Pinto FNZ<sup>1</sup>, Fernandes CH<sup>1</sup>, Meirelles LM<sup>1</sup>, Ejnisman B<sup>1</sup>, Cohen M<sup>1</sup>, Faloppa F<sup>1</sup>

<sup>1</sup>Department of Orthopedic Surgery, Universidade Federal de São Paulo, São Paulo, Brazil

Email: drfernandozambone@gmail.com

### Summary

The objective of this study was to develop radiographic indexes that help the diagnostic confirmation of perilunate injuries. A descriptive, cross-sectional, retrospective study was carried out with the objective of finding radiographic indexes that facilitate the diagnosis of perilunate injuries. Eighty lateral wrist radiographs were evaluated, divided into 20 radiographs without changes and 20 radiographs with the following diagnosis: scapholunate ligament injury, transscaphoid fracture dislocation, lunate dislocation. Bone points were selected that originated lines to evaluate the anatomical relationship between the carpal bones.

So the radiolunate index was calculated and a statistical analysis were made.

### Introduction

Perilunate injuries can present very subtle changes in the initial imaging exams, which go unnoticed in emergency care [1,2,3]. Despite its severity, 25% of patients do not have their diagnosis identified in the initial assessment [4]

### Methods

This index was created to assess the position of the lunate bone in relation to distal surface of the radius. For this purpose lateral radiographs of the wrist were evaluated. Despite the possibility of difficult identification of the carpal bones, we chose intracarpal landmarks. The D line connects the dorsal edge of the distal surface of the radius to the dorsal edge of the distal surface of lunate. The P line connects the volar edge of the distal surface of the radius to the volar edge of the distal surface of the lunate. By measuring the length of lines D and P, we created the radiolunate index, that was calculated from the P/D ratio (figure1).

**Figure 1:** Production of the lines P and D, which measurements allows the calculation of the radiolunate index (RLI).

The Kruskal-Wallis test, Mann-Whitney test and graphical analysis using box-plot was used in the statistical analysis. The result of each comparison presents a p, being defined as a significance value of 0.05 (5%).

### Results and Discussion

The radio-lunate index (RLI) on the radiographs of the wrists without changes ranged from  $1,136 \pm 0,172$ . In the radiographs with diagnosis of scapholunate ligament injury, the index ranged from  $1,907 \pm 0,428$ , in the radiographs with diagnosis of transscapho-lunate fracture dislocation, it varied from  $0,743 \pm 0,099$  and in the radiographs with diagnosis of lunate dislocation it ranged from  $0,47 \pm 0,086$ . The p-value for RLI was less than 0.001.

	Group	Interval
IRS	Without changes	$1,136 \pm 0,172$
	Scapholunate ligament injury	$1,907 \pm 0,428$
	Transscaphoid fracture dislocation	$0,743 \pm 0,099$
	Lunate dislocation	$0,47 \pm 0,086$

**Table 1:** Radiolunate index range for different diagnoses

When comparing the ratio of the RLI of the radiographs of the wrist without changes with the ratio of the RLI of the radiographs with perilunate injuries, there was a statistically significant difference between the groups.

So the proposed method demonstrated an easy and quick way to facilitate the radiographic analysis of perilunate injuries, which can provide a faster diagnosis and may reduce misdiagnosis in these injuries.

In the next studies we intend to evaluate intraobserver and interobserver variability, in order to determine the accuracy of this method.

### Conclusions

The application of the IRS demonstrated that there is a change in the position of the lunate in relation to the articular surface of the radius in perilunate injuries. Thus, it can be applied clinically to aid in the diagnosis of perilunate injuries.

## Recent advances in wrist biomechanics

Veronique Feipel, Université Libre de Bruxelles, Brussels, Belgium

With the advances of technology and methodologies used in Biomechanics, our understanding of wrist biomechanics has progressed over the past decades and has led to improved patient care.

The techniques used today to measure global and segmental wrist kinematics *in vivo* will be discussed and obtained results will be reviewed in a practical (clinical) context. State of the art knowledge on load transfer across the wrist joints suggests the high relevance of musculoskeletal modelling. In this context, the biomechanics of wrist muscles and ligaments will be presented. The role of these structures on wrist stability will be highlighted and linked to current concepts on neural control and cognitive factors.

Even if the main accent of the lecture will concern recent advances in *in vivo* wrist biomechanics, we will remember that our current understanding of this topic was shaped by the work of pioneers many decades ago. We will also summarize the contribution of *in vitro* and *in silico* studies to the fundamental and applied knowledge of wrist biomechanics.

# Knee Implant Wear Predictions are Altered by Including Fluoroscopy-Measured Kinematics in the Boundary Conditions

<sup>2</sup>Laboratory for Mechanical Systems Engineering, Empa, Dübendorf, Switzerland

Email: [michael.dreyer@hest.ethz.ch](mailto:michael.dreyer@hest.ethz.ch)

## Summary

The CAMS Knee datasets provide novel in vivo measurements of knee implant forces and kinematics during walking. We simulated the wear on knee implants using these datasets and the ISO standard wear testing boundary conditions (BCs). The choice of force or displacement BCs impacted wear location and magnitude. Wear produced by the ISO standard force BCs was similar to that produced by applying in vivo forces, but the application of in vivo kinematics yielded more posterior wear.

## Introduction

Wear of the polyethylene (PE) inlay limits the longevity of knee implants. Currently, implant wear is evaluated using the ISO 14243 force- and displacement-controlled BCs derived from analytical musculoskeletal models. The novel CAMS-knee datasets provide synchronized knee contact forces measured using instrumented implants and implant kinematics measured using a moving fluoroscope for six subjects [1]. We investigated if applying these in vivo implant kinetics and kinematics to simulated wear tests leads to altered predictions of inlay wear compared to the ISO standard.

## Methods

We developed finite-element models of the Innex FIXUC implant (Zimmer Biomet, CAMS-knee datasets) and simulated ISO standard knee implant wear tests with force control (FC) and displacement control (DC) in Abaqus. Both prescribe the knee flexion angle and axial force. The DC model further prescribes anterior-posterior (AP) displacement and internal-external (IE) rotation. The FC model prescribes an AP force and an IE torque instead and has nonlinear AP and IE spring restraints added. We derived representative knee loads and kinematics from the CAMS walking dataset using the Orthoload HIGH100 averaging method [2] and applied the corresponding components to the DC and FC ISO models.

The tibial inlay was assigned an elastic-plastic PE model, while the femoral component was modelled as rigid. The mesh size of the inlay (quadratic tetrahedral elements) and femoral component (rigid shell elements) was chosen based on a mesh convergence study. A coefficient of friction of 0.04 [3] was used for the tibiofemoral penalty contact formulation.

PE wear and creep were predicted for 3 million cycles using a cross-shear and contact-pressure dependent wear model [4] and compressive creep model [5] using custom Python scripts. The inlay geometry was updated intermediately to reflect the geometry change caused by wear and creep.

Predicted wear volume, rate, and location produced by the FC and DC CAMS models was compared to that of the standard

FC ISO model. The standard DC ISO model was excluded due to unrealistic contact conditions.

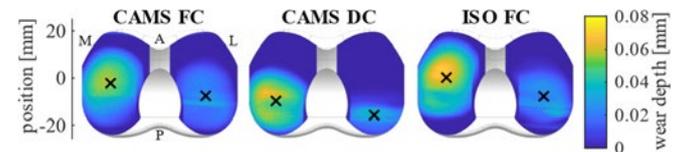

## Results and Discussion

The FC ISO model showed the highest wear rate followed by the FC CAMS model and the DC CAMS model (Table 1). The FC models showed larger average contact area and more relative sliding than the DC CAMS model, which showed much higher maximum cycle-averaged contact pressure. This suggests a weak dependence of wear volume on contact pressure and a stronger dependence on contact slip and area.

**Table 1:** Predicted wear rate, cycle-averaged contact area, max. total sliding distance and max. cycle-averaged contact pressure.

	wear rate [mm <sup>3</sup> /Mc]	avg. area [mm <sup>2</sup> ]	max. sliding dist. [mm]	max. avg. press. [MPa]
CAMS FC	11.6	671	51.2	5.2
CAMS DC	10.0	363	33.1	12.6
ISO FC	13.7	442	46.2	3.2

A small average cross-shear-ratio ( $\leq 0.01$ ) across all models indicated unidirectional sliding. For all models, the medial side showed 2–4 times more wear, even though the medial contact force was only 1.5 times higher. For the DC CAMS model the medial and lateral wear scar centroids were located ~10mm more posterior than for the FC models (Figure 1).

**Figure 1:** Wear scar depth and centroid after 3 Mc.

## Conclusions

Wear predicted by the FC ISO loads provides a good approximation of that produced by in vivo loads for this highly constrained implant. However, neither set of FC BCs resulted in wear locations that corresponded with those predicted from measured in vivo kinematics, thus indicating the value of fluoroscopy to improve future wear testing standards.

## Plantar pressures in custom foot orthoses with and without heel plugs

Megan E.R. Balsdon<sup>1</sup>, Colin E. Dombroski<sup>1,2</sup>

<sup>1</sup>SoleScience Inc., Fowler Kennedy Sports Medicine Clinic, London, Ontario, Canada

<sup>2</sup>School of Physical Therapy, Faculty of Health Sciences, Western University, London, Ontario, Canada

Email: megan@solescience.ca

### Summary

The goal of foot orthoses (FOs) for treating plantar fasciitis (PF) is to decrease pain and increase function by reducing pressures on the heel at the insertion of the plantar fascia. This study compared two types of custom foot orthoses (CFOs) that are typically made to treat PF – one with a heel plug, and one without. Plantar pressure measurements objectively compared average pressure, peak pressure, and pressure contact area at the hindfoot, midfoot and forefoot in fourteen healthy participants during treadmill walking. The heel plug CFO showed a statistically significant reduction in all three metrics at the hindfoot while a significant increase was seen at the midfoot for average and peak pressures ( $p < .05$ ), compared to the CFO without the heel plug. These findings are significant as offloading the hindfoot is critical for people with PF to decrease pain while walking, lessening compensation.

### Introduction

Studies have shown that custom-made foot orthoses (CFOs) were better at improving morning pain in people with plantar fasciitis compared to both prefabricated foot orthoses (FOs) and sham devices[1]. Foot specialists aim to reduce the pressure at the heel with FOs by increasing support in other areas of the foot. FOs have shown to decrease pressures in the heel compared to a flat insole[2] and shoe alone[3]. A finite element study identified the effect of plugs on peak pressure and pressure distribution under the calcaneus, while validating the simulation with in-shoe pressure measurements using a single subject[4]. This study quantified plantar pressures in two CFOs, one with a heel plug, and one without.

### Methods

Fourteen healthy participants (8 male) who were free of lower extremity injuries participated in the study after providing informed consent (35.4 years; 174.9cm; 76.3kg). The regular (REG) orthosis was made with a 3mm RCH 500 Shell, 45 durometer posting material, 3mm Multiform top cover, 1.5 puff bottom cover, and blue poron with 3mm heel lifts, while the full length heel plug (HP) orthotic was made with the same materials but with a heel hole cut out and a blue poron heel plug added. Plantar pressure measurements (F-scan, Tekscan) were recorded in both FOs, the order randomized among

participants, while walking on a treadmill (4.2±0.6 km/h). Three regions of the foot – the hindfoot, midfoot and forefoot were measured with three metrics: average pressure (kPa), peak pressure (kPa) and pressure contact area (kPa/cm<sup>2</sup>). A paired samples t-test determined differences between the two conditions ( $p < .05$ ).

### Results and Discussion

The results across all participants showed that the HP CFO significantly reduced the average pressure, peak pressure, and pressure contact area across all participants ( $p < .05$ ). The HP device also saw a significant increase in average and peak midfoot pressures ( $p < .05$ ) (Table 1). These findings were expected since the goal was to reduce pressure at the heel by increasing pressures in the midfoot to aid in offloading. These findings are consistent with a study that simulated insoles with heel plugs where reductions in peak pressures were greater as the heel plugs increased in width of the calcaneus (95%)[4]. Direct *in vivo* comparisons cannot be made; however, one study showed a CFO device was the only device (among EVA and flat sham FOs) to show both lower peak pressures at the medial heel and higher peak pressures at the midfoot, compared to the control condition, demonstrating the efficacy of CFOs in redistributing pressures in the foot[5].

### Conclusions

This study investigated the objective effects of two CFOs on plantar pressures in healthy participants. CFOs with heel plugs were more effective at offloading pressures at the hindfoot, while increasing pressures at the midfoot. Future research should investigate this same effect on patients with plantar fasciitis and include subjective efficacy measures such as the foot function index and comfort rating.

### Summary

In contrast with healthy individuals who typically employ an elevating strategy (immediately lifting the swing leg over the obstacle) [1], transfemoral prosthesis users utilize a variety of recovery strategies when reacting to early swing, prosthetic-side obstacle perturbations. Here we examine how these recovery strategies relate to a user's prosthetic knee type (e.g., hydraulic vs. mechanical) to inform the design of future prosthetic devices that further improve stumble recovery and reduce fall risk.

### Introduction

Healthy individuals use an elevating strategy to recover from early swing perturbations and maintain their balance [1]. While the elevating strategy is a common reflexive response in this population, it is not for transfemoral prosthesis users, who are 200 times more likely to fall than their age-matched, healthy equivalents [2,3]. Early swing phase perturbations are a fall-risk for this group because most commercial prostheses provide no way to easily control the leg's trajectory after the perturbation. Limitations in prosthetic knee functionality force users to adopt a variety of stumble recovery strategies with varying degrees of effectiveness. While multiple strategies may be effective in preventing a fall, certain strategies may be superior in terms of reducing recovery effort, such as the number of recovery strides required to return to steady state.

This work investigates a case series demonstrating the varying recovery strategies of transfemoral prosthesis users in response to early swing, prosthetic-side perturbations while wearing their prescribed prosthesis to determine how effective each strategy is and which features of each strategy provide the most potential benefit, to better inform future prosthetic designs.

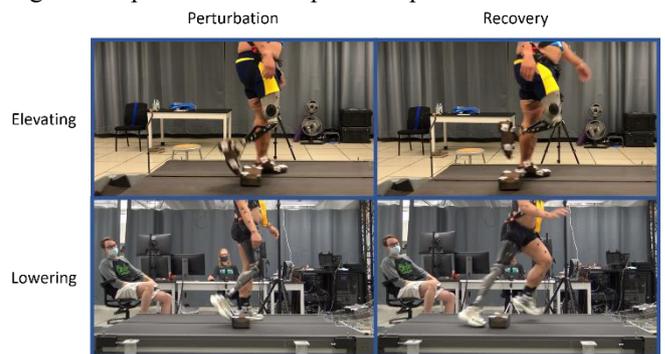

### Methods

Six participants were introduced to a series of swing phase obstacle perturbations, including 1-2 early swing, prosthetic-side perturbations, while walking on a treadmill at 0.8 m/s. The perturbation system is detailed in [1]. Motion capture and force plate data were collected and falls were monitored through a load-instrumented harness (>50% bodyweight = "likely fall"). Participants included: four Ottobock C-Leg users, one Ottobock 3R80 user, one Blatchford KX06 user.

### Results and Discussion

Nine early swing phase, prosthetic-side perturbations were recorded across the six participants. Five perturbations resulted in falls (56%) with four out of six participants falling at least once (67%). The majority of participants utilized a lowering strategy in which the user terminated their swing phase after the perturbation and took a quick contralateral step to recover [1]. Healthy individuals often use this strategy in response to perturbations much later in swing when the stride is nearly complete, as it is typically difficult to transfer one's weight back to the swing limb early in the swing phase due to the body's momentum [1]. This lowering strategy was the

only strategy used by C-Leg users, likely due to the higher swing impedance of the knee joint compared to other prostheses, preventing enough swing flexion to clear the obstacle. However, mechanical knee users (3R80 and KX06) attempted an elevating strategy, similar to what healthy individuals use in early swing phase. These mechanical knee users were able to effectively emulate an elevating strategy, which was enabled in part by the low swing impedance of their knees which resulted in exaggerated knee flexion in response to the perturbation, which then provided enough clearance to pass over the obstacle prior to subsequent knee extension. The elevating strategy resulted in one successful recovery out of the two attempts (50%) by the mechanical knee users, while the lowering strategy was successful three out of seven attempts (43%) with three out of the five participants successfully recovering using this strategy (60%). Further analysis will be presented to gain insight into which aspects of these strategies are most effective, and how they might be improved in future powered prosthesis interventions.

**Figure 1.** Two examples depicting the elevating (top, KX06) and lowering (bottom, C-Leg) recovery strategies, showing the moment of perturbation (left) and the recovery (right).

### Conclusions

Unlike healthy individuals, C-Leg users exhibited a lowering strategy in response to early swing perturbations, relying on their prosthetic knee's stance resistance to flexion to support them when lowering, while mechanical knee users employed an elevating strategy due to the low swing impedance and quick swing extension of those devices. C-Leg users required more time to return to steady state gait relative to the mechanical knee user who successfully employed an elevating strategy. The authors hypothesize that the desirable characteristics from each type of prosthesis could be combined into a single robotic prosthesis in the future to improve the ability of users to recover from various perturbations.

# Bi-linear Natural Ankle Quasi-Stiffness During Walking: Characterization & Implications for Orthosis Design

Luke Nigro<sup>1</sup>, Elisa S. Arch, PhD<sup>2</sup>

<sup>1</sup>Dept. of Mechanical Engineering, University of Delaware, Newark, DE, USA

<sup>2</sup>Dept. of Kinesiology & Applied Physiology, University of Delaware, Newark, DE, USA

## Summary

This research expands on an existing definition of natural ankle-quasi stiffness (NAS) as *bi-linear* – using two distinct portions of the loading phase of stance instead of one single region – to understand how ankle joint mechanics change during stance. A bi-linear ankle-foot orthosis (BL-AFO) prototype was constructed and tested as proof-of-concept for future AFO designs that can implement bi-linear stiffness.

## Introduction

Natural ankle quasi-stiffness (NAS), defined as a linear regression of the sagittal ankle moment vs. ankle angle during the loading (second rocker) phase of stance, can be used as a design parameter to customize passive-dynamic AFO (PD-AFO) bending stiffness. This spring-like stiffness can substitute for lost plantar flexor (PF) function for individuals with PF weakness [1]. Historically, a single NAS value has been defined over the entire loading phase of stance [2]. NAS increases during the loading phase of stance in healthy gait [3] often with two regions of nearly linear stiffness – a lower stiffness early in loading and higher stiffness later in loading (Fig. 1). Tuning a single PD-AFO bending stiffness to the entire loading phase of stance may result in a device stiffness that is too stiff to initiate bending, or not stiff enough to provide appropriate support in late loading. This research focuses on characterizing *bi-linear* NAS – or dividing the loading phase into two distinct regions of stance, each with its own stiffness [4]. A PD-AFO prototype with bi-linear bending stiffness (BL-AFO) was then built as proof-of-concept that such a device could be designed around this concept of bi-linear NAS.

Sagittal ankle angle vs. sagittal ankle angle (NAS curve)

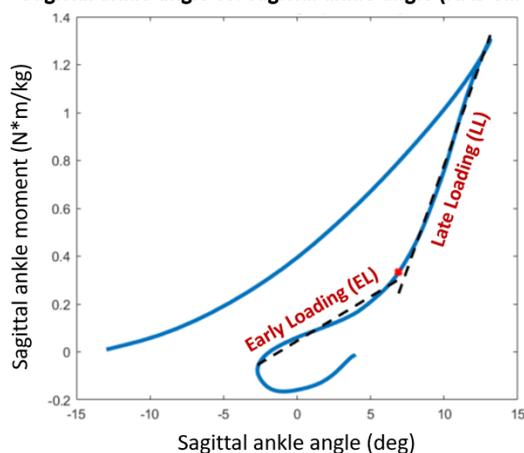

Figure 1: NAS curve of typical stance phase with the loading phase divided into EL and LL phases.

## Methods

10 individuals walked at three speeds (0.6, 0.8, and 1.0 statures/s) over level ground. Sagittal ankle angles and moments were calculated from 3D kinematics and ground reaction forces (GRFs). Early loading (EL) and late loading (LL) phases were separated at the instant at which the vertical GRF reached a local minimum in the typical M-shaped profile at ~50% stance [4]. Ankle angles at the transition were calculated as the difference between the angle at that instant and the angle at which loading phase began. NAS was calculated for EL and LL regions separately for each trial and each speed. One-way ANOVA tests were used to determine significant differences in speed conditions. A BL-AFO was constructed from a single-stiffness PD-AFO with steel strips attached to a rear strut. As the BL-AFO flexes, only the rear strut bends initially. An adjustable grabber engages the steel strips once a certain angle is reached, thus adding their stiffness to the rear strut.

## Results and Discussion

Average EL-NAS was 0.056 N\*m/deg/kg and did not change significantly with walking speed. Average LL-NAS was 0.113, 0.162, and 0.210 N\*m/deg/kg at 0.6, 0.8, and 1.0 statures/s, respectively, which is significantly greater than LL-NAS at every speed ( $p < 0.001$ ). The average transition angles for each speed were 8.7, 9.1, and 8.1 degrees for 0.6, 0.8, and 1.0 stat/s, respectively. Transition angles were significantly different from 0.8 to 1.0 stat/s only ( $p < 0.001$ ). The BL-AFO was able to achieve distinct bi-linear stiffness properties with an EL stiffness of 2.2 N\*m/kg and LL stiffness of 4.2 N\*m/kg and an adjustable transition angle (7-11 deg).

## Conclusions

This research presents a thorough investigation of bi-linear NAS and its changes with walking speed. It also presents a BL-AFO prototype as a proof-of-concept that bi-linear stiffness can be used as design criteria for AFOs in the future.

## Fuzzy-logic Inference System for Transfemoral Socket Rectification

Mike Karamousadakis<sup>1</sup>, Antonis Porichis<sup>1</sup>, Panagiotis Vartholomeos<sup>1</sup>

### Summary

A Decision Support System (DSS) is developed that outputs suggestions for rectification action to the prosthetist, aiming to improve the fitness of transfemoral prosthetic socket design. For this purpose, the DSS employs a fuzzy-logic inference engine (IE). A set of rules are used by the IE, which models the thought process followed by the prosthetist for deciding rectification actions. The novel feature of the proposed DSS is that the rules of the IE take into account measured pressures on the stump, provided by sensors embedded in the socket's walls. The rectification actions (proposed by the IE) are then processed by an algorithm which receives, manipulates and modifies a 3D digital socket model as a triangle mesh formatted inside an STL file. The updated STL file offers to the prosthetist a visual representation of the suggested rectifications in 3D.

### Introduction

Many patients experience serious discomfort wearing a conventional prosthetic limb because of pain, instability during walking, and skin irritation [1]. These are due to poor socket fitness, which results in pistoning, friction and instability of the socket with respect to the stump. The current practice for improving the socket design is based on empirical rules and visual inspection and involves skilled manual crafting. Usually, the patient is required to visit a clinic multiple times over one or more weeks for a complete socket rectification (i.e. socket design corrections). Hence, there is a need for improved design tools that exploit digital technology to expedite and improve the rectification procedure. To this end, computer aided methods for socket re-design are presented in [1-2]. These approaches redesign the socket based on biomechanical models and patient's characteristics. In this work, we present a computer aided method which takes into account socket-stump interaction pressures, based on measurements made by embedded sensors, and suggests rectification actions of the socket, so that the pressures are adjusted in a way to improve the socket fitness and comfort.

### Methods

The first step is the input data generation. For this purpose, the patient dons the socket and stands upright. Pressure measurements, taken by the embedded sensors, are sent as crisp inputs to the DSS. Next, the crisp inputs are fuzzified into membership functions that represent the degree of certainty that a pressure over each anatomical region of the socket is high. A set of fuzzy rules that encode the thought process followed by a prosthetist are expressed using propositional logic whose premisses are the membership functions values. The IE processes the rules and produces a set of implied fuzzy sets, which are aggregated into one set representing the proposed rectification conclusions. Defuzzification generates the most certain rectification output (crisp value), meaning that this output has the highest

certainty to be the action of the prosthetist. The rectification actions are visualized by modifying the 3D mesh of the socket STL file. The proposed IE workflow is depicted in Figure 1.

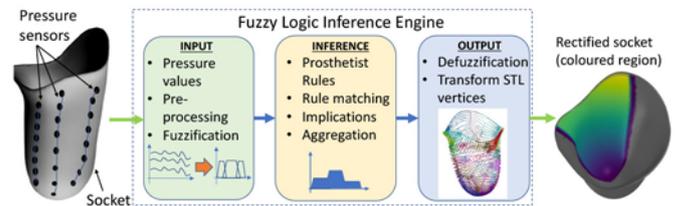

Figure 1: Fuzzy logic-based expert system for socket rectification.

### Results and Discussion

Consider the following typical case. The rule states that:

$$P \wedge (\neg Q) \Rightarrow R \text{ and } P \wedge Q \Rightarrow S$$

Where  $P$  is "high pressure at distal-end",  $Q$  is "high pressure at scarpas's triangle",  $R$  is "reduce volume of anterior area" and  $S$  is "socket is too short and has to be replaced". Measured pressures indicate high degree of certainty for linguistic statement  $P$  and low for  $Q$ . The IE workflow is executed and outputs the rectification depicted in Figure 2.

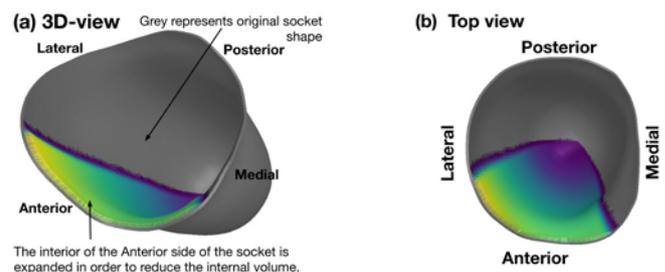

Figure 2: (a) 3D view, and (b) top view of the rectified socket.

The light-green is max expansion; the purple is min expansion. From the proximal to the distal anterior, expansion reduces smoothly. This rectification offers a tighter socket at proximal regions that prevents the stump sliding towards the distal-end. Therefore, no high pressures are exerted on the stump distal-end and the user does not experience discomfort.

### Conclusions

A DSS has been developed that outputs rectification suggestions to the prosthetist aiming to improve the fitness of the prosthetic socket design and increase patient's comfort.

## Predictive Simulation of Human Motion using SCONE

T. Geijtenbeek<sup>1</sup>, F.C.T. van der Helm<sup>1</sup>

<sup>1</sup>Biomechatronics and Human-Machine Control, Delft University of Technology, Delft, The Netherlands  
Email: t.geijtenbeek@tudelft.nl

### Summary

Predictive simulation is a powerful tool for research on human motion, with enormous potential for the development of assistive devices and clinical treatment. Despite its promise, adoption in the biomechanics community has been limited – largely due to its complexity and multidisciplinary nature. SCONE is open source that aims to remove these barriers and make predictive simulations accessible to a wide audience of researchers, clinicians and developers.

### Introduction

Despite a wealth of knowledge of the individual components comprising biological motion, the fundamental question of how the neural, muscular and skeletal systems operate together to produce efficient and purposeful motion remains largely unanswered. Predictive simulations from first principles provide an exciting avenue for exploring human motion on a systems level, allowing a level of control and inspection that is unimaginable in real-world experimentation.

In predictive simulations, motion is generated based on controller output, which is optimized to perform a given task according to high-level objectives, such as energy efficiency and pain avoidance. They permit fundamental *what-if?* questions, allowing researchers to investigate the effects of individual model parameters on the motion as a whole, and enable many real-world applications, such predicting treatment outcome and optimizing assistive devices *in silico*.

Unfortunately, the number of studies that successfully employ predictive simulations is limited. One important contributing factor is complexity: predictive simulations require expertise in musculoskeletal simulation, neuromuscular control and optimization – plus the software development skills to tie these components together. Software from successful projects is often either unavailable or lacks proper structure and documentation, limiting collaborations between researchers.

SCONE [1] is a free, open-source software initiative designed to help overcome these obstacles, and has been applied to answer various neuromuscular research questions.

### Methods

**Neuromuscular control.** SCONE implements several building blocks for neuromuscular control, including spinal feedback from proprioceptive sensors, neural delays, finite state machines for gait [2], feedforward control, neural network control, and controllers based on *Lua* scripting. Together, these can be combined to develop a wide range of neuromuscular control strategies for a variety of tasks.

**Musculoskeletal simulation.** SCONE uses external simulation software to evaluate controllers, through a software API. Currently supported are the free and open-source *OpenSim*

(<https://opensim.stanford.edu>), as well as the commercially available *Hyfydy* (<https://hyfydy.com>), which allows for a 50-100x speed-up in simulation time over OpenSim.

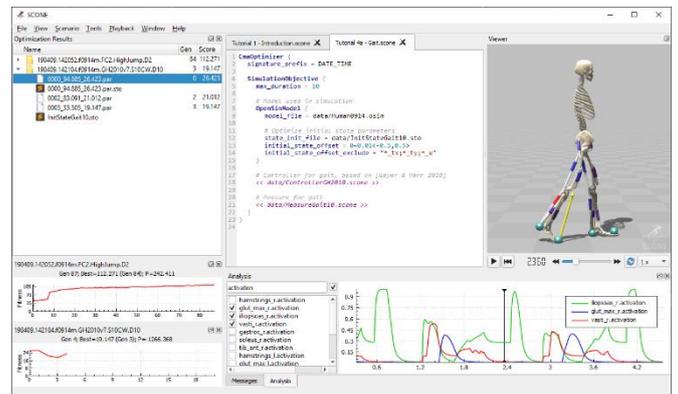

Figure 1: The SCONE User Interface

**Optimization.** Both model and control parameters can be optimized for user-defined objectives, which are made up from individual components including gait velocity, energy consumption, muscle activation, *etc*. Parameters are optimized through shooting-based methods (the Covariance Matrix Adaptation Evolutionary Strategy by default).

**User interface and documentation.** The SCONE user interface allows users to perform optimizations and analyze the results without software development skills. Tutorials, examples and documentation are available on-line (see link below).

### Results and Discussion

SCONE has been successfully applied in a number of scenarios, including investigation of plantarflexor weakness [3], the development of assistive robotic devices, optimization of the stiffness for ankle-foot-orthoses, and prediction of treatment outcome. SCONE has also been part of a teaching program for biomechanics MSc students.

### Conclusions

SCONE provides access to predictive simulations for a wide audience of researchers, clinicians and developers, and we believe further adoption will greatly benefit the biomechanics community. SCONE is freely available under the GNU Public License. See <https://scone.software> for more details.

Email: marlies.nitschke@fau.de

### Summary

We propose trajectory optimization for estimation of three-dimensional (3D) kinematics and kinetics of running from inertial data which resulted in high correlations for the sagittal plane and moderate for the frontal and transverse plane.

### Introduction

Inertial measurement units (IMUs) consist of accelerometers and gyroscopes and are light weighted and cheap wearable sensors which have the potential to replace lab-based optical motion capturing (OMC). For walking, conventional inverse dynamic methods were used after estimating kinematics and ground reaction forces and moments from inertial data [1]. In contrast to that, we first presented trajectory optimization to directly track noisy inertial data with a planar musculoskeletal model for walking and running [2]. Trajectory optimization ensures a dynamically consistent simulation. However, the planar lower-body model used in [2] is not capable of capturing for example lateral stability required to evaluate running shoes. Here, the trajectory optimization driven by IMU data is extended towards the estimation of 3D kinematics and kinetics of running.

### Methods

A 3D musculoskeletal model with 33 degrees of freedom and 92 Hill-based muscle tendon units [3] was used to track inertial data of seven IMUs at the lower body in a trajectory optimization. Sensor signals were simulated by placing virtual sensors on the model. Gyroscope signals were obtained from the skew-symmetric matrix  $[\omega]_{\times} = \mathbf{R}^T \dot{\mathbf{R}}$ , where  $\mathbf{R}$  describes the global orientation of the segment and  $\dot{\mathbf{R}}$  its time derivative. Accelerations  $\mathbf{a}$  were computed as follows:

$$\mathbf{a} = \mathbf{R}^T (\ddot{\mathbf{r}}_{Seg} + \dot{\mathbf{R}} \mathbf{p}_{Sen} - \mathbf{g}),$$

where  $\ddot{\mathbf{r}}_{Seg}$  denotes the global acceleration of the segment,  $\mathbf{p}_{Sen}$  denotes the sensor position in the segment coordinate system, and  $\mathbf{g}$  denotes the global gravity vector.

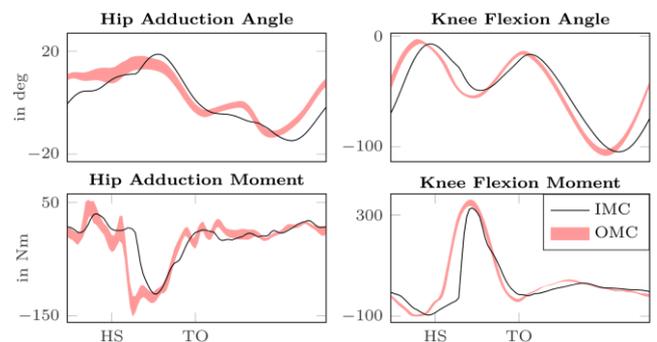

The state  $\mathbf{x}(t)$  and control  $\mathbf{u}(t)$  trajectories of a gait cycle were simulated by minimizing a combination of tracking error, cubic neural excitation, torque controls actuating the arms, and a small regularization term. The tracking error of the 42 sensor axes was expressed as squared difference between the virtual signal and the mean measured signal normalized to the measured variance. The trajectory optimization was constrained to be periodic and by the model dynamics which were formulated implicitly as  $\mathbf{f}(\mathbf{x}, \dot{\mathbf{x}}, \mathbf{u}) = \mathbf{0}$  [3]. The simulation was solved by 100-node direct collocation using Backward Euler and IPOPT.

The approach was evaluated using running at three different speeds of nine subjects with OMC as reference [2]. Coefficients of multiple correlation (CMCs) [4] were

computed between IMC and OMC for joint angles and joint moments of the hip, knee, ankle, subtalar and mtp joint and for ground reaction forces. Finally, CMCs were averaged over running speeds and subjects using Fisher's z-transform.

### Results and Discussion

The simulation tracked the measured IMU data well and rejected soft tissue artifacts. Sagittal plane kinematics and kinetics showed excellent (CMC: 0.93-0.98) and strong (CMC: 0.81-0.92) correlations, respectively (see Figure 1). However, correlations were weak for joint angles and moments of the subtalar and mtp joint.

**Figure 1:** Comparison of inertial motion capturing (IMC) and optical motion capturing (OMC) for running of one subject.

Similar correlations have been reported for sagittal plane kinematics and kinetics [1,2] whereas frontal and transverse plane variables appear to be harder to estimate [1]. Variables of the subtalar and mtp joint are sensitive to the ground contact model which could be further improved. Trajectory optimization results in consistency between kinematics and kinetics in contrast to inverse dynamics [1] or machine learning. Simulation quality for motions with directional changes, like curved running, will be further evaluated.

### Conclusions

We have shown that the full state and muscular control of a 3D musculoskeletal model can be estimated by tracking inertial data with trajectory optimization. The results agreed well with optical motion capturing for the sagittal plane and moderately for the frontal and transverse plane.

### Acknowledgments

We acknowledge the support of adidas AG and the German Research Foundation.

# Stochastic optimal control predicts features of sensorimotor control during walking

Tom Van Wouwe<sup>1</sup>, Lena H. Ting<sup>2</sup>, Friedl De Groot<sup>1</sup>

## Summary

It is unclear whether stochastic optimal control theory explains motor control of walking. Here, we applied a novel optimal control framework to simulate gait based on a five degree-of-freedom (dof) torque-driven model controlled by both feedforward and time-varying full-state feedback in the presence of sensorimotor noise. We solved for control policies that resulted in stable gait patterns while minimizing expected effort at two gait speeds. Our model predicted experimentally observed motor control features that were not prescribed, such as downregulation of feedback gains with speed and COM feedback to control the ankle torque during perturbed walking.

## Introduction

Deterministic optimal control simulations capture main features of gait mechanics and energetics, but provide limited insight into the underlying control. In contrast, stochastic optimal control simulations that take into account physiological noise, have described underlying control mechanisms for movements that could be simulated with simple, linearized models (e.g. reaching and standing balance) [1]. Here, we leveraged recent computational advances that improved efficiency of deterministic simulations of movement [2]. This allowed us to simulate more complex, non-linear models in the presence of sensorimotor noise. Applying this framework to gait, we demonstrated that stochastic optimal control predicts experimentally observed motor control features.

## Methods

We simulated a five dof torque-driven walker model with contact mechanics approximated as impulsive collisions [3]. Joint torques were determined by a combination of feedforward and time-varying linear feedback of the observed states. Dynamics were stochastic in the sense that sensory noise ( $\sigma_{pos}^2 = 0.25 [(\text{°})^2 \cdot \text{s}]$ ;  $\sigma_{vel}^2 = 2.25 [(\text{°}/\text{s})^2 \cdot \text{s}]$ ) was added to the feedback signal and motor noise ( $\sigma^2 = 0.2 [\text{Nm}^2 \cdot \text{s}]$ ) was added to the torques.

We approximated the stochastic state trajectory by the state mean trajectory and state covariance trajectory. We described the propagation of the state covariance by the Lyapunov equation [4]. The resulting deterministic optimal control problem was solved using direct collocation.

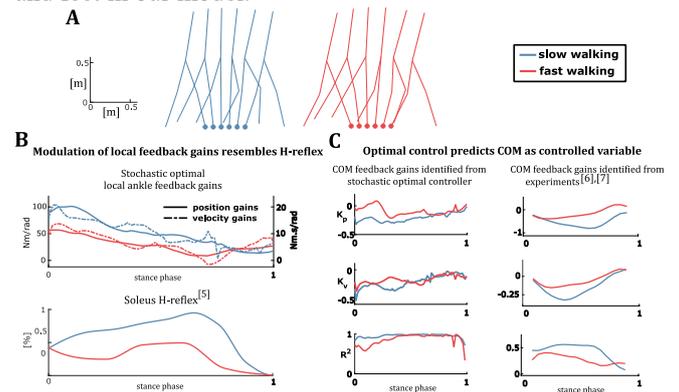

We solved for feedforward torques and feedback gains by minimizing expected effort, (time-integral of the expected control torques squared), while imposing an average speed of 0.625m/s and 1m/s. To achieve a stable limit cycle, we imposed periodicity of the state mean and the state covariance trajectory.

We evaluated whether our simulations predicted (1) modulation of local reflexes throughout stance and with gait speed in agreement with observed modulation of the H-reflex, and (2) experimentally observed correlations between

corrective ankle torques and COM kinematics in perturbed walking. We therefore simulated treadmill walking with random belt accelerations and decelerations [6] and analyzed how much of the corrective ankle torque ( $\Delta T_{corr}$ ), was explained by COM feedback:  $\Delta T_{corr}(t) = K_p(t) \cdot \Delta COM_x(t) + K_v(t) \cdot \Delta \dot{COM}_x(t)$ . We compared the gains identified from stochastic optimal control simulations to those identified from experiments [7].

## Results and Discussion

Similar to the soleus H-reflex, simulated local ankle feedback gains are downregulated at increased walking speed (Fig. 1 – B). Deviations in COM kinematics from the nominal trajectory due to perturbations were correlated (high  $R^2$  values) with ankle torque as observed in walking experiments (Fig. 1 – C). Both COM feedback gains identified from experiments and simulated COM feedback gains are downregulated at increased walking speed (Fig. 1 – C). Differences in simulated and experimental modulation of feedback gains might be due to the absence of double support and feet in our model.

**Figure 1:** A: Gait pattern at slow and fast walking speeds. B: Optimal local ankle feedback gains; soleus H-reflex. C: Identification of COM feedback gains from perturbed walking in simulation and experiments.  $K_p$  COM position feedback,  $K_v$  COM velocity feedback,  $R^2$  goodness-of-fit of COM feedback model.

## Conclusions

Stochastic optimal control predicts experimentally observed motor control features that were not prescribed. This suggests that control of walking might be governed by the single overarching goal of minimizing effort in the presence of sensorimotor noise.

## **Quo vadis, *Tyrannosaurus*? Predictive simulations of locomotor function and performance in modern and extinct animals**

P.J. Bishop<sup>1,2,3</sup>.

<sup>1</sup>Museum of Comparative Zoology and Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, Massachusetts, USA

<sup>2</sup>Structure and Motion Laboratory, Royal Veterinary College, Hatfield, Hertfordshire, UK

<sup>3</sup>Geosciences Program, Queensland Museum, Brisbane, Australia

The study of locomotor function in non-human species – both living and extinct – can improve our understanding of the complex interplay between anatomy, mechanics, function and performance in a range of behaviours. Yet, animals are frequently difficult to study experimentally; combined with other logistical constraints or data scarcity, this can limit the breadth or depth of insight able to be gained in a given system. Computational musculoskeletal modelling provides a means of addressing this problem, shedding insight on aspects that are otherwise difficult or impossible to study. In particular, predictive simulations using these models hold incredible potential, because they are freed from the constraints of available empirical datasets, such as those involved with collecting experimental data, or the limited anatomical variation observed across living species. By facilitating investigation of “what if” questions, predictive simulations allow us to explicitly and mechanistically relate observed anatomy to whole-animal function, behaviour and performance. This talk will summarize recent predictive simulation efforts of walking, running and jumping in modern animals (e.g., birds), using this as a vehicle to demonstrate the promises and challenges of predictive simulations for understanding animal function. A wide variety of questions are able to be explored, and key areas requiring future research (e.g., tendon properties) will be outlined. The talk will culminate with discussion of application to extinct species, using high-speed running in theropod (carnivorous) dinosaurs as an example. Theropods stood and moved with a pronograde trunk and possessed a long, heavy tail, and so this provides a powerful demonstration of where predictive simulations can unravel the function of anatomies that have no modern equivalent, further broadening our perspective on the interplay between biology and physics.

## Supine versus weight-bearing computer tomography in surgically-treated patella instability: an investigation on ligament length change between two different loading conditions

Belvedere C.<sup>1</sup>, Weyer H.<sup>1</sup>, Marcheggiani Muccioli G.M.<sup>2</sup>, Lullini G.<sup>1</sup>, Durante S.<sup>3</sup>, Zaffagnini S.<sup>2</sup>, Leardini A.<sup>1</sup>  
<sup>1</sup>Movement Analysis Laboratory, <sup>2</sup>II Clinical Department & <sup>3</sup>NTRAS, IRCCS Istituto Ortopedico Rizzoli, Bologna, Italy  
 Email: [belvedere@ior.it](mailto:belvedere@ior.it)

### Summary

Many knee-related image-based evaluations are performed in supine but a more realistic joint loading should be in weight-bearing. In this study on patients treated for patellar instability, differences in the knee ligament lengths were observed between these two different joint loading conditions, these revealing interesting biomechanical aspects.

### Introduction

Abnormal Patello-Femoral (PF) joint motion may result from unnatural load transfer between the knee articulating bones, this altering the stabilizing/guiding role of a number of soft tissues. This may result from several causes, acting even in combination, like congenital deformities, e.g. bone dysplasia, altered nearby joints function, and lifestyle, including sport activity [1]. More specifically, patellar instability (PI) is a common knee disorder in the young and active population. PI is associated with Medial PF Ligament (MPFL) injury, and is treated surgically via ligament reconstruction [1,2]. PI is diagnosed via medical imaging, but controversies exist on how image-based inspections must be carried out to depict the real bone-ligament interaction [2]. Accordingly, reliable and more PI revealing evaluations are needed both for diagnosis and in surgically treated patients. In conventional, i.e. Supine, Computed-Tomography (SCT), PI is evaluated routinely with the patients lying on CT scanner bed, i.e. in non-weight-bearing. Recently, Weight-Bearing-CT (WBCT) has been introduced in the clinical practice, and allows patient imaging in upright-standing position. The aim of this study is to assess via CT the fibre length changes between supine and weight-bearing conditions of those knee ligaments associated to PI.

### Methods

16 patients (BMI<25; 18-35 years) affected by PI were treated with MPFL reconstruction. At 5-year follow-up, all patients were scanned via SCT and WBCT, the latter based on cone-beam technology (Fig. 1). A 3D image-based methodology was adopted to reconstruct the bone CAD models for the femur, tibial and patella, and to identify the attachment footprints of the Patellar Tendon (PT), natural Lateral PF Ligament (LPFL) and reconstructed MPFL. The latter was modelled with 3 bars connecting the PF insertion grafts. LPFL and PT were modelled with 3 and 5 bars, respectively, joining the natural bone-ligament attachments. Relevant fibre lengths were calculated in the two loading conditions as the distance between the bar extremities. Tibio-femoral and PF joint alignments in both conditions was also

assessed using original proposals [3]. Pearson correlation and paired t-test analysis were used to extract significance differences. This study was IRB-approved.

### Results and Discussion

Considerable differences in fibre lengths between the two loading conditions were observed, these being up to about 9, 6 and 14 mm for MPFL, LPFL and PT, respectively. For MPFL and LPFL, these length changes were found not consistent over the patients; conversely, a significant negative correlation ( $R=-0.51$ ;  $p=0.03$ ) between the length change of the two ligaments was observed, this confirming the opposition in lengthening for these two structures. Only the LPFL and PT fibres were significantly longer in weight-bearing ( $p<0.001$ ). The length changes of MPFL and LPFL were found significantly correlated, directly and inversely respectively, with the PF tilt angle change between the two loading conditions.

**Figure 1:** WBCT scan. The patient is in monopodal upright posture. The moving bore is centered at the knee level.

### Conclusions

The reported differences between SCT- and WBCT-based assessments support joint loading as a key factor in the assessment of ligament tensioning and PI. Furthermore, these confirm the knee as a complex mechanism coupling translations and rotations when moving between different loading configurations. In this context, within medical imaging, WBCT offers the possibility to extract more realistic information depicting the knee during its natural function, i.e. load transmission, this potentially leading to more reliable clinical and biomechanical evaluations.

### Summary

It remains unclear if the short-term recovery of weight-bearing symmetry (WBS) after total hip arthroplasty (THA) improves upon pre-THA function with time similarly across different activities of daily living. Here, only two activities showed lasting improvements in post-THA WBS compared to pre-THA, suggesting that WBS recovery is sensitive to the activity investigated. Additionally, pre-THA WBS appears to have a critical role when assessing post-THA functional recovery, which may assist to optimize rehabilitation by clarifying the origin of post-THA deficits in WBS.

### Introduction

Deficits in WBS often persist after THA, with reduced ipsilateral limb loading observed in various activities [1]. Over time, this may overload the contralateral joint and contribute to the development of contralateral osteoarthritis [2]. It remains unclear if THA patients improve upon pre-THA deficits in WBS with time similarly across different activities of daily living. This study investigated WBS both pre- and post-THA across different activities of daily living, in order to identify if deficits in pre-THA WBS are similarly improved upon.

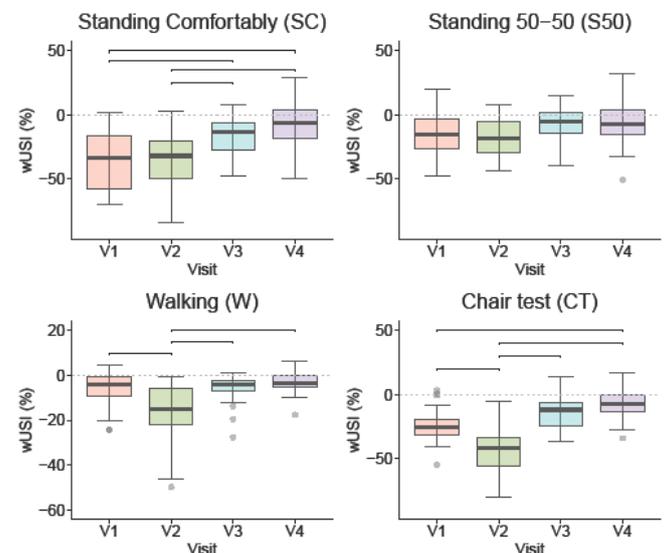

### Methods

Twenty-two patients (13 female, 66.5±7.0 years, 32.1±5.9 kg/m<sup>2</sup>) were recruited pre-THA. Instrumented insoles (novel GmbH) measured plantar normal force at 1 week pre-THA (V1), at 1, 3 to 6, and 6 to 12 weeks post-THA (V2, V3 and V4, respectively). Standing comfortably (SC), standing 50-50 (S50, patients directed to load limbs evenly without feedback), walking (W) and sit-to-stand-to-sit (chair test, CT) activities were performed. The weighted Universal Symmetry Index (wUSI) [3] computed WBS, where wUSI=0 indicates perfect WBS and wUSI<0 indicates higher contralateral loads. Depending on data normality, either one-way ANOVA or Kruskal-Wallis tests examined the effect of time point on wUSI for each activity (significance  $p<0.05$ ).

### Results and Discussion

A significant effect of time point ( $p<0.05$ ) on wUSI values was identified for SC, W and CT. S50 did not yield wUSI differences across visits ( $p=0.08$ ). Post hoc tests revealed further significant differences (Figure 1), which were not consistent across activities. This indicates that WBS recovery differs across activities, in agreement with previous findings [1]. Between V1 and V2, differences were only identified for W and CT ( $p<0.01$ ). Between V1 and V3, no wUSI significant differences were found for W and CT ( $p>0.1$ ), revealing that patients reached pre-THA wUSI levels, whilst SC wUSI values improved significantly ( $p=0.013$ ). Between V1 and V4,

differences were only observed for SC and CT ( $p<0.01$ ), indicating an improvement of WBS from pre-THA deficits. Pre-THA (V1), W was the most symmetrical activity, yet patients still applied more weight to the contralateral limb. This was not significantly improved upon at V3 and V4, which supports previous suggestions that gait adaptations learned pre-THA may be carried over throughout post-THA recovery [4]. When considering only post-THA periods, wUSI differences (V2-V3 and V2-V4) were observed for SC, W and CT (all  $p<0.05$ ) with no differences observed between V3 and V4. This suggests that the majority of the WBS recovery occurs between V2 and V3 for the three activities, with reduced recovery between V3 and V4.

**Figure 1:** Boxplot depicting wUSI (%) values at all visits (V1, V2, V3 and V4) for the standing comfortably, standing 50-50, walking and chair test activities. Brackets indicate post hoc test results.

### Conclusions

The recovery of WBS depends on the activity performed and on the inclusion of pre-THA values. Only two of the four investigated activities (SC and CT) exhibited functional improvements in WBS compared to pre-THA levels. This work highlights the critical role of pre-THA WBS in assessing functional recovery, as they can further optimize rehabilitation by clarifying the origin of post-THA deficits in WBS.

### Summary

External forces, as assessed in gait analyses, suitably characterized with respect to the knee anatomy may be of help in revealing instant and location of forces peaks. In this study an original methodology merging patient-specific knee anatomy, from medical imaging, and ground reaction forces is reported potentially useful for diagnosis and surgery.

### Introduction

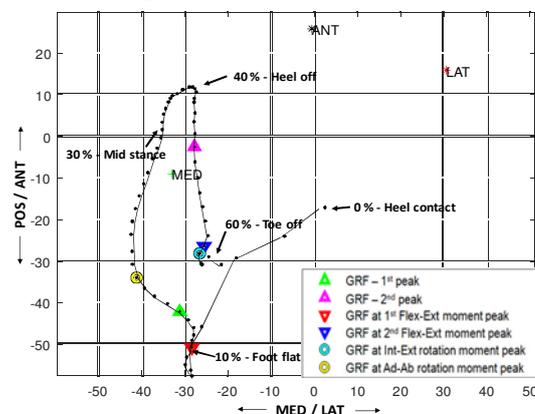

Medial Knee Osteoarthritis (MKO) is generally associated with abnormal varus joint alignment [1]. During locomotion, this results in altered lower limb locomotion and loading, especially at the knee level. To delay or prevent end-stage disease, misalignment correction via high tibial osteotomy (HTO) may be considered at an early disease stage to restore normal alignment restoration and provide medial compartment decompression [1,2]. For the latter, efficacy information may be provided by the analysis of the ground reaction forces (GRF), whose orientation would reflect knee misalignment if depicted upon real patient-specific knee anatomy.

Unfortunately, although multi-instrumental evaluations are reported, this rarely involves combination of medical imaging and gait analysis (GA), including GRF data, in a fully personalized way. The aim of this study was to create an original methodology merging CT imaging with GA and GRF data in order to depict a realistic patient-specific representation of the knee status during motion.

### Methods

25 patients (BMI<25; 40-65 years) affected with MKO and with a <20° varus deformity were selected for HTO. So far, 16 patients received pre-operative clinical scoring, and radiological, and instrumental evaluations. In detail, standard GA [3] was performed during walking, squatting and stair climbing/descending. An 8-camera motion systems (Vicon, Oxford, UK), combined with wireless electromyography, and force platforms (Kistler, Einterthur, CH) for GRF tracking, was used together with updated standard procedures. The latter implied data collection of 4 additional skin-based non-collinear markers, positioned around palpated tibial plateau bony rim. By still wearing the GA markers, patients received medical imaging examinations, i.e. full lower-limb X-ray and CT in weight-bearing condition (Carestream, Rochester, NY-USA). In data processing, relevant DICOM files were segmented to extract STL models for the tibia and the 4 additional reference markers; an anatomy based reference frame was defined on

the tibia, centered on the tibial plateau spine. The trajectories of the 4 additional markers as derived from GA during motion were then registered on the corresponding from CT reconstruction. Resulting registration matrices were used to superimpose GRF data on the reconstructed tibia model. Marker cluster deformation with respect to the target was assessed; intersections of GRF vectors with the tibial plateau were calculated/depicted throughout motions.

**Figure 1:** GFR pattern and peaks reported on patient-specific tibial plateau from a representative patient during walking phases

### Results and Discussion

Clinical scoring confirmed the expected impaired knee status. Abnormal varism, up to 18° was confirmed via X-ray inspections. Cluster deformation resulted in <1.5 mm error. The morphological characterization of GRF (Fig. 1) was successfully achieved on patient-specific tibial plateau morphology, barring an acceptable level of error. Generally, GFR patterns and peaks, including those related to anatomical joint moments, are concentrated on the medial compartment, as expected in varus knees.

### Conclusions

This novel approach allows a linkage between motion data, including GFR, and knee misalignment exactly at the knee level. Relevant pre-/post-operative routine application, as in HTO, may offer a quantification of the effect of the executed joint realignment and as well assisting surgery planning.

## Relationship between knee range of motion and gait function pre and post-total knee replacement

### Summary

Total knee replacement (TKR) surgery aims at improving pain, knee range of motion (ROM) and lower limb function in people with end-stage knee osteoarthritis (OA). In this study, knee ROM did not improve one-year post-TKR. Gait function improved post-TKR but less than 23% of patients displayed a gait pattern similar to non-pathological participants. There was a moderate relationship between knee ROM and gait function both pre and post-TKR suggesting that there may be other factors affecting the lower limb function.

### Introduction

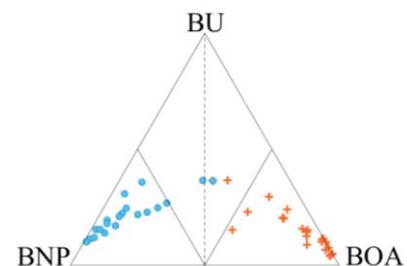

Knee OA is a degenerative disease that causes pain and functional limitations. TKR surgery aims at reducing symptoms and improving lower limb function in people affected by knee OA [1]. Knee ROM is frequently used as an objective outcome measure for TKR. However, it is not clear whether an increased knee ROM post-TKR is sufficient to ensure an improved gait. This study aims to investigate whether knee ROM and gait improve after TKR and if knee ROM correlates with an objective classification of gait function (Cardiff Classifier (CC)) [2] in patients pre and one-year post-TKR.

### Methods

In this longitudinal study, 3D gait analysis (Qualisys system, Bertec force plates) was performed on 41 participants walking at self-selected speed (20 non-pathological (NP), 21 with knee OA – 22 knees – pre and post-TKR). The patients' knee active-assisted ROM (AAROM) was measured. Patients' data were recorded pre and one-year post-TKR. Principal Component (PC) analysis was performed on pelvis, hip, knee and ankle biomechanics waveforms of the affected side and of a randomly selected side in NP (frontal, sagittal and transverse planes). The first 3 PCs of each variable were used to train the CC, a classification system based on the Dempster-Shafer theory. The CC outputted three values for each participant: belief in NP (BNP), belief in OA (BOA) and belief in uncertainty (BU), each ranging from 0 to 1 and whose sum is 1. A predominant BOA value indicated the presence of a pathological gait. The 18 PCs that ranked the highest in classifying each participant as NP or with knee OA were retained and used to quantify the biomechanical changes pre and post-TKR. The significance of the changes in AAROM and BOA pre to post-TKR was explored with the Wilcoxon matched-pair test ( $p \leq 0.05$ ). The correlations between patients' BOA and AAROM values pre and post-TKR were tested with Spearman's correlation coefficient ( $p \leq 0.05$ ).

### Results and Discussion

The CC identified NP and OA patients pre-TKR with 97.6% accuracy (Figure 1). Interestingly, the CC highlighted that the highest-ranking features classifying the gait as pathological or NP, are related to the joints that are distal or proximal to the knee. In fact, the PCs that had the highest accuracy ( $>79\%$ ) in classifying each participant as NP or OA were ground reaction force, hip and ankle moments, pelvis, hip and ankle angles; the PCs representing knee sagittal angles and moments only ranked 11<sup>th</sup>, 14<sup>th</sup> and 15<sup>th</sup> in terms of classification accuracy. Knee AAROM did not improve significantly post-TKR (median difference=2.65°,  $p=0.149$ ), with 45.5% of patients ( $n=10$ ) experiencing a decrease in AAROM. The BOA value improved significantly post-TKR (median difference=0.15,  $p<0.001$ ) but it was still predominant over the BNP and BU values in 77.3% of patients ( $n=17$ ). There was a moderate, negative correlation between BOA and knee AAROM both pre-TKR ( $r_s = -0.596$ ,  $p=0.003$ ) and one-year post-TKR ( $r_s = -0.448$ ,  $p=0.037$ ). This means that pre and post-TKR, a more restricted knee AAROM was associated with a more compromised gait pattern. This relationship was weaker one-year post-TKR.

**Figure 1:** Cardiff classifier simplex plot: classification of NP (blue dots) and OA patients pre-TKR (orange crosses); the black, dashed line indicates the boundary between BNP and BOA.

### Conclusions

One-year post-TKR, knee AAROM did not improve, the gait pattern improved but it was still classed as pathological for most patients. The moderate relationship between knee AAROM and gait classification both pre and post-TKR may suggest that knee AAROM on the affected side is not the sole variable influencing the gait pattern in people with knee OA and especially after TKR. The findings from the CC suggest that pelvis, hip and ankle joints should also be considered when assessing gait function in patients with end-stage knee OA and when examining the outcome post-TKR.

## Biomechanical characterization of the primary fixation stability of different acetabular cups with respect to segmental acetabular bone defects

Christian Schulze<sup>1</sup>, Maeruan Kebbach<sup>1</sup>, Rainer Bader<sup>1</sup>

<sup>1</sup> Biomechanics and Implant technology Research Laboratory, Department of Orthopaedics, Rostock University Medical Center, Rostock Germany

Email: christian\_schulze@med.uni-rostock.de

### Summary

In the present study we compared the primary stability of a commonly used primary and revision acetabular cups by push-in and lever-out tests in a biomechanical cup block model considering segmental acetabular bone defects. Thereby the revision cup showed higher push-in forces and lever-out moments in all defect types.

### Introduction

Fixation stability of cementless acetabular cups is influenced by the implant design and the quality of the acetabular bone stock. Particularly, fixation can be compromised by joint dysplasia and acetabular bone defects. Therefore, our experimental study aimed to characterize the primary fixation stability of a primary acetabular cup in comparison to a revision cup design with respect to different stages of segmental acetabular bone defect.

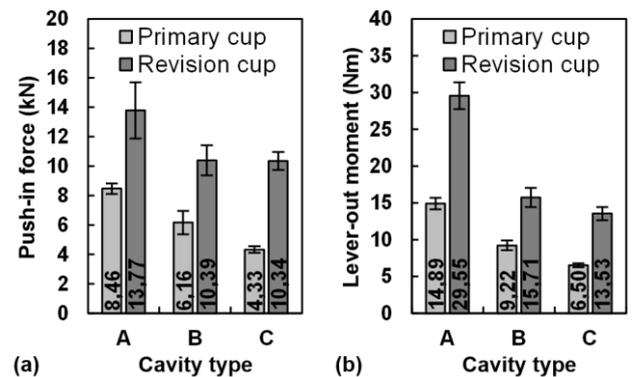

### Methods

For the characterization of the fixation stability of uncemented primary acetabular and revision cup designs (Allofit<sup>®</sup> 54/JJ vs. Trabecular Metal<sup>™</sup> Acetabular Revision System, Zimmer GmbH, Wintherthur, Switzerland) a standardized supero-lateral acetabular defect model [1] was used. The extent of the segmental defect ( $\alpha/\beta$ ) is defined in anterior-posterior direction by the angle  $\alpha$  and in lateral-medial direction by the angle  $\beta$  with regard to the center of rotation of the reamed acetabulum. Three stages of acetabular defects ( $\alpha/\beta$ ) were considered, intact cavity (0/0) (A), a 90/45 defect (B) and a 120/45 defect (C). For each type of uncemented cup,  $n = 5$  cavities per defect type were created in blocks made of 20 pcf Polyurethane foam (Sawbones<sup>®</sup>, Malmö, Sweden) using CNC milling. Both acetabular cup types ( $n = 2$  cups for each type) had a nominal outer diameter of 56 mm and were displacement controlled pushed ( $v = 20$  mm/min) into the cavities with a diameter of 54 mm by means of a universal testing machine (Zwick/Roell Z050, Zwick GmbH & Co. KG, Ulm, Germany) until the recommended final implant position was reached. Subsequently, the acetabular cups were displacement controlled ( $v = 20$  mm/min) levered out of the cavities in the opposite direction to the defect. The push-in force and the lever-out moment were continuously recorded during the experimental testing.

### Results and Discussion

For the primary cup, push-in forces were determined in a range from  $8.46 \pm 0.36$  kN (intact) to  $4.33 \pm 0.23$  kN (120/45) and for the revision cup from  $13.77 \pm 1.92$  kN (intact) to  $10.34 \pm 0.61$  kN (120/45). The

primary cup showed lever-out moments in a range from  $14.89 \pm 0.77$  Nm (intact) to  $6.50 \pm 0.26$  Nm (120/45), while the revision cup showed lever-out moments in a range from  $29.55 \pm 1.81$  Nm (intact) to  $13.53 \pm 0.88$  Nm (120/45) (Figure 1). The 90/45 defect reduced in comparison to the intact cavity the lever-out moment of the primary cup by about 38% and of the revision cup by about 46%, whereas the 120/45 defect reduced lever-out moment of the primary cup by about 56% and the revision cup by about 54%.

**Figure 1:** Experimentally determined test parameters (a) push-in force and (b) lever-out moment for the primary and revision acetabular cup with respect to different defect cavities. The bars represent the mean values and the error bars represent the standard deviation of each test group ( $n = 5$ ).

In the case of the 90/45 defect, the lack of superior bone support leads to a significant decrease in moment in both cup types. In contrast to the primary cup, an increase in the anterior-posterior defect extend (angle  $\alpha$ ) from  $90^\circ$  to  $120^\circ$  only slightly reduces the lever-out moment for the revision cup. The push-in forces show a similar behavior; however, the high push-in forces of the revision cup should be noticed. The higher fixation stability of the revision cup is due to higher press fit within the bone cavity at the level of the cup equator. It should be noted that the defect model and the artificial bone material used do not reproduce all the anatomical and material properties of the native acetabular bone cavity.

### Conclusions

Compared to the primary cup, the revision cup investigated showed higher push-in forces and lever-out moments, which are associated with a higher equatorial press fit.

# Inclination of talocrural joint axis: In vitro studies and morphological considerations not confirmed in walking condition

P. Wolf<sup>1</sup>, R. Moor<sup>1</sup>, E. Graf<sup>2</sup>

<sup>1</sup>Sensory-Motor Systems Lab, Department of Health Sciences and Technology, ETH Zurich, Zurich, Switzerland

<sup>2</sup>Institute of Physiotherapy, ZHAW School of Health Professions, Winterthur, Switzerland

Email: [pwolf@ethz.ch](mailto:pwolf@ethz.ch)

## Summary

Knowledge about the orientation of the talocrural joint axis is limited to studies on tarsal morphology and quasistatic studies. Here, we determined the talocrural joint axis during walking. In contrast to literature, the mean axis was inclined upwards laterally during dorsiflexion while being inclined rather upwards medially in plantarflexion.

## Introduction

Already 70 years ago, the two different arcs and radii of the medial profile of the talus were used to highlight that the talocrural joint has no fixed axis of rotation. It was postulated that in talocrural dorsiflexion the axis of rotation is inclined upwards medially whereas in talocrural plantarflexion the axis of rotation is inclined upwards laterally [1]. Subsequent studies confirmed this postulation *in vitro*, e.g. [2], as well as (at least partly) *in vivo* [3]. As related studies were either based on morphological data only or on data gained quasi-statically, the aim of this study was to determine the orientation of the finite helical axis (FHA) of the talocrural joint during the stance phase of walking.

## Methods

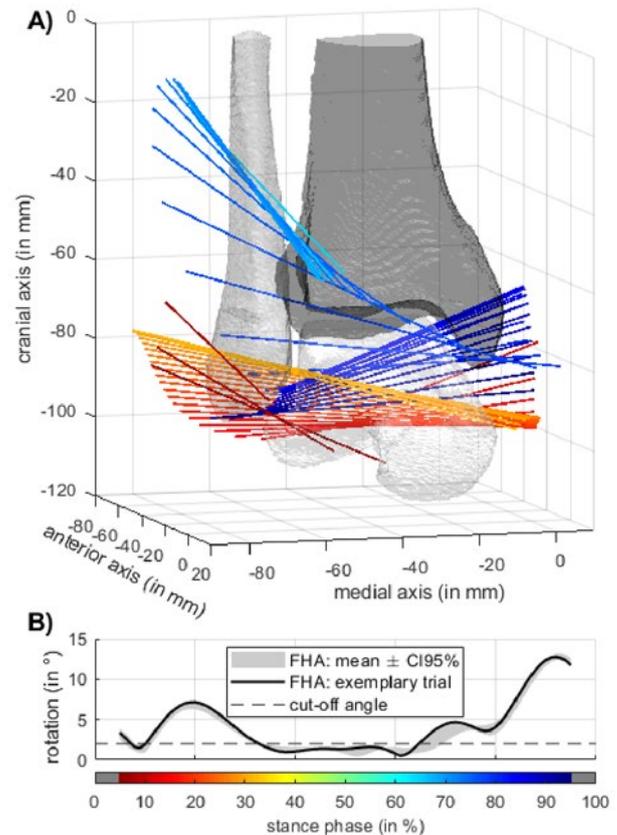

Using intracortical pins, kinematics of the talus and tibia were recorded during self-paced walking of five participants [4]. The FHA was determined [5] for a moving window of 10% stance phase and reported when the rotation was more than 2° to reduce the influence of noise. The mean helical axis was calculated for 15-30% stance phase, i.e. a phase known for talocrural dorsiflexion, and for 80-95% stance phase, i.e. a phase known for talocrural plantarflexion. Computer tomography of the bones was done while the pins were inserted to facilitate the visualization of the FHA.

## Results and Discussion

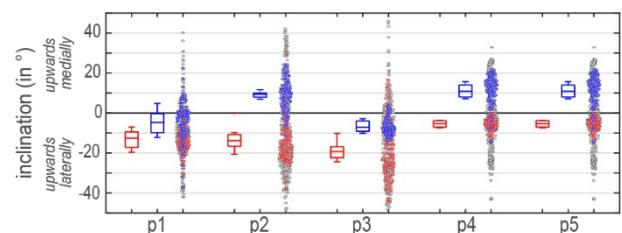

As expected, we could confirm that the talocrural joint acts not like a hinge joint with one single fixed axis of rotation (Figure 1). In contrast to existing literature, however, we observed that during a phase of talocrural dorsiflexion the axis of rotation was inclined upwards laterally and that in talocrural plantarflexion the axis turned more medially upwards (Figure 2).

## Conclusions

Although recent designs of ankle joint prostheses have considered different inclinations for dorsi-/plantarflexion axes, their necessity could be justified differently than previously thought as in waking, we observed axes inclinations opposite to the expected ones.

**Fig. 1** (A) Exemplary trial: Bones displayed in reference (standing) position. (B) Rotation along the FHA of exemplary trial (black) and of all trials of participant p4 (grey).

**Fig. 2** Inclination of helical axes: Red (blue) boxplots represent mean helical axes of all trials of participant p1 to p5 in early (late) stance phase. Grey dots of swarm plot represent inclination of all FHA, red (blue) those of early (late) stance phase.

## Which metabolic cost models most accurately predict energetics at different speeds of walking?

Israel Luis<sup>1</sup>, Maarten Afschrift<sup>2</sup>, Friedl De Groot<sup>2</sup>, Elena M. Gutierrez-Farewik<sup>1</sup>

<sup>1</sup>KTH MoveAbility Lab, Dept. Engineering Mechanics, KTH Royal Institute of Technology, Stockholm, Sweden

<sup>2</sup>Department of Movement Sciences, KU Leuven, Leuven, Belgium

Email: ailp@kth.se

### Summary

Energy expenditure during walking at 7 different speeds was predicted based on motion capture, musculoskeletal simulation, and 6 different metabolic cost models, and compared to measured energy expenditure and gross cost of transportation. All metabolic cost models predicted a U-shaped relation between walking speed and cost of transport but the models from Uchida 2016 and Lichtwark and Wilson 2005 agreed better with the measured metabolic cost than the other models.

### Introduction

Energy expenditure (EE) provides a quantitative measurement to assess metabolic demand of locomotion; accurate prediction may support rehabilitation treatments or design of assistive devices. The metabolic cost models (MCMs) formulated by Bhargava 2004 (BH04), Lichtwark and Wilson 2005 (LW05), Houdijk 2006 (HO06), Umberger 2003 (UM03), Umberger 2010 (UM10), and Uchida 2016 (UC16) consist of a set of equations that relate muscle excitations, states and state derivatives to metabolic energetics from different animal species, and have served to explain muscle energetics [1,2]. There are, however, significant differences between them: BH04, HO06, and UM03 allow negative mechanical work to decrease EE. UM03, UM10 and UC16 were derived from similar experimental data sets. Whether these relationships are able to predict salient characteristics of walking energetics such as the U-shaped cost of transport (COT) curve and optimal speed (OS) has not been examined. The objectives of this study were to evaluate six MCMs and determine which provides the best prediction of EE and COT across different speeds of walking.

### Methods

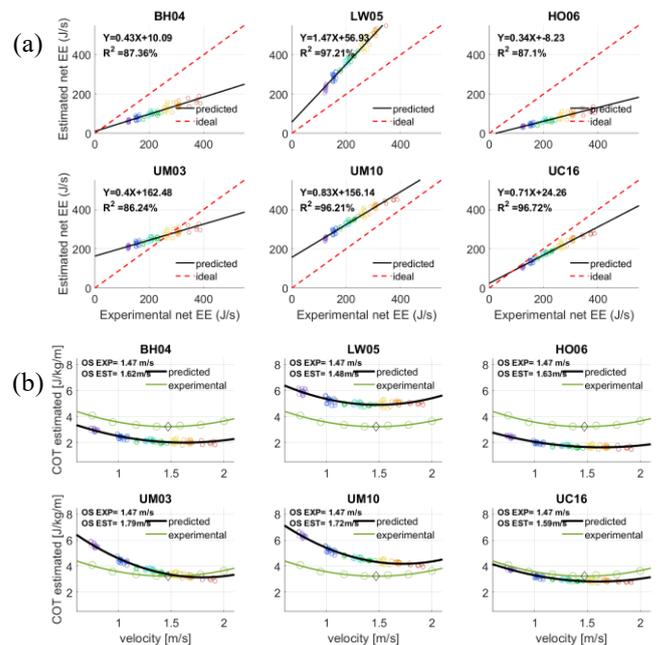

Ten able-bodied adults were asked to walk at 55%, 70%, 85%, 100%, 115%, 130% and 145% of their preferred walking speed in two conditions: treadmill (TRE) and overground (OVG). In TRE trials, gross EE was recorded as O<sub>2</sub>/CO<sub>2</sub> consumption (Cortex Metamax 3B) during 6-minute trials at each speed (randomized). Net EE measured was then computed as gross EE minus EE during resting/sitting. Each subject's average cadence at each speed was recorded.

In OVG trials, gait kinematics (Vicon V16), ground reaction forces (AMTI Optima) and EMG (Myon nano) were recorded. Participants were asked to walk at approximately the same 7 speeds by matching their cadences from TRE trials. Data from all OVG trials was processed (inverse kinematics and inverse dynamics) using OpenSim 4.1 based on the musculoskeletal model proposed by Lai Arnold 2017 [3] scaled to the subject's dimensions. A muscle-redundancy solver based on direct collocation [4] was used to estimate the muscle states. EE and

COT (energy required to move 1 kg per meter) were computed from the 6 MCMs (BH03, LW05, HO06, UM03, UM10 and UC16) at each speed and compared to the measured net EE. Net EE in the different speeds was linearly fit and COT was fit to second order equations.

### Results and Discussion

All MCMs captured main trends, i.e., predicted EE increases and predicted COT follows a U-shape with respect to walking speed (Fig. 1). Among different subjects, LW05 and UM10 usually overestimated net EE, while BH04 underestimated it. Overall, EE estimated from UC16 and LW05 agreed best with experimental data, and HO06 agreed least.

**Figure 1:** a) experimental and predicted net EE and (b) COT and OS for one representative subject walking at 7 speeds ranging from very slow (purple) to very fast (red).

### Conclusions

While none of the MCMs entirely predicted EE that matched with experimentally measured EE, UC16 and LW05 agreed better than the other 4 models. All MCMs predicted U-shape relation, wherein the models of UC16 and LW05 tend to provide the best estimates.

Email: [raphael.hamard@univ-nantes.fr](mailto:raphael.hamard@univ-nantes.fr)

### SUMMARY

The aim of this study was to determine whether the higher activation in the medial gastrocnemius (MG) compared to the lateral gastrocnemius (LG) during walking translates into different mechanical behavior of the fascicles. To address this aim, we used an experimental approach, which combined electromyography (EMG) and ultrasound imaging. Our results show that the higher activation of MG compared to LG translates into less MG fascicle lengthening and a greater change in MG pennation angle during the fascicle shortening period. No difference in the amount of fascicle shortening or peak shortening velocity were found.

### INTRODUCTION

The triceps surae contributes more than half of the total propulsive power during the push-off phase of walking [1]. Although functional differences between the soleus and the gastrocnemii are well documented, MG and LG muscles are often considered to share the same functions and thus to behave similarly. Evidence suggests that during walking, muscle activity is greater in the MG than the LG [2]. However, it is unknown whether these differences in activation translate to differences in the mechanical behavior of the fascicles. The aim of this study was to determine whether the differences in activation between the MG and the LG during walking translate into different mechanical behavior.

### METHODS

Fifteen healthy participants walked on a treadmill at their preferred walking speed under two conditions: (1) level walking and (2) incline walking (10% grade). Participants performed both conditions twice, to first record MG and LG muscle activations using surface EMG (Trigno Delsys Inc., USA; 10 mm interelectrode distance) and second to measure MG and LG fascicle behaviors using B-mode ultrasound imaging (120 Hz, 5-8 MHz, 60mm field-of-view, LV8-5L60N-2, ArtUS, Teleded, Lithuania).

Raw EMG signals of fifteen strides were filtered, rectified and normalized to the maximal activation level previously determined during maximal voluntary contractions. We used a semi-automated tracking algorithm to determine fascicle length and pennation angle during five strides of walking.

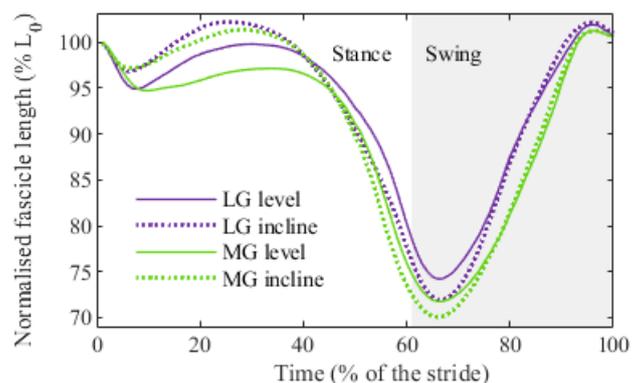

To assess the muscle effect, the condition effect and the muscle x condition interaction, we conducted a two-way repeated measures ANOVA on the EMG and ultrasound parameters. Then, we used correlations to determine the relationship between activation and mechanical behavior.

### RESULTS AND DISCUSSION

Peak EMG amplitude was higher in MG than LG ( $p=0.01$ ), regardless the condition, with no interaction effect ( $p=0.67$ ).

During early stance, the LG fascicle lengthened 26% more ( $p=0.02$ ) and rotated 1 degree more ( $p<0.01$ ), compared to the MG. However, we found no differences in the amount of fascicle shortening following this lengthening ( $p=0.21$ ) (Figure 1) or in peak shortening velocity during this shortening ( $p=0.85$ ) between the MG and LG. During the fascicle shortening period, the MG underwent greater increases in pennation angle compared to the LG ( $p=0.04$ ). We did not find any significant interaction effects (All:  $p>0.29$ ).

Finally, we did not find any significant correlation between EMG parameters and ultrasound parameters.

**Figure 1** : MG and LG fascicle length change patterns during level (solid) and incline (dashed) walking.

### CONCLUSIONS

In this study, we found that during walking the MG is activated more than the LG, consistent with previous studies. The higher MG activation was associated with a less fascicle lengthening and greater increases in the change in pennation angle, compared to the LG. However, the greater MG activation did not lead to more fascicle shortening or changes in peak shortening velocity, suggesting the motor coordination control and fascicle dynamics are uncoupled.

# Model-based Closed-loop Control of Locomotion via Muscle Reflexes and Spinal Synergies: A Direct Collocation-based System Identification Approach.

Huawei Wang, Massimo Sartori

Neuromechanical Modeling and Engineering Lab, Technical Medical Centre, University of Twente, Enschede, The Netherlands  
Email: h.wang-2@utwente.nl

## Summary

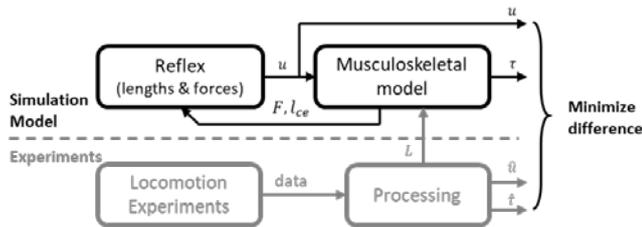

Computational models of motor control (i.e., spinal synergies, and muscle reflexes) in human locomotion are often based on empirical knowledge and hence are not subject-specific. This study showed that detailed reflex structures for leg muscles can be directly identified from human walking data *in vivo*, which has the potential to explain specific individuals' movement neuromechanics. The identification framework can also be extended to a variety of movements, such as sit-to-stand and jumping.

## Introduction

Muscle reflexes and spinal synergies have been studied via both avatar-based simulations and *in vivo* experiments [1,2], showing that they can explain complex locomotion tasks. In addition, they can also be used to close the control loop between real-time neuromechanical model-based (NM) controllers and wearable robots (i.e., robotic exoskeleton and bionic limbs), to relax or even eliminate the needs of electromyography sensors [3]. In this study, we answer the question about whether can personalized reflex models be directly identified from walking data.

## Methods

Kinetic and muscle activation data of 5 healthy adults at 4 walking speeds (0.9, 1.8, 2.7, 3.6km/h) were collected. Models of muscle reflexes are identified from this dataset, through an indirect identification approach (Figure 1). These identification problems were solved through trajectory optimization with the direct collocation method [4].

**Figure 1:** Structure of the reflex-synergy controller identification. Where,  $u$  represents muscle excitations;  $\tau$  represents joint torques;  $F$  represents muscle forces;  $L$  represents muscle lengths;  $l_{ce}$  represents lengths of muscle contractile element.

In the identification, reflex model was defined as a fully connected network with all possible muscle force and length linear feedback loops. To find the minimal reflex structure, besides the data tracking terms, another term was added to the objective function:  $O_{min-loops} = \sum_{j=1}^{M_f} |\bar{k}_f|^{\frac{1}{2}} + \sum_{j=1}^{M_l} |\bar{k}_l|^{\frac{1}{2}}$ , where  $\bar{k}_f$  and  $\bar{k}_l$  are the normalized reflex gains. By minimizing the objective function, one strong reflex loop was preferred, instead of two weak reflex loops, in explaining muscle excitations. The optimization problem was defined as:

$$\text{optimize: } [\bar{k}_f, \bar{k}_l, u(t), l_{ce}(t)]$$

$$\text{minimize: } \int_{t=0}^T [(u(t) - \hat{u}(t))^2 + (\tau(t) - \hat{\tau}(t))^2] \cdot dt + O_{min-loops}$$

$$\text{subject to: } f_r(l_{ce}(t), F(t), \bar{k}_f, \bar{k}_l) - u(t) = 0$$

$$f_m(L(t), u(t), l_{ce}(t), \dot{l}_{ce}(t)) - F(t) = 0$$

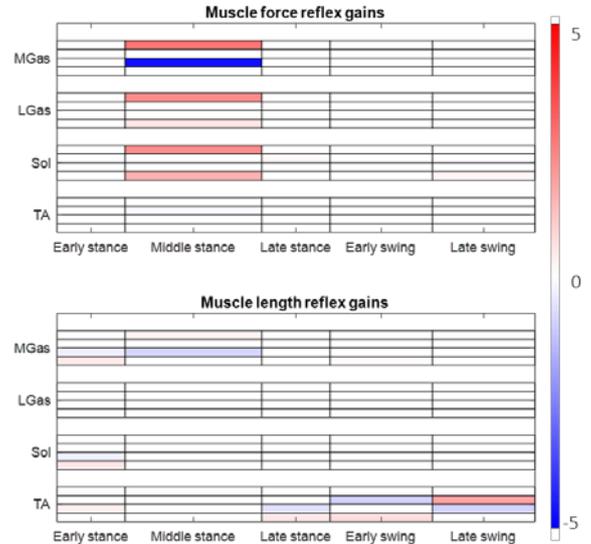

$$F(t) \cdot r - \tau(t) = 0$$

$$0.01 \leq u(t) \leq 1$$

$$K_{lb} \leq \bar{k}_{f,l} \leq K_{ub}$$

## Results and Discussion

Preliminary results (Figure 2) showed that similar but more detailed reflex structures can be identified from the walking data, comparing to the commonly used reflex model [1].

**Figure 2:** Identified reflex gains. An averaged gait cycle was divided into five phases. One constant reflex gain was defined in each phase and each reflex loop. Each muscle has four reflex feedbacks (four sub-rows) from four muscles. Colors in each block indicate the significance of this reflex loop in explaining the muscle excitation.

## Conclusions

Our study showed that subject-specific muscle reflex models can be directly identified from locomotion data.

### Summary

Effects of bracing on trunk and pelvis range of motion (ROM) for patients with adult spinal deformity (ASD) were compared for immediate- and short-term benefits. When wearing brace, normal trunk ROM was maintained, and pelvic kinematics during gait were improved. Bracing could help improve gait mechanics in addition to pain reductions.

### Introduction

ASD is characterized as a spectrum of abnormalities that affect the thoracolumbar or lumbar spine throughout the ageing process. Literature supports significant reductions in worst pain, back pain, and leg pain with bracing in adult female idiopathic scoliosis patients [1]. Due to the rigidity of adult spines, bracing in patients with ASD is not meant to correct spinal curvature, but rather aims to relieve the pain and other symptoms by temporarily placing their spine/trunk into the best physiological alignment possible [2]. Paucity of investigations on effects of bracing on trunk or pelvis ROM during gait is known [2]. Therefore, the purpose of this study was to investigate the impact of bracing on trunk and pelvis ROM during gait for individuals with ASD.

### Methods

Thirty patients (26 females, age: 72.7±4.5, Height: 1.58±0.09m, Weight: 67.7±16.1kg) with clinically diagnosed thoracolumbar and/or lumbo-sacro-pelvic deformity (SRS/Schwab classification; Cobb angle >25°) were recruited. Three-dimensional (3D) trunk and pelvis kinematics were recorded as each patient performed 5 acceptable trials of 10-meter walk test at self-selected speed (Vicon®-100Hz) at initial evaluation (pre), 45min post fitting (post45m) with Peak™ scoliosis brace and after 8 weeks (average 4.5 hour/day) of bracing (post8w). A one-way RM-ANOVA was performed to determine kinematic differences between the 3 time points. Post-hoc analyses were also performed using the Bonferroni correction (p<.05).

### Results and Discussion

Statistically significant changes in trunk ROM were found in all three planes of motion (p<0.01), and in the frontal and transverse planes (p<0.019) for pelvis ROM. Post-hoc analyses showed significant reductions between Pre- and Post45m measurements in trunk ROM in all three planes (p<0.01), and the frontal and transverse (p<0.05) planes for pelvis ROM (Figure 1). No other significant changes were observed. Difference in Post45m and Post8w could be due to testing performed without the brace for Post8w session.

For the trunk sagittal and frontal planes, both the Pre- and Post45m motion stayed within the normal ranges compared to

the literature [3]. However, for Post45m, transverse plane ROM was lower than the expected mean ranges. These results indicate the brace does not restrict trunk movement in a way that would cause gait or balance impairments related to trunk and head stiffness as seen with other bracing methods [4].

Pre-bracing, all three planes of pelvis motion were outside of the normal ranges reported in the literature [5]. Immediately after bracing, frontal and transverse plane ranges reduced to within the normal limits but not for the sagittal plane. Restoring pelvic motion to a normal range could lead to a smoother and energetically more efficient gait [5]. Minimal changes were observed with 8 weeks of bracing, suggesting a need for continued use during activities of daily living or increased hours/day compliance for sustained effects.

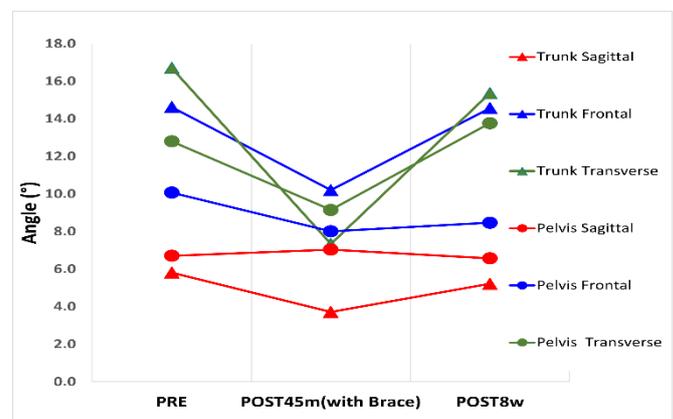

Figure 1: Pre-, Post45m, and Post8w kinematics

### Conclusions

Bracing for individuals with ASD resulted in a healthy reduction in pelvis ROM and although trunk ROM was reduced, it remained in normal range in the sagittal and frontal planes. With immediate use, these kinematic changes could lead to improved gait biomechanics in patients with ASD in addition to the previously shown reductions in pain [1].

### Summary

Despite the ability to assess joint loading and muscle force, musculoskeletal models (MSM) are still not widely used clinically. A review of the recent literature revealed that over the last 10 years, only 39 published works featured the use of these models in the design of training programs, surgical decision making, and informing general healthcare practice. Collaborations should be encouraged between model developers and clinical teams to create accessible software, usable with minimal input and programming skills.

### Introduction

MSM are simulation tools through which biomechanical analysis of human movement can be performed non-invasively, the outputs of which include muscle and joint contact forces (JCF). This enhanced analysis requires complex optimization [1], which can be time-consuming and requires additional expertise beyond that of routine clinical training. The utility of such models in a healthcare environment is largely unknown. Therefore, a narrative review was performed to classify the most recent uses of MSM in clinical practice.

### Methods

A search of the literature was performed using the online databases Scopus and PubMed. Titles, keywords and abstracts were searched using terms which included *Musculoskeletal model\**, *biomechanical model\**, *inverse dynamic\**, *joint contact force\**, *joint reaction force\**, and *muscle*. Papers were collated up to 24<sup>th</sup> August 2020.

Only peer reviewed articles, published in 2010 onwards, were considered. Exclusions included: robotics, finite-element analysis, animals, cadavers, unrelated to clinical outcomes, validation/model development, not using MSM, or not featuring a patient population or clinical intervention. Work containing only healthy controls was included if assessing a clinical intervention for patients. Articles were classified by use, iterating groups to find the minimum number that would contain all included studies. The authorship of each article was also noted as a surrogate measure of clinical utility.

### Results and Discussion

4662 abstracts were found and 39 full papers were deemed appropriate for review. Of these papers, 38 were co-authored by clinical and engineering/modelling authors, with 1 paper

authored solely by the latter. Five distinct categories were created: Assessment of non-surgical treatment (3/39); Assessment of orthotic devices (10/39); Surgical decision making (3/39); Assessment of surgical interventions (10/39) and the assessment and/or design of exercises and rehabilitation programmes (13/39). Reviewed work included the assessment of knee braces in the treatment of osteoarthritis [2], optimizing rehabilitation programmes using JCF [3], and deciding on the necessity of hamstring lengthening surgery in adolescents with cerebral palsy [4].

Only 7 of the reviewed papers analysed movements other than gait. Expanding the list of tasks analysed in treatment decision making is vitally important in improving outcomes. Higher functioning patients, such as elite athletes and those in the military, will desire a return to activity beyond ambulation. Validation studies should routinely address a greater number of tasks to ensure the needs of a population are met.

Reviewed articles regularly commented that individualised care could be optimised through the use of MSM. However, there is still a lack of published work showing the use of MSM as tools for patient care despite the ability to assess long- and short-term joint loading, and muscle overuse, during clinical decision making. The large number of papers focused on the development/validation of MSM, and associated authorships of the reviewed papers, highlight the absence of mature software available for clinical use.

### Conclusions

There is an absence of evidence, and therefore numerous challenges to overcome, for the use of MSM in regular clinical practice. The reviewed work mainly contained efforts to assess existing treatment methods, as opposed to employing MSM as a tool itself. The authors call for further model developer collaborations and increased awareness of these modelling techniques in clinical fields, combining the numerous available platforms to produce MSM which can be used in the healthcare decision-making process.

## Computational modelling of proximal and distal epiphyseal and appositional growth of the femur in children

Andreas Lipphaus<sup>1</sup>, Andreas Wegener-Panzer<sup>2</sup>, Ralf-Bodo Tröbs<sup>3</sup>, Ulrich Witzel<sup>1</sup>

<sup>1</sup>Biomechanics Research Group, Chair of Product Development, Ruhr-University Bochum, Bochum, Germany

<sup>3</sup>Department of Pediatric Surgery, Helios Hospital St. Johannes, Duisburg, Germany

Email: [andreas.lipphaus@rub.de](mailto:andreas.lipphaus@rub.de)

### Summary

Mechanical loading of the growth plate modulates bone shape. Combined modelling of epiphyseal and appositional growth can predict bone development.

### Introduction

Longitudinal growth of the femur occurs at the epiphyseal plates where the distal plate contributes to 70% of femoral growth. Epiphyseal growth is influenced by biological and mechanical factors. The predominant mechanobiological theory states that mechanical stimulated growth accounts for 50% of the total growth and is determined by deviatoric shear and hydrostatic stress [1]. Appositional growth takes place at the bone surfaces and increases the bone diameter. It has been assumed that the benefit of mechanical modulation of pediatric bone growth is to correct deformities [2], leading to bending-minimized lightweight design. Several computational models of bone growth have been established. However, most models only include a single growth plate, neglect different plate specific growth rates or do not include appositional growth. Our aim is to provide a comprehensive mechanobiological model of femoral growth.

### Methods

A finite element model from literature of a femur based on MRI scans of a healthy 8-year-old child (20.4 kg, 1.24 m) is used [3]. The growth plate in the femoral neck and the distal growth plate are modeled as two layers each 0.6 mm thick representing the proliferative and the hypertrophic zone. Hypertrophic growth is modeled as unidirectional expansion in the direction of the highest absolute principal stress and proliferation by isotropic expansion. Biological baseline growth is 0.9 month<sup>-1</sup> for the proximal and 2.1 month<sup>-1</sup> for the distal growth plate. Mechanically stimulated growth is described by the weighted sum of the deviatoric shear stress  $\sigma_S$  and hydrostatic stress  $\sigma_H$ . Appositional growth is simulated by displacement of the external nodes normal to the bone surface. Periosteal apposition rate is fixed at 2  $\mu\text{m}/\text{day}$  for areas with compressive 3<sup>rd</sup> principal stresses of more than 20 MPa. Young's modulus is 12000 MPa for cortical and 500 MPa for spongy bone and 6 MPa for the growth plate. All calculations are performed in ANSYS Mechanical 19.2 (ANSYS Inc, Canonsburg). One iteration represents growth during one month and six iterations are performed.

### Results and Discussion

After six simulated months, an increase of femoral length by 16.8 mm is predicted. The femoral shaft diameter enlarges

by 0.36 mm. Appositional growth is highest on the concave side of the bone leading to a reduced curvature and hence a more homogenous stress distribution in the femoral shaft. However, structural adaptations are relatively slow and cannot fully compensate bending stresses after six simulated months. Muscle forces seem to play a predominantly role in skeletal lightweight design. Limitations of this study include the non-consideration of changes in muscle lines of actions, muscles forces, or the bone density during growth as well as resorption of bone.

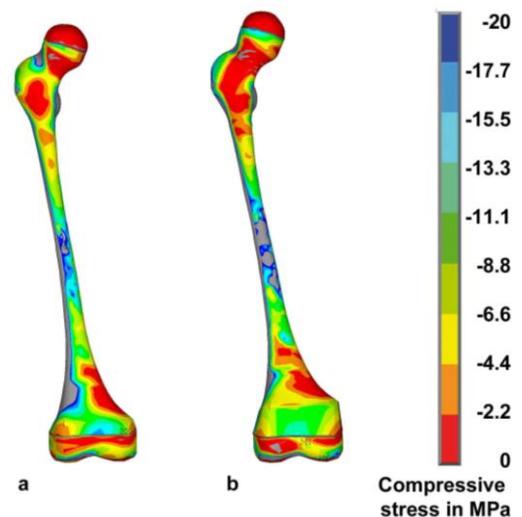

Figure 1: Frontal view of bone shape and 3rd principal stresses a) before and b) after 6 months of simulated growth

### Conclusions

Combination of epiphyseal and appositional growth is necessary to model bone development. The contribution of both mechanisms to reduce bending stress in terms of lightweight design needs further investigation.

# Identification of Optimal Laxity Tests To Stretch Individual Parts of Knee Ligaments

Michael S. Andersen<sup>1</sup>, Dennis Pedersen<sup>2</sup>

<sup>1</sup>Biomechanics Research Group, Department of Materials and Production, Aalborg University, Aalborg, Denmark

<sup>2</sup>Regional Development, Central Denmark Region, Denmark

Email: msa@mp.aau.dk

## Summary

We developed a novel approach to identify optimal knee laxity tests to stretch knee ligaments relatively more than other ligaments and applied it to identify optimal tests on a biomechanical model. For some ligaments, the optimal load cases resemble those applied clinically while for others, the optimal tests are much different. Our results have implications for the development of new laxity tests to diagnose ligament injuries or identify ligament properties from laxity tests.

## Introduction

Knee instability can arise for several reasons and can lead to pain, joint degradation and an overall reduced quality-of-life [1]. To advance our understanding of knee instability, it is important to gain insight into the mechanical properties of the knee ligaments *in vivo*, which cannot be measured directly.

Recently, we developed a novel 3D laxity measurement technology [2] that enables applying any load case to the knee. This provides an opportunity to re-think how laxity tests are performed and tailor the applied loads to stretch some ligaments relatively more than others and thereby having the best data to estimate the ligament properties from. The purpose of this study was to identify such optimal laxity tests.

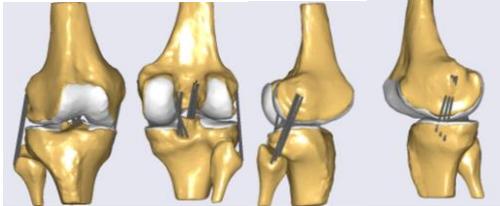

Fig. 1 Illustration of the applied knee model.

## Methods

A subject-specific knee model based on a MRI scan of a female subject (27 year-old, 1.72 m, 61 kg) was developed in the AnyBody Modeling System (AnyBody Technology, Denmark) using the Force-dependent Kinematics (FDK) approach [3](Fig. 1). The contact between the tibial and femoral cartilage and the four major ligaments were included.

As inputs to the model, we provided the knee flexion angle as well as an applied force and an applied moment to tibia. The force was applied to the tibial tuberosity and the moment as a pure moment in a tibial ISB anatomical coordinate system.

We introduced five FDK degrees-of-freedom that were allowed to equilibrate according to the applied loads, ligament and contact forces. A reaction moment around the knee flexion axis was included to simulate a fixated knee flexion as typically done during laxity tests. To identify what we will denote the optimal load cases to stretch each element of the ligaments, we solved the following optimization problem:

$$\max_{\mathbf{x}^1, \mathbf{x}^2} (F_i^2 - F_i^1)^2 - \frac{1}{N-1} \sum_{j=1, j \neq i}^N (F_j^2 - F_j^1)^2 \quad (1)$$

where  $\mathbf{x}^1$  and  $\mathbf{x}^2$  denote two load cases (i.e. each containing the knee flexion angle and applied force and moment on tibia).  $F_k^1$  and  $F_k^2$  denote the force in the  $k$ th ligament bundle under load cases  $\mathbf{x}^1$  and  $\mathbf{x}^2$ , respectively. The first term in the equation specifies the squared difference in the ligament bundle of interest ( $i$ th) from which the second term subtracts the average force in all other ligament bundles.  $N$  denotes the number of ligament bundles in the model.

## Results and Discussion

Load cases for all ligaments were found but for the sake of brevity, we present the results for the antero- and posterior-medial bundles of the Anterior Cruciate Ligament (ACL) only (Table 1). For the anteromedial ACL bundle, the optimal knee angles were found to be  $6.0^\circ$  and  $22.4^\circ$  and with a clear anterior and posterior force difference between the two loads. The posteromedial bundle of ACL, however, required one load at  $7.3^\circ$  of knee flexion, primarily directed anteriorly and the other at  $93.2^\circ$  directed posterolaterally.

## Conclusions

In this study, we presented a method to identify optimal loads to stretch individual ligament bundles. This approach, and the obtained results, can be applied to develop future measurement protocols, ultimately leading to a better estimation of knee ligament properties *in vivo*.

### Summary

This paper presents the development of an *in vivo* 3D knee laxity measurement method, combining robotics- and image-based technologies, to measure tibiofemoral poses under static 3D loads. With the robotic device, single and combined loads can be applied and it allows measurements of primary and secondary knee laxity, providing information about knee ligament integrity. The method also serves as a basis for improved patient-specific computational modeling, diagnoses and treatment.

### Introduction

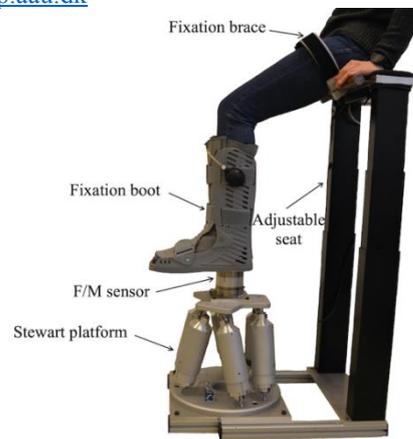

Instability in the knee joint, which is often attributable to instable knee ligaments, can lead to meniscal tear and osteoarthritis [1]. Therefore, knee ligament properties and knee stability are increasingly important areas in orthopedic treatment, surgery planning as well as prosthesis design [2].

Because of drawbacks such as soft tissue artifacts and constrained range-of-motion in the knee joint within current knee laxity investigations, Pedersen et al. [3] developed a methodology to measure knee ligament laxity in four degrees of freedom (DOF) *in vitro*, thereby overcoming aforementioned complications. As this technology has only been applied *in vitro*, this study provides a proof-of-concept of 3D knee laxity measurements of healthy subjects *in vivo*.

### Methods

The device (see Figure 1) was designed to fit into the EOS bi-planar imaging system (EOS imaging, France). To demonstrate the method, it was applied to four healthy male subjects. Seven different loads were applied during the experiment: No load, Internal/External (IE) rotation (6Nm), Anterior/Posterior (AP) translation (100N), Medial/Lateral translation loads (ML) (10Nm).

During peak stationary application of the load, x-rays were simultaneously taken from the frontal and lateral side. Magnetic Resonance Imaging (MRI) scans were obtained from whole lower limbs. After completion of data acquisitions, the following steps were accomplished: 1) segmentation of the 3D bone geometries from the MRI scans, 2) registration of the 3D bone geometries to the EOS bi-planar x-rays for each load case using an iterative closest point algorithm developed in MATLAB 2017b (Mathworks, USA) and 3) computation of the tibiofemoral poses in accordance with the ISB recommendations using the AnyBody Modeling System 7.3.0 (AnyBody Technology, Denmark).

**Figure 1:** Experimental setup showing all important components.

### Results and Discussion

Primary laxity, which refers to the knee laxity in the direction of the load application, was obtained. AP loading resulted in a tibial translation of  $1.8 \pm 1.2$ mm and  $1.4 \pm 2.2$ mm, respectively. IE rotational loading resulted in a tibial rotation of  $11.3 \pm 7.7^\circ$  and  $6.0 \pm 4.6^\circ$ , respectively. ML loading resulted in a tibial translation of  $-1.5 \pm 1.3$ mm and  $1.3 \pm 1.0$ mm, respectively.

Secondary laxity measurements, which refer to the knee laxity in all other directions, revealed an association between AP translations and IE rotations during AP loading.

Due to the fact that only healthy subjects were included in the study, the calculated mean of AP translations in part did not exceed the reported measurement uncertainty. This was expected, as intact ligaments do not allow for bigger than reported poses under a medically justifiable load application.

### Conclusions

A methodology that combines robotics- and image-based technology to assess knee laxity in four DOF *in vivo* was presented. The advantages of this new approach include accurate measurements of primary and secondary laxity, the ability of making unconstrained measurements as well as the ability of applying multiplanar load cases.

### Summary

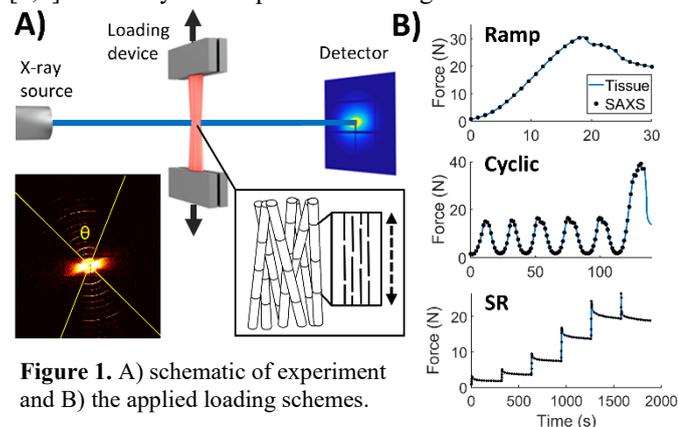

The collagen response in rat Achilles tendons to *in situ* tensile loading was studied using small-angle X-ray scattering (SAXS), to evaluate the relationship between the elastic and viscoelastic behavior of the tissue and collagen fibrils. The fibril strains were substantially lower than the applied tissue strains. Fibril strains increased linearly before yielding and breaking prior to tissue failure.

### Introduction

The mechanical properties of tendons are depending on a complex hierarchical design, where collagen is arranged into fibrils in a periodic, quarter staggered pattern at an intermolecular distance referred to as d-spacing. This study aimed to characterize the Achilles tendon's mechanical response to *in situ* loading at the nanoscale and how it relates to the resulting macroscopic tissue mechanical behavior.

### Methods

Achilles tendons (n=16) were harvested from Sprague Dawley rats (10-14 weeks) and stored frozen in NaCl until measurements at the SAXS beamline (cSAXS, Swiss Light Source, PSI) (energy 12.4keV, beam size 150 $\mu$ m). The tendons were loaded using a custom-made uniaxial tensile device (Fig 1) [1] while SAXS patterns ( $q=0.05-1.45\text{nm}^{-1}$ ) were acquired simultaneously from the center of the tendon. A radiation damage test was conducted prior to testing which ensured that all analysis was conducted below 28kGy. The tendons were loaded (5mm/min) in ramp to failure (N=5), cyclic loading (N=5) or stress relaxation (N=6). From collagen peaks identified from the azimuthally integrated scattering intensity over the angular sector  $\theta$  (Fig 1.A), local fibril strain and collagen structural parameters were extracted [2,3]. All analysis was performed using MATLAB.

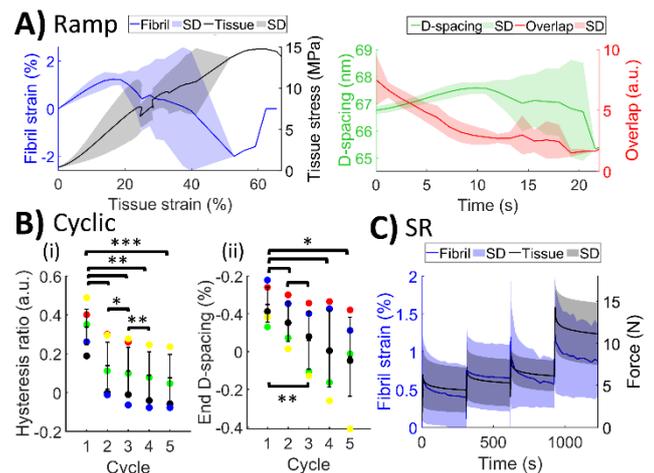

**Figure 1.** A) schematic of experiment and B) the applied loading schemes.

### Results and Discussion

For all loading schemes, the fibril strain, strain heterogeneity and overlap followed the macroscopic load. During ramp to

failure, the fibril strain increased linearly with tissue strain in the elastic region (Fig 2.A). The fibrils in the beam path yielded and broke (fibril strains  $1.3\pm 0.3\%$ ) prior to global tissue failure, which could be the result of an accumulation of nanoscale ruptures throughout the specimens. With increasing load, the fibril d-spacing increased and the overlap region decreased, which indicates fibril stretching and sliding simultaneously. During cyclic loading, the tissue hysteresis decreased with number of cycles (Fig 2.B, i). Interestingly, while the d-spacing at maximum load remained constant for all cycles ( $0.9\pm 0.5\%$ ), it decreased sequentially at the end of each cycle (Fig 2.B, ii). This suggests that the initial decline in tissue hysteresis is accompanied by an increase in fibril recovery and stretchability. During stress relaxation, most of the collagen parameters experienced transient relaxation simultaneously as the tissue (Fig 2.C).

**Figure 2.** Changes in fibril parameters during A) ramp to failure, B) cyclic loading and C) stress relaxation.

### Conclusions

Different loading scenarios enabled linking of the nano and macroscale in the Achilles tendon in terms of mechanics, such as accumulation of local fibril ruptures before global failure and adaptation of the nanostructure to the applied load.

### Acknowledgments

This project was funded by the European Union's Horizon 2020, No 731019 (EUSMI) through beamtime at cSAXS beamline, PSI, and by the Knut and Alice Wallenberg Foundation.

# Functional Performance Associated with Triceps Surae Muscle and Tendon Morphology in Patients with Achilles Tendinopathy

Kayla D. Seymore<sup>1,2</sup>, Haraldur B. Sigurðsson<sup>1</sup>, Karin Grävare Silbernagel<sup>1</sup>

<sup>1</sup>Dept. of Physical Therapy, University of Delaware, Newark, DE, USA

<sup>2</sup>Biomechanics and Movement Science Program, University of Delaware, Newark, DE, USA

Email: [seymorek@udel.edu](mailto:seymorek@udel.edu)

## Summary

This study determined the association between functional performance and triceps surae muscle and tendon morphology in patients with Achilles tendinopathy. Eighty-nine participants with confirmed Achilles tendinopathy had triceps surae muscle size and Achilles tendon viscoelasticity quantified with ultrasound imaging and continuous shear wave elastography (cSWE) prior to functional performance testing. Heel rise and hopping performance was associated with triceps surae muscle size and tendon shear modulus in patients with Achilles tendinopathy, when controlling for sex, limb, age, weight, and physical activity level.

## Introduction

Achilles tendinopathy is an overuse injury, often accompanied by alterations in tendon morphology, triceps surae muscle weakness, and impaired functional performance [1,2]. Though these tissues have complimentary roles in ankle and knee joint mechanics, the contribution of triceps surae muscle and tendon morphology to lower limb function has not been established in the Achilles tendinopathy population. Thus, the purpose of this investigation was to determine the association between functional performance and the triceps surae muscle size and tendon material properties of patients with Achilles tendinopathy.

## Methods

Eighty-nine (44 F, 47.6 ± 11.7 yrs) participants with clinically confirmed mid-portion Achilles tendinopathy were included in the study. Triceps surae size was obtained with B-mode ultrasound and characterized by cross-sectional area (CSA) of the medial (MG) and lateral (LG) gastrocnemius muscle, as well as thickness of the soleus (SOL) muscle, according to previously published protocol [3]. Achilles tendon material properties of shear modulus and viscosity were obtained in accordance with previously published cSWE protocol [4].

Functional performance was then quantified with a test battery. Total work and repetitions for a single-leg maximum endurance heel-rise test were measured using a linear encoder affixed to the heel. Hop frequency was calculated using a light

field comprised of infrared beams, which triggered a timer when the field was disrupted. The middle 20 hops during a 25-repetition continuous single-leg hopping test were analyzed.

Dependent variables of triceps surae muscle size and tendon material properties and independent variables of heel rise and hopping tests were analyzed with a two-way multivariate analysis of covariance to determine the association between functional performance and triceps surae muscle and tendon morphology, when controlling for sex, limb, age, weight, and physical activity level, measured via Physical Activity Scale questionnaire. Alpha was  $p < 0.05$ .

## Results and Discussion

Heel rise work ( $p=0.004$ ) and heel rise repetitions ( $p=0.031$ ), but not hop frequency ( $p=0.081$ ), were associated with triceps surae muscle and tendon morphology. Heel rise and hopping performance correlated to MG ( $p<0.001$ ,  $r^2=0.539$ ), LG ( $p<0.001$ ,  $r^2=0.490$ ), and SOL ( $p<0.001$ ,  $r^2=0.168$ ) muscle size and tendon shear modulus ( $p=0.001$ ,  $r^2=0.145$ ), after controlling for sex, limb, age, weight, and physical activity level. However, large differences in performance were required for appreciable change to morphology (Table 1). There were significant effects of sex, age, weight, and physical activity level ( $p<0.01$ ), with no effect of limb nor interaction of sex and limb on muscle and tendon morphology.

## Conclusions

Functional performance correlates to the triceps surae muscle size and Achilles tendon shear modulus of patients with Achilles tendinopathy. Future studies are needed to investigate the impact of changes in calf tissue morphology on functional performance.

## Summary

Despite the advantages of using biodegradable metals in implant design, their uncontrolled degradation and release remain a challenge in practical applications. A validated computational model of the degradation process can facilitate the tuning of implant biodegradation by changing design properties. In this study, a physicochemical model was developed by deriving a mathematical description of the chemistry of magnesium biodegradation and implementing it in a 3D computational model. The model was validated by comparing the predicted and experimentally obtained hydrogen evolution and change of pH during the corrosion tests in both immersion and perfusion setups, showing a good agreement between the results.

## Introduction

Due to their bio-friendly properties and non-toxic contribution to body metabolism, biodegradable metallic biomaterials, including magnesium (Mg), iron (Fe), and zinc (Zn), are regaining attention in recent years for fixation applications [1]. Despite these advantages, their fast degradation rate and uncontrolled release have always been a challenge. These issues are usually investigated by conducting *in vitro* and *in vivo* tests of biodegradable metallic scaffolds and implants, which requires conducting multiple experiments for different scenarios. In this research, we have developed a mathematical model to predict the degradation behavior of biodegradable metallic materials *in silico*, which makes it possible to study their corrosion in a simulated environment.

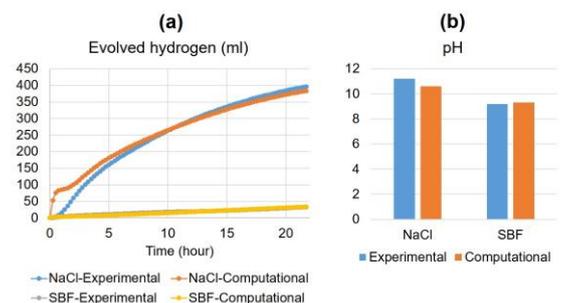

## Methods

In this study, a mathematical model of the biodegradation process of commercially-pure Mg was developed by deriving a set of partial differential equations (PDE), formulating the mass transfer and fluid flow phenomena as well as tracking the location of the moving corrosion surface during degradation. The equations were derived from the chemistry of biodegradation of Mg in saline (NaCl) and buffered (SBF) solutions, which includes the oxidation of the metallic part, reduction of water, changes in pH, formation of a protective film on the surface, the effect of different ions in the medium, and the effect of a perfusion setup. Tracking the movement of the surface was done by constructing a PDE based on the level set method, which captures the movement of the medium-scaffold interface by defining an implicit surface. The derived equations were coupled and solved using finite element methods. The degradation data to validate the models was collected from corrosion tests performed by using circulating media for simple scaffolds made of Mg. The model parameters were calibrated using a Bayesian optimization

approach, and the obtained parameters were used to simulate the pH changes in NaCl and SBF solutions.

## Results and Discussion

In order to obtain the degradation rate over time, instead of direct mass loss measurement, we measured the volume of formed hydrogen gas in Mg corrosion, which can be converted to mass loss by considering the stoichiometry of the reactions. Figure 1 shows the model output for the predicted produced hydrogen and the pH changes in immersion tests. The graph of the evolved hydrogen is used as input during the parameter calibration process, but the pH results are produced by the simulations using the optimized parameters to demonstrate the validation of the developed mathematical and computational models. The predicted pH result shows a difference of 5.35% for the simulation in NaCl and 1.03% for SBF simulation. Although the pH simulations are insufficient in terms of experimental input to call the model fully validated, the obtained validation results show that the developed mathematical and computational models give a correct *in silico* representation of the studied process.

**Figure 1:** Comparing the quantitative output of the model for the rate of degradation (a) and the pH changes (b) in NaCl and SBF solutions with experimentally measured values.

## Conclusions

Once fully validated, the models will serve as an important tool to find the biodegradable metal properties and predict their biodegradation behavior for improving the current workflows of designing biomedical implants and scaffolds.

## Changes in ankle and foot joint kinematics after fixed-bearing total ankle replacement

P.-A. Deleu<sup>1,2</sup>, B. Devos Bevernage<sup>1</sup>, L. Chèze<sup>2</sup>, R. Dumas<sup>2</sup>, A. Naaïm<sup>2</sup>, J.L. Besse<sup>2</sup>, T. Leemrijse<sup>1</sup>.

Email: pa.deleu@footandankleinstitute.be

### Summary

Total ankle replacement (TAR) is considered to be an optimal treatment strategy to relieve pain during walking in patients suffering from end-stage ankle osteoarthritis. The aim of this study was to investigate the post-operative effect of TAR on the foot joint angles. We included 28 patients suffering from post-traumatic end-stage ankle osteoarthritis scheduled for primary TAR. A multi-segment foot model was used to measure the kinematics of Ankle, Chopart, Lisfranc and MTP1 joints during gait. Post-operatively, patients demonstrated a significant increase in plantarflexion ankle joint angle and in dorsiflexion Chopart joint angle during loading response. No differences in joint angles were observed during midstance. During propulsion, an increase in the MTP1 dorsiflexion was observed. Clinical significance of this study dictates that patients after TAR preserve their residual pre-operative ankle dorsiflexion and the neighbouring foot joints seem also to be affected.

### Introduction

Recently, multi-segment foot models showed that one-segment foot model could lead to clinical misinterpretations of the benefits of TAR on estimates of range of motion [1]. Furthermore, one-segment foot model neglects our clinical understanding of how TAR benefits the function of neighbouring foot joints. Nevertheless, gait analysis studies continue to implement a one-segment foot modeling approach to assess the effect of TAR [2]. Therefore, the purpose of this study was to assess changes in the intrinsic foot angles after TAR providing in-depth insight into the joints distal to the affected joint.

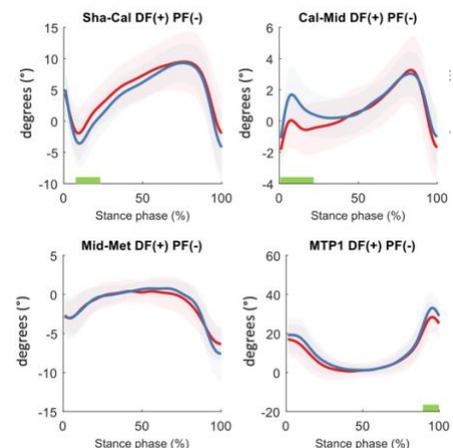

### Methods

This study investigated 28 patients suffering from post-traumatic end-stage ankle osteoarthritis scheduled for primary TAR between May 2017 and January 2020. The subjects were asked to walk at self-selected speed barefoot over a 10 m walkway. Inter-segment foot kinematics were obtained using a motion-capture system of 10 Miquis cameras (Qualysis, Sweden) at a 200Hz frequency. An adapted Rizzoli foot model proposed by Deschamps et al. [3] was used. All 1D data were time-normalized to 100% of the stance phase. A paired Hotelling's  $T^2$  (SPM{T2}) was performed to assess the time varying 3-component angles of the Ankle, Chopart, Lisfranc and MTP1 joints.

### Results and Discussion

A waveform comparison of foot joint angles is displayed in Figure 1. Differences in waveform patterns were limited to dorsi-/plantarflexion inter-segment joint angles. At loading

response, the ankle plantarflexion joint angle as well as the Chopart joint dorsiflexion increased slightly. These differences may be explained by the fact that patients were not afraid to land properly on their affected ankle joint after surgery during walking. No differences in joint angles were observed during midstance. This finding confirms that TAR preserves the residual pre-operative dorsiflexion range of motion after surgery. During propulsion, an increase in the MTP1 dorsiflexion was observed. The results of this analysis suggest that the kinematic behavior of the foot joints distal to the affected ankle joint seem to improve post-operatively. The reason for this is not clear to determine conclusively to what extent the changes in joint foot angles are attributable to pain relief and to what extent they are related to improvement in a more "functional" foot. The main limitation of this study is the use of skin markers to estimate segment foot kinematics. Soft-tissue artefact reported as angular errors in the dorsi-/plantar-flexion, ev-/inversion and add-/abduction axes respectively has been estimated to be as much as 2.45°, 3.57° and 4.28° [4]. Through, this artifact is supposed to affect similarly pre- and post-operative kinematics, allowing for comparative analysis.

**Figure 1:** Pre- and Post-operative kinematic of the Ankle, Chopart, Lisfranc and MTP1 joints (Red line : pre-op; Blue line : post-op; significant differences highlighted with a green box)

### Conclusions

The outcome of this study showed that changes in foot joint angles after TAR are not restricted to the affected ankle joint, but seem also to affect the neighbouring foot joints.

### Summary

This work presents an improved spine model with an articulated ribcage capable of simulating scoliosis deformities. In this model, joint constraints were defined based on experimental data. A set of clinically accepted parameters that can be measured from bi-planar radiographs, controls the spine curve and ribcage configuration of the model. The normalized compression and lateral shear forces of the intervertebral joints along the spine were reported for a normal and a scoliotic spine. Future use of the model will include investigation of the pathomechanism behind adolescent idiopathic scoliosis, simulation of brace effects, and optimization of brace treatments.

### Introduction

The pathomechanism underlying Adolescent Idiopathic Scoliosis (AIS) has remained unclear [1], and a better biomechanical understanding of the phenomenon might contribute to uncovering the phenomenon. The linked system of spinal vertebrae, ribs, and sternum is highly constrained with multiple closed loops, and an anatomically valid constraint definition is essential for reliable force transmission through the model. This work presents an improved and kinematically determinate musculoskeletal spine model with an articulated ribcage, capable of simulating various spine deformities.

### Methods

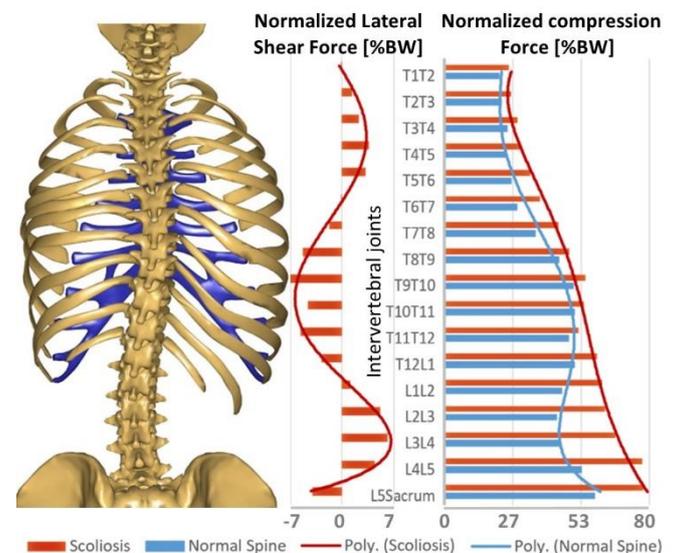

A previously presented spine model [2] forms the basis of the new model. The model was developed in the AnyBody Modeling System, and different types of kinematic joints were implemented [3], based on reported clinical data of intact ribs, leading to a kinematically determinate model, which can simulate healthy spines and ribcage kinematics as well as scoliotic deformations without violations of anatomical constraints.

The posture is defined by a set of fifteen clinically accepted measures (such as Cobb angle) and anatomical degrees-of-freedom (DOF) from the patient's bi-planar radiographs. Muscle and joint reaction forces are simulated by an inverse dynamics analysis.

### Results and Discussion

The patient's spine curve and rib rotations were constructed from radiographs (Figure 1). The normalized compression (NC) and normalized lateral shear forces (NLS) of the intervertebral joints along the lumbar and thoracic spine were presented for normal and scoliotic spines, and polynomial curves were fitted to them.

The lumbar and thoracic apical vertebrae of the scoliosis patient were L3 and T8, respectively. The NLS of the normal spine is zero. However, scoliosis seems to increase the NLS corresponding to the curve shape, indicating that the turning points of the spine curve (L1 and T6) occurred where the NLS polynomial curve hits zero. Besides, the progression of scoliosis appears to increase the NC, especially in the lumbar region.

**Figure 1:** Posterior view of the scoliosis model. Normalized lateral shear and compression forces of the intervertebral joints for the normal and scoliotic spine, and their fitted polynomial curves. All forces are normalized to body weight [BW].

### Conclusions

This work presents an improved spine-ribcage model for simulation of scoliosis deformities, suitable for investigating the pathogenesis of AIS by analyzing force trends. In a future perspective, the model can simulate the effect of supportive forces from braces, which can contribute to an optimization of brace interventions.

# Applied Biomechanics and Computational Modelling to Prevent and Manage Upper Extremity Injuries in Rowing

Caryn A. Urbanczyk<sup>1,2</sup>, Alison H. McGregor<sup>2</sup>, Anthony M.J. Bull<sup>1</sup>

<sup>1</sup>Musculoskeletal Mechanics Lab, Dept. Bioengineering, Imperial College London, London, UK

<sup>2</sup>Biodynamics Lab, Dept. Surgery & Cancer, Imperial College London, London, UK

Email: c.urbanczyk17@imperial.ac.uk

## Summary

Investigating shoulder loading during rowing is a major step toward understanding mechanisms of injury, tailoring training programs, and improving performance coordination across all rowing athletes. Optical motion capture and musculoskeletal modelling were used to assess 3D shoulder biomechanics during rowing. Differences between athlete cohorts in glenohumeral joint forces, shoulder stability and muscle recruitment have implications for performance and pathology.

## Introduction

Coaches and trainers rely on years of experience to visually assess athlete movement and posture relative to aesthetic characteristics representing an ideal style, [1] ultimately used as a surrogate to indicate high performance. When movements deviate from the circumscribed style, rower technique is manipulated through visual and audio cues to improve performance characteristics of force and timing.

Expert testimony, observational data and visual analysis are powerful and beneficial but lack rigor needed to sufficiently quantify the rowing stroke. Quantitative methods like computational modelling can identify biomechanical parameters crucial to rowing performance and athlete health.

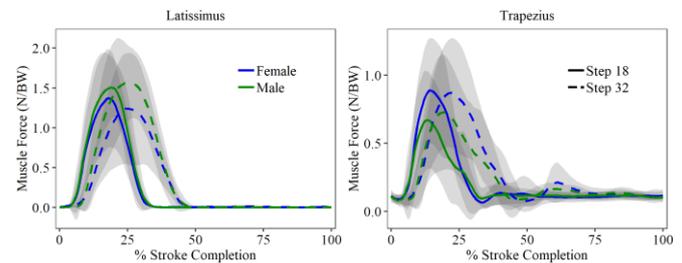

## Methods

A 10-camera optical motion capture system (Vicon, UK) was used to track kinematics ( $f_c=100\text{Hz}$ ) of 39 athletes (22 female/17 male) regularly rowing at the time of study participation. 24 reflective markers tracked the torso, scapula, arm, and hand while athletes performed four, 3-minute rowing trials at increasing rate (18/24/28/32 strokes per minute, spm) on an instrumented ergometer (Concept 2, USA), with load cells at the handle and seat, strain gauges under the footplates, and a rotary encoder on the flywheel.

Motion data and external forces, normalized to percent stroke completion, where 0% is the *catch*, provided inputs to the UK National Shoulder Model [2], Glenohumeral joint reaction forces and surrounding shoulder muscles forces at the *catch*, max handle force (*MHF*), and *finish* were analyzed by repeated measures ANOVA ( $\alpha<0.05$ ).

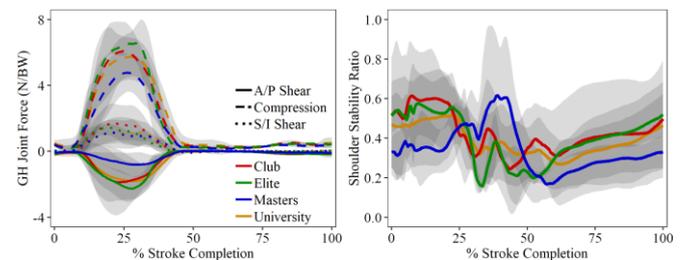

## Results and Discussion

Males generate force through prime shoulder movers, latissimus dorsi ( $p=0.048$ ) and serratus anterior ( $p=0.005$ ), focusing on large back muscles for humeral extension and internal rotation. However, women show a wider distribution of cumulative muscle force (Figure 1), including higher max force in trapezius ( $p=0.003$ ). Females also emphasize biceps brachii and brachialis muscle recruitment for shoulder extension and abduction.

**Figure 1:** Male v. female BW normalized muscle force (mean  $\pm$  sd).

Age related decline in skeletal muscle mass, aerobic fitness [3] manifest in biomechanical changes in ergometer rowing. Compared to younger rowers in university, club, and elite cohorts, masters rowers ( $>27\text{yrs}$ ) show less GH compression, S/I shear ( $p=0.013$ ), and a distinct shoulder stability pattern (SSR) near the *finish* position (Figure 2).

**Figure 2:** GH joint forces (mean  $\pm$  sd) at 32spm (*left*) & SSR at 18spm (*right*) per age/competition level.

## Conclusions

Training programs should include greater focus on shoulder muscular endurance to minimize effects of fatigue, and females may benefit specifically from upper extremity strength and conditioning programs. GH instability is affected by stroke rate and position within the stroke. Chronic shoulder pain in rowers results from compromised shoulder positioning [4], instability under high load and acceleration, and likely worsens with age. Computational modelling can sensitively delineate the effects of rowing dynamics, making it valuable to athletes, coaches, and trainers for technique optimization, training impact, and strength and conditioning balance. In this case, specifically to ensure proper scapular and glenohumeral mechanics.

# Sensitivity analysis of joint contact forces to individual muscles maximal isometric force using a Gaussian process emulator

Erica Montefiori<sup>1</sup>, Ivan Benemerito<sup>1</sup>, Alberto Marzo<sup>1</sup>, Claudia Mazzà<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering & INSIGNEO Institute for *In Silico* Medicine, The University of Sheffield, UK  
Email: e.montefiori@sheffield.ac.uk

## Summary

Identifying model parameters that mostly influence the outputs of musculoskeletal models (MSKMs) would allow to simplify model personalisation. In this study, a Gaussian process emulator (GPE) enabled a sensitivity analysis to identify seven muscles in the lower limb whose muscle maximal isometric force ( $F_{max}$ ) mainly influences the estimate of joint contact forces (JCFs). This suggests that their personalisation should be prioritised among others.

## Introduction

MSKMs, widely adopted to estimate JCFs, require numerous input parameters, ideally to be personalised to increase their accuracy. An example is muscle  $F_{max}$ , computed from personalised muscle volumes, characterised by high between- and within-subject variability [1]. Sensitivity studies analysing the effect of  $F_{max}$  on model output reached contrasting conclusions depending on the range of values assigned to each muscle's  $F_{max}$  and on the adopted MSKMs [2] highlight the need to further investigate the model- and subject-specificity of MSKM outputs. Moreover, previous analyses were limited to one muscle at the time over few thousands of simulations, due to model complexity and computational time. GPEs are statistical tools using minimal training data to investigate models' input-output relationship, enabling low-cost sensitivity analyses [3]. This study investigated the suitability of GPEs to test the sensitivity of JCFs to lower-limb muscle  $F_{max}$  and identify those muscles whose  $F_{max}$  mostly affects the estimate of JCFs.

## Methods

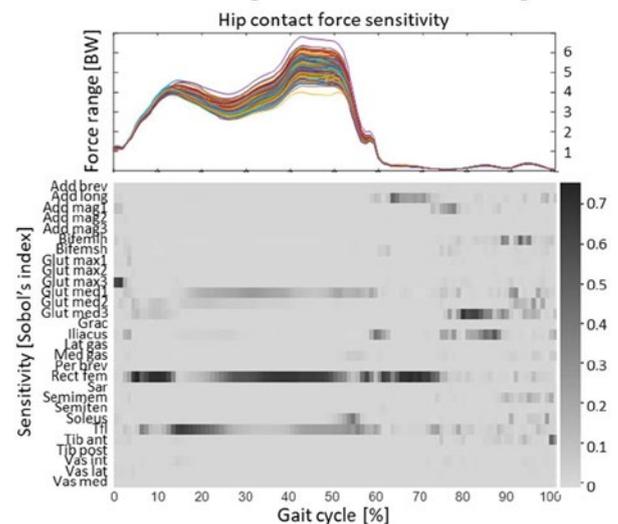

Gait analysis and magnetic resonance imaging (MRI) were collected from one woman (70.5y, 61.4kg, 1.64m). MRI was used to build a MSKM of the lower limb following established methods [4].  $F_{max}$  was personalised for twenty-nine muscles according to  $F_{max} = \sigma * V_M / (l_{opt})$ , where  $V_M$  is the volume of the MRI-segmented muscle,  $\sigma$  is the specific tension,  $l_{opt}$  is the optimal fibre length estimated from the MSKM [1,4].

Normal distributions of  $F_{max}$  were calculated from mean and standard deviation of twenty-nine muscle volumes measured across a cohort of eleven older women [1]. Random sampling of  $F_{max}$  distributions allowed to determine two hundred combinations of lower-limb muscle  $F_{max}$  input to the original MSKM, i.e. generating two hundred variations. MSK simulations were run in OpenSim (<https://simtk.org/>) for one walking trial to estimate resultant JCFs.

$F_{max}$  and associated JCFs (hip, knee and ankle) were used to train ( $n = 50$ ) and validate ( $n = 150$ ) the emulator, whose quality was quantified as the root mean square percentage error between predicted (from GPE) and simulated (from OpenSim) JCFs. 150000  $F_{max}$ -JCF couples generated by the GPE were used to investigate the effect of each  $F_{max}$  on the JCFs, as quantified by the Sobol's index ( $S_i$ ) [3].

## Results and Discussion

GPE predictions showed  $1.08 \pm 0.54\%$ ,  $2.06 \pm 1.1\%$  and  $1.47 \pm 1.22\%$  error for the hip, knee, and ankle validation data, respectively. The sensitivity analysis showed that the hip JCF was mainly influenced by Gluteus medius, Rectus femoris, and Tensor Fasciae Latae (Tfl) (max  $S_i$ : 0.31, 0.75, and 0.65, respectively), especially at the two force peaks (Figure 1). Knee JCFs were influenced by Rectus femoris, Soleus, and Tfl (maximum  $S_i$ : 0.90, 0.76, and 0.55, respectively), and ankle JCFs by Semimembranosus, Soleus, and Tibialis anterior and posterior (maximum  $S_i$ : 0.30, 0.68, 0.90, 0.55, respectively). Indeed, these muscles are known to contribute maximally to the JCFs of the respective joint [2] and our results confirm that their personalisation should be prioritised.

**Figure 1:** Two hundred hip JCF curves resulting from changes in  $F_{max}$  (top) and sensitivity to muscles'  $F_{max}$  over time (bottom).

Including measurable input and more subjects in a comprehensive analysis, using computationally efficient tools such as GPE, will enable to unveil dependence between each parameter and model output.

## Conclusions

Personalisation of MSKMs can be informed by GPE to discriminate between the parameters that need personalisation and those that can be scaled from literature values.

## Summary

Herein, a novel atlas-based multiscale musculoskeletal (MS) finite element (FE) modeling pipeline was used to investigate mechanics of knee cartilage and menisci during different daily activities and rehabilitation exercises of individuals with knee osteoarthritis (KOA). The pipeline comprised of an electromyography (EMG) assisted MS model linked to an FE model with fibril-reinforced poroviscoelastic (FRPVE) cartilages and menisci. In general, smaller tissue mechanical responses were observed during walking (compared to other daily activities), and during the non-weight-bearing exercise (compared to other rehabilitation exercises).

## Introduction

Knee joint contact force (JCF) and tissue mechanics (such as stress and strain) are known as important quantities in the onset and progression of MS disorders and the success rate of rehabilitation protocols. Yet, no studies have investigated all these quantities during different activities in KOA individuals. Hence, we utilized a novel pipeline, developed as a rapid MS-FE analysis toolbox, to investigate joint- and tissue-level cartilage mechanics during different daily activities and rehabilitation exercises of individuals with KOA.

## Methods

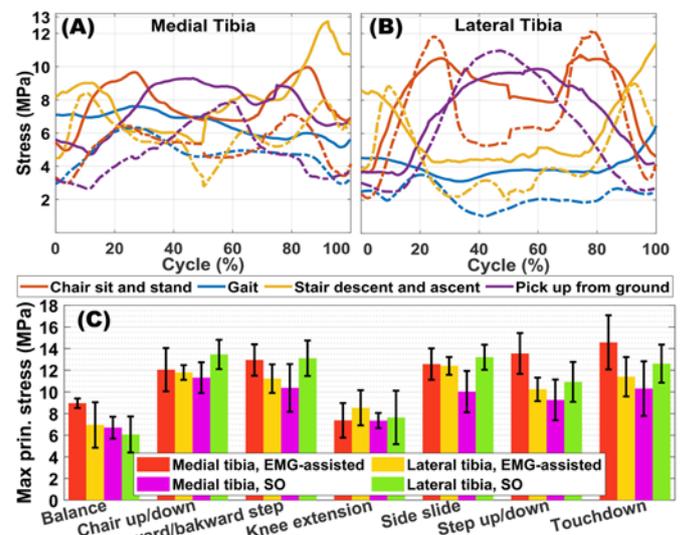

**Data Collection:** Fifteen participants with KOA performed six different daily tasks and seven rehabilitation exercises [1] while marker trajectories, ground reaction forces, and EMGs (from 8 muscles of the leg of interest) were recorded. Magnetic resonance images were acquired to create FE models.

**Analyses:** The pipeline consisted of an EMG-assisted muscle-force driven FE model with FRPVE cartilages and menisci [2]. EMG-assisted MS analyses were done within CEINMS toolbox [3]. An atlas-based FE modeling toolbox [4] was utilized to rapidly create the FE model geometries (i.e., 15 FE models), which consisted of subject-specific femoral, tibial, and patellar cartilages, menisci, and knee ligaments. The maximum JCFs, stresses, collagen fiber strains, and fluid pressures within different regions of knee cartilages and menisci were compared between activities using repeated measures ANOVA. Also, similar analyses were done with a static-optimization (SO) driven MS-FE pipeline [5] to investigate how the exclusion of subject-specific muscle activations alters tissue mechanics.

## Results and Discussion

The EMG-assisted pipeline estimated either comparable or greater magnitudes in tissue mechanics compared to the SO

pipeline, due to higher muscle activations/co-contractions. In general, mechanical stresses of smaller magnitudes were observed during walking compared to other activities ( $p < 0.05$ , Figure 1A-B), and during knee extension exercise compared to other dynamic exercises ( $p < 0.001$ , Figure 1C).

**Figure 1:** Maximum principal stresses: (A, B) timeseries during daily activities (solid-lines = EMG-assisted, dashed-lines = SO), and (C) maximum of entire rehabilitation exercises that is averaged over all study participants (error bars = 95% confidence interval). Statistics are not included to improve readability.

## Conclusions

This study's results provide insights into the more efficient design of subject-specific rehabilitation protocols and daily activity modifications concerning the onset and progression of KOA or post-surgery rehabilitation. Assisting the pipeline with EMGs significantly altered estimated knee mechanics, which may emphasize the importance of considering the subject's muscle activation patterns when subject-specific mechanically-induced cartilage remodeling is of interest.

## Summary

Anterior cruciate ligament (ACL) loads during drop vertical jump (DVJ) were estimated via a musculoskeletal finite element (MSFE) model. Simulation conditions with or without inputs of ground reaction force (GRF) and muscle forces showed hamstrings activation significantly decreased and regulated magnitude and timing of ACL loading.

## Introduction

ACL injury reduction training focused on lower body strengthening and landing stabilization [1]. *In vitro* studies showed that quadriceps forces increase ACL strain, as opposed to hamstring forces that decrease strain. However, the magnitudes of the effects of quadriceps and hamstrings forces on ACL loading and their timing during *in vivo* landings has remained unclear. The purpose of this study was to investigate the effects of knee muscle forces on ACL loading and their timing during landing.

## Methods

Thirteen young female athletes performed three DVJ trials and their motion was recorded with three-dimensional motion capture. Electromyography-informed optimization was performed to estimate lower-limb muscle forces with an OpenSim musculoskeletal model [2]. To estimate ACL loading during landings, a whole body MSFE model was developed with a previously validated FE knee model [2]. The joint motion and muscle forces obtained from the OpenSim simulations were applied to the MSFE model. In the FE simulations, pelvis, knee, and ankle joint centers were kinematically driven while the muscle forces and GRF were applied. Hip rotations and knee rotational and translational degrees of freedom (DOF) remained free. This strategy was used to simulate knee biomechanics, in which hip rotation and knee abduction/adduction and knee translational DOF adjust their position as a function of forces at the knee.

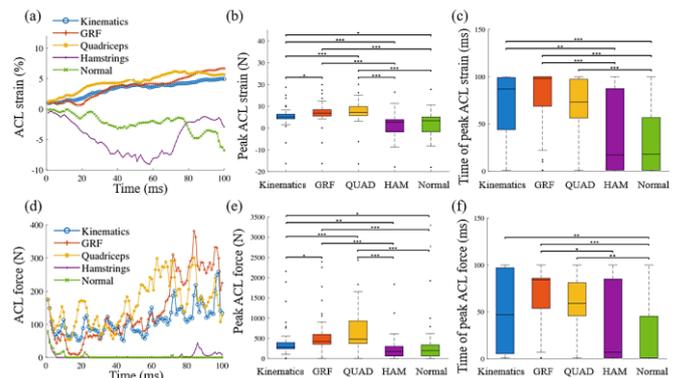

The FE simulation was conducted with five different conditions in order to investigate the individual effects of GRF and muscle forces on ACL loading:

1. Kinematics (No application of GRF or muscle force)
2. GRF (kinematics + GRF)
3. Quadriceps (kinematics + GRF + quadriceps)
4. Hamstrings (kinematics + GRF + hamstrings)
5. Normal (kinematics + GRF + all muscles)

The Friedman test with a *post-hoc* Nemenyi multiple comparison test was used to examine the differences in ACL loading and peak time between the 5 conditions.

## Results and Discussion

Simulation of landing kinematics without GRF or muscle forces yielded an estimated median ACL strain and force to be 5.1% and 282.6 N, respectively (Fig. 1). Addition of GRF to kinematic simulations increased ACL strain and force to 6.8 % and 418.4 N ( $P < 0.05$ ). Addition of quadriceps force to kinematics + GRF simulations insignificantly increased ACL strain and force to 7.2 % and 478.5 N. Addition of hamstrings force to kinematics + GRF simulations decreased ACL strain and force to 2.6 % and 171.4 N ( $P < 0.001$ ). Addition of all muscles to kinematics + GRF simulations decreased ACL strain and force to 3.3 % and 195.1 N ( $P < 0.001$ ). ACL loading in the simulation with hamstrings force decreased from initial contact (time of peak: 1–18 ms) while the simulations without hamstrings force showed peak values at 47–98 ms ( $P = 0.024-0.001$ ; Fig. 1-c,f). These findings provide strong evidence that hamstring muscle activation contributes to protection of the ACL during landing tasks.

**Figure 1:** (a,d) Median waveforms and (b-c,d-e) comparisons of magnitude and timing of peak ACL strain and force with 5 different conditions (\*\*\*)  $P < 0.001$ ; \*\*  $P < 0.01$ ; \*  $P < 0.05$ .

## Conclusions

Hamstrings muscle activation had both a protective and greater relative effect to GRF and quadriceps activation on ACL loading and significantly decreased and regulated magnitude and timing of ACL loading during landing *in vivo*.

### Summary

Reduction is a primary objective of most treatments for vertebral fractures. However, the pre-fracture height and 3D shape of the vertebral body are unknown. Therefore, it is unclear how much height to restore in order to reestablish the pre-fracture biomechanics of the spine. In this study we propose a method based on Singular Values Decomposition (SVD) to predict the shape of a lumbar vertebral body from adjacent ones. A dataset of 20 patients was processed in a leave-one-out experiment. The L1 shape of the left-out vector was reconstructed with good accuracy. This method, once validated on a large cohort of patients, could be used to estimate the pre-fracture shape of a vertebra during the planning of the treatment strategy.

### Introduction

Vertebral fractures are a widespread disease which is often related to age and low bone mineral density [1]. The main goals in treating vertebral fractures are the reduction of the fracture and the stabilization of the structure to allow bone healing [2], but the shape of the vertebral body before the fracture is unknown. The goal of this study was to develop and evaluate a method based on SVD to predict the shape of the vertebral body of L1 from the shapes of T12 and L2.

### Methods

The geometries of T12, L1 and L2 of 20 patients were extracted from the VerSe'20 database [3]. The STL file of each vertebra was cut to remove the posterior elements. The resulting surfaces of the vertebral bodies were aligned based on 14 anatomical landmarks identified on the two endplates. Each surface was morphed to a template mesh in Scalismo [4]. For each patient, a vector  $\mathbf{h}$  with the nodes coordinates of the morphed T12, L1 and L2 surface meshes was built. Each time, one vector was left out, and the dataset of 19 remaining vectors was compressed with SVD keeping the first 15 modes. The left-out vector can be expressed as a linear combination of the 15 modes as:  $\mathbf{h}_{proj} = \mathbf{A} * \boldsymbol{\alpha}$ , where  $\mathbf{A}$  is a matrix composed of the 15 modes and  $\boldsymbol{\alpha}$  is a vector of 15 parameters. The L1 vertebral body was reconstructed from  $\mathbf{h}_{proj}$  and compared with the reference shape (morphed) to evaluate the compression. Then, a vector  $\mathbf{h}_{T12-L2}$  was obtained by considering only the coordinates of T12 and L2 from the left-out vector. The following linear system of equations was considered:  $\mathbf{A}_{T12-L2} * \boldsymbol{\alpha} = \mathbf{h}_{T12-L2}$ , where  $\mathbf{A}_{T12-L2}$  is the part of the  $\mathbf{A}$  matrix that includes only the coordinates corresponding to T12 and L2 from the 15 modes. A linear-least-squares (LLS) solution  $\boldsymbol{\alpha}'$  of the system was

calculated. These coefficients  $\boldsymbol{\alpha}'$  were used to reconstruct the vector of coordinates of L1 ( $\mathbf{h}_{L1}$ ) as:  $\mathbf{h}_{L1} = \mathbf{A}_{L1} * \boldsymbol{\alpha}'$ , where  $\mathbf{A}_{L1}$  includes only the nodes coordinates corresponding to L1 from the 15 modes. The mean and max relative distances between the predicted and the morphed shapes of L1 were calculated for each left-out vector.

### Results and Discussion

The mean and max projection distances between the morphed and original vertebral bodies, averaged over the 60 vertebrae, were  $0.31 \pm 0.03$  mm and  $2.51 \pm 0.44$  mm. The mean and max projection distances between the L1 vertebral body projected in the basis of modes and the reference morphed shape were  $0.93 \pm 0.19$  mm and  $4.08 \pm 0.71$  mm. The mean and max projection distances between the shape of L1 predicted from the shapes of T12 and L2 and the reference morphed shape were  $0.95 \pm 0.22$  mm and  $4.23 \pm 0.83$  mm, on average over the 20 bases built during the leave-one-out (Figure 1). The results suggest that this method can predict the shape of the vertebral body of L1 from the shapes of the two adjacent vertebrae with a reasonable accuracy. The distances obtained by LLS optimization were similar to the distances obtained by projecting the left-out vector in the basis of modes.

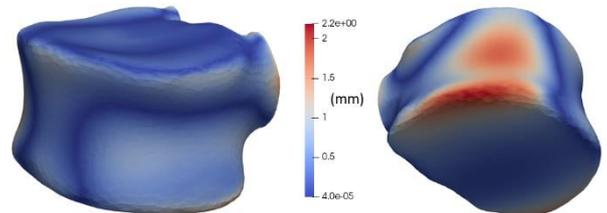

Figure 1: Distance map between predicted and morphed shapes (Patient #10).

### Conclusions

The shape of a L1 vertebral body could be predicted by the adjacent ones. This method will be tested on a large database of patients.

# High Density and Bipolar sEMG Based Ankle Joint Torque Prediction Using Machine Learning

Asta Danauskiene<sup>1</sup>, Federica Aresu<sup>1</sup>, Balázs Szabó<sup>1</sup>, Ruoli Wang<sup>1</sup>

<sup>1</sup>KTH MoveAbility Lab, Dept. Engineering Mechanics, KTH Royal Institute of Technology, Stockholm, Sweden  
Email: astad@kth.se

## Summary

The relationship between electromyography (EMG), muscle force and associated joint torque provides valuable information for development of rehabilitation robotics. In this study, high density surface EMG (HD-sEMG) data was collected simultaneously with ankle joint torque during sub-maximal and maximal voluntary contractions (MVCs) of plantar- and dorsi-flexors at different ankle angles. Machine learning (ML) approaches were implemented and evaluated to best predict measured joint torque profiles given extracted features from bipolar-sEMG and HD-sEMG recordings in two study cases. In both study cases, the usage of HD-sEMG data leads to a higher prediction accuracy.

## Introduction

Torque prediction driven by sEMG data has a great potential for use in rehabilitation [1]. This study aims to improve the accuracy of sEMG data driven joint torque prediction by employing HD-sEMG data and evaluate the prediction accuracy under different test protocols using Multi-Layer Perceptron (MLP) and Long short-term memory (LSTM).

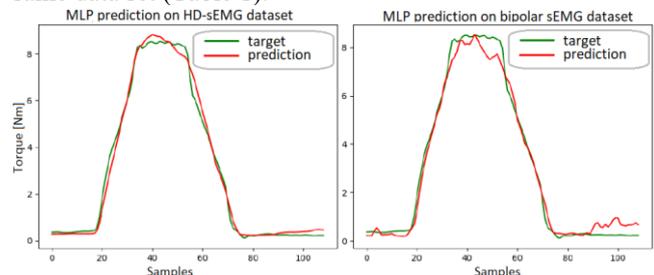

## Methods

Five healthy adults (3F/2M, age:  $28.6 \pm 5.4$  yrs) voluntarily participated in the study approved by the local ethics committee. The experiments were designed as isometric contractions of plantarflexors and dorsiflexors at 4 angles ( $15^\circ$  and  $7.5^\circ$  plantarflexion, neutral position, and  $10^\circ$  dorsiflexion) in a random order. Muscle contraction was performed at each angle with 70%, 50% and 30% of MVC by instructing subjects to follow a real-time trapezoidal force profile on the display with  $\pm 10\%$  error allowed. HD-sEMG signals of medial and lateral gastrocnemius, soleus, peroneus longus and tibialis anterior were collected using a multichannel bioelectrical signal amplifier (Quattrocento, OT Bioelettronica) simultaneously with torque data recorded using a load cell. The HD-sEMG data was filtered with a bandpass filter at 10 - 500Hz and two consecutive channels from each grid were chosen to represent bipolar sEMG signals. Features such as Maximum Absolute Value, the Waveform Length and the Root Mean Squared were used as input to predict torque using MLP and LSTM algorithms. Each algorithm is used for torque prediction in intra-session (prediction of torque profile on same conditions) and intra-subject (prediction of torque profile on a different footplate

angle) study cases and the performances were evaluated using RMSE and  $R^2$  scores.

## Results and Discussion

Preliminary results based on one subject are presented here. In both study cases, it was shown that the usage of HD-sEMG data, instead of bipolar sEMG data leads to a superior prediction accuracy (Table 1, Figure 1) due to the additional spatial distribution information given by HD-sEMG. Overall, MLP and LSTM performed similarly when applied on the same data set (Table 1).

**Figure 1:** A sample torque prediction in 70% MVC of dorsiflexors at  $7.5^\circ$  plantarflexion in an intra-session case using MLP

## Conclusions

This study investigated the ankle torque prediction using HD-sEMG and bipolar sEMG recordings during sub-maximal isometric contraction. The preliminary results showed that using HD-sEMG data as an input can give a more accurate torque prediction, as compared to bipolar sEMG input. Detailed analysis of the input data type and ML algorithms can provide useful information in design sEMG-informed rehabilitation devices. Further investigation with more subjects and other ML algorithms are needed to determine whether HD-sEMG is preferable in joint torque prediction.

### Summary

In this study, sagittal plane ankle and knee torques, and both sagittal and frontal plane hip torques during several different motions were predicted using two alternative deep learning approaches; a direct Long short-term memory (LSTM) [1] approach and a multi-step approach based on movement clusters. The agreement between predicted and measured joint torque using these two methods were analysed and compared.

### Introduction

In exoskeleton control and rehabilitation robotics, deep learning algorithms have been widely studied to predict limb joint torque, as they do not require explicit descriptions of the complex relationships between body kinematics and muscle states. There are, however, few studies that describe torque prediction in multiple lower-limb joints and degrees of freedom, nor evaluate the generalizability of deep learning models across subjects and daily activities. The objective of this study is to compare two deep learning approaches that predict lower-limb joint torques. Our hypothesis was that a multi-step approach based on clustering movement types would have a better performance than a direct approach.

### Methods

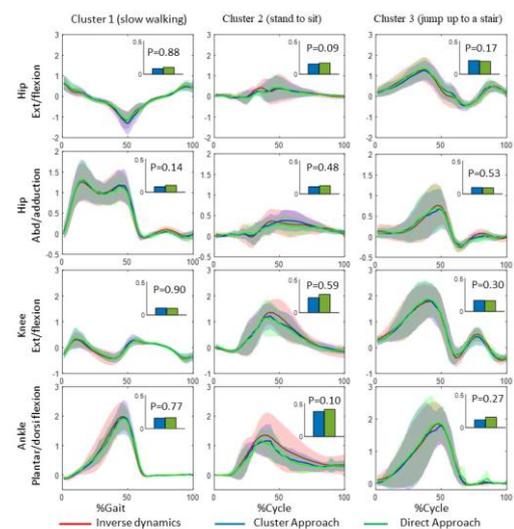

Twelve able-bodied subjects performed ten types of daily activities, including fast walking, normal walking, slow walking, jump down from a stair, jump up to a stair, jump up, land, squat, sit to stand and stand to sit. Surface EMG electrodes (Myon nano) were placed on 13 muscles, including soleus, peroneus longus, tibialis anterior, gastrocnemius medialis, gastrocnemius lateralis, rectus femoris, vastus medialis, vastus lateralis, biceps femoris, semitendinosus, gluteus maximus, gluteus medius, and tensor fasciae latae of one leg. Marker trajectories were recorded (Vicon V16 cameras, AMTI Optima force plates), and kinematics and kinetics were computed based on the CGM2.3 model [2].

Hip flex/extension, hip abd/adduction, knee flex/extension and ankle dorsi/plantarflexion torques were predicted using two deep learning approaches, with EMG signals and joint angles as inputs. In the first direct approach, torque values were predicted using a single LSTM model. In the multi-step approach, t-distributed stochastic neighbour embedding was first used to reduce dimensionality and define clusters of movements with similar features, and then separate LSTM regression models were trained for each cluster. During the inference, the first 0.01 second is used to identify which cluster the movement belongs to, and the corresponding LSTM network is used for regression. Predicted torques from both deep learning methods were compared to measured

torques from motion analysis. Agreement between measured and predicted joint torque using the two approaches were compared with paired t-tests.

### Results and Discussion

Both approaches predicted lower limb joint torques accurately and with relatively low error (Figure 1). Root mean square error (RMSE) of predicted torque was slightly lower in the cluster model than in the direct model, but there was no significant difference between the two approaches.

**Figure 1:** Lower limb torques (Nm/kg) in seven subjects during slow walking, stand to sit and jump up to stair, computed from inverse dynamics and predicted by the cluster and the direct approach. Both models' prediction RMSEs are illustrated in the small column plots.

### Conclusions

Both approaches predicted lower limb joint torques during various activities accurately and with relatively low error. Our findings indicate no apparent benefit of the cluster method based. Further investigation to study whether one of approaches performs better in more activities and more subjects, is currently underway.

### Summary

Intuitive control of myoelectric hand prostheses is still far from being precise, fast and robust. Machine learning is a promising field to decode user's intention in real-time and drive a prosthesis accordingly. We inspected if a reservoir-computing neural network (RC-NN) can predict the finger kinematics from electromyographical (EMG) data. RC-NN were able to predict kinematic data with an average  $R^2$  of  $0.82 \pm 0.01$ .

### Introduction

A limb loss is an incisive event and has major impact on daily life and quality of life. Muscle-driven prostheses rely on remnant muscle activity and may reduce the patients' burden. An approach to intuitively control such prostheses is to use machine learning to decode user intention from muscle activation in real-time. The aim of this study is to investigate the use of a RC-NN to predict the corresponding hand movement with given EMG signals after training with the fullFORCE method [2]. We do it by training the RC-NN on EMG and kinematic data provided by the first iteration of the Ninapro dataset [1] and test with EMG and kinematic data not used during training. Accordance was defined as the absolute error and coefficient of determination between measured and predicted data.

### Methods

Our analyzes are based on the Ninapro dataset's [1] first iteration. Network training was done by splitting data into a training set with 5 repetitions, and a testing set with 4 repetitions of each movement. EMG data and corresponding kinematic data of the training set was fed into a RC-NN of 3000 neurons) using the fullFORCE method [2]. For network training, the learning took place online by feeding training data sets in sequence rather than parallel. Each training sequence consisted of 20 repetitions, and reservoir weights were updated. After each sequence, current network error was calculated separately for each finger. Furthermore, a coefficient of determination index was calculated between measured and calculated output [4].

### Results and Discussion

After learning, the RC-NN could describe the measured finger angles based on the time-depending EMG input (Fig. 1 left). For the training sets, the coefficient of determination showed values of  $R^2 = 0.97 \pm 0.06$  and absolute errors  $0.13 \pm 0.02$ . Depending on the repetition, coefficient of determination

showed values around  $R^2 = 0.82 \pm 0.01$  and mean absolute error of  $13.72 \pm 3.81$ .

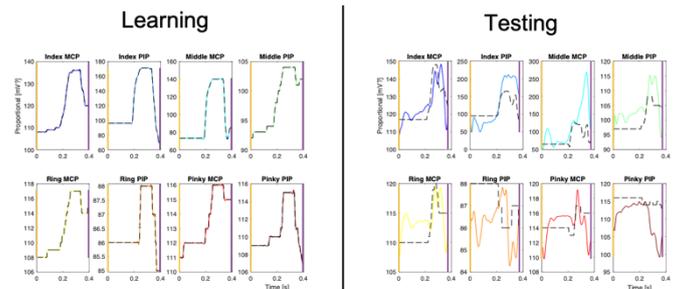

Figure 1: Predicted values (colored lines) and the measured values (dashed line) for each of the eight finger angles used. Left: Measured and Estimated Data after training. Right: Measured and Estimated Data after testing.

Testing on untrained data lead to a decrease in  $R^2$  and an increase in prediction absolute error (Fig. 1, right). Due to motor variability during measurement, subjects perform same movements slightly different. This results in differences between each repetition, which reflects on network performance. Furthermore, the measurement was continuous, so splitting the data in training and testing sets led to a loss information regarding starting values for each repetition and previous recorded repetitions. To better mimic daily use of a prostheses, no feature extraction or dimensionality reduction was performed, which showed improvement of accuracy in other studies [4, 5].

### Conclusions

It is possible to predict the corresponding hand movement with a given EMG signal after training a RC neural network with the fullFORCE method. To further increase prediction accuracy of the network, additional improvement e.g through data processing and different network parameters must be tested.

## Summary

Brain-Computer Interfaces (BCI) [1] has recently shown potential in predicting gait kinematics by assessing motor intentions. However, neural signals based on Electroencephalogram (EEG) are nonlinear and nonstationary which makes their synchronization with knee positional information for gait trajectory and phase prediction difficult. This study presents a novel frontal-parietal delta microstate BCI for improvising performance of traditional position based Long Short Time Memory (LSTM) in Knee Gait Trajectory and Phase Prediction.

## Introduction

Knee gait trajectory and phase prediction [2] play vital role in the development of lower extremity exoskeletons. Frontal-posterior cortical networks [3] are known to be involved in gait motor intention decision making. However, decoding motor intentions from these cortical regions is a challenging task due to the non-stationary nature of EEG signals. This makes the synchronization of neural intention decoders with positional information difficult. Hence, present study estimates a stable microstate-based frontal-parietal delta information and evaluates its ability in improving performance of traditional position-based LSTM model.

## Methods

20 healthy volunteers walked for ten rounds of 100 meters distance and their gait information were acquired using wireless 8 Channel EEG and Noraxon IMU system with sampling rates of 500 and 60 Hz respectively. The acquired data was initially subjected to the development of traditional IMU - LSTM based knee gait trajectory and phase prediction system. Subsequently stable microstate-based frontal-parietal delta information is estimated and synchronized with traditional IMU-LSTM gait prediction system. At first, the acquired knee gait has been classified into 4 gait phases [Initial-Contact (IC), Mid-Swing (MS), Pre-Swing (PS), Terminal-Swing (TS)]. Non-Walking Gait (NWG) were also marked from extracted knee gait cycles. Encoder-decoder based LSTM architecture was employed for both traditional and BCI enabled gait prediction system. At first, both knees angle data were processed through a sliding window to form 12 features (2 knee angles, 2 synchronization of peaks of both knees and 4 distinct crests and trough of each knee). This information was subjected to LSTM model with an input window of 120 frames (2 sec), an output window to predict the next 60 frames (1 sec). The hidden state and the cell state generated from the last timestep(context) is fed into the decoder LSTM. The decoder outputs hidden state for every timestep, the vectors are connected to a dense layer and reshaped into the next 60 frames vector. The network weights and biases were updated at the end of each batch using an adaptive moment estimation (Adam) optimization algorithm with mean square error (MSE). The training was carried out till MSE reached less than 0.05. 50%of the dataset was used for the

training and rest each 25% of the data was utilized as validation and testing set. Subsequently, to improve the gait trajectory and phase prediction, a deep neural BCI system based on stable frontal-parietal motor intention neural mechanism was developed. For this purpose, the acquired, preprocessed, and filtered (1 to 4Hz: Delta) EEG data of F3, F4, Fz, C3, C4, CP3, CP5, and Pz were subjected to k-means based microstate analysis [4]. The resultant microstates were back fitted to every individual's EEG data and subsequently appended to the input feature data used to train the LSTM gait prediction system. Training and testing of BCI enabled prediction system is similar to IMU-LSTM.

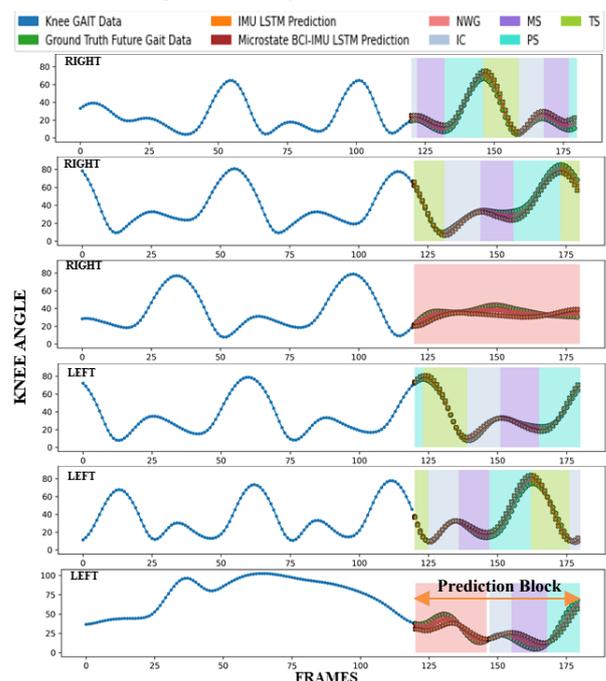

Figure 1: Overall performance of methodologies employed.

## Results and Discussion

The accuracy of IMU-LSTM system in predicting gait phase's trajectories are as follows. Right knee: - IC :91.4%, MS: 91.5%, NWG: 90.0%, PS: 91.2%, TS: 92.2% and Left knee: - IC :90.8%, MS: 91.8%, NWG: 90.0%, PS: 91%, TS: 92%. On the other hand, frontal-parietal delta microstate-based BCI enabled LSTM's accuracy for right knee are as follows. IC :91.9%, MS: 92.3%, NWG: 93.1%, PS: 92.2%, TS: 93.6% and Left knee: - IC :92.5%, MS: 93.2%, NWG: 93.1%, PS: 93%, TS: 93.1%.

## Conclusions

The frontal-parietal delta microstate-based BCI enabled LSTM system performs better than traditional IMU-LSTM based knee gait trajectory and phase prediction system.

## Summary

A novel three-dimensional musculoskeletal model of an alpine skier with two skis (53 degrees of freedom, 94 three-element Hill-type muscles) was developed. The model was successfully applied to track experimental data of a turning maneuver and to investigate muscle and knee ligament forces.

## Introduction

During turning maneuvers in alpine skiing, competitive skiers face a high risk of sustaining a serious knee injury. Musculoskeletal simulation models can estimate individual muscle forces, provide insight into tissue loading and neural control and can thus contribute to a better understanding of injury mechanisms during dynamic movements.

The purpose of the present study was to develop a three-dimensional musculoskeletal model of an alpine skier. The model was applied to determine muscle and knee ligament forces during a turning maneuver in alpine skiing.

## Methods

We developed a three-dimensional musculoskeletal model of an alpine skier and two skis with 53 degrees of freedom (19 for the skier and 17 for each ski) and 94 three-element Hill-type muscles (43 per leg and 8 actuating the lumbar joint). The model of the skier was based on the full-body OpenSim model of Catelli et al. (2019), where we added additional muscles for the lumbar and hip joints.

Each ski was discretized into 18 rigid segments (7 rear segments, 1 center segment and 10 front segments) and connected by revolute joints with spring damper elements to incorporate mechanical properties of the skis (bending stiffness and damping). We modeled the ski-snow contact using three types of forces acting on each segment of the ski (Mössner et al., 2014). We applied a frictional force, a penetration force acting normal to the snow surface, and a shear force parallel to the snow surface, which provided resistance against lateral shearing.

To simulate a turning maneuver, we formulated an optimal control problem (OCP), where measured experimental data of an alpine skier was tracked. Muscle redundancy was resolved by minimizing the sum of squared muscle activations. The OCP was solved using direct collocation and the nonlinear optimization solver IPOPT. To increase computational speed, we provided analytical derivatives of the objective function and constraints (van den Bogert et al. 2011). Knee ligament forces were estimated in a postprocessing step using the 3D knee model of Weinhandl et al. (2014).

## Results and Discussion

Tracking the measured kinematics of the turning maneuver (right turn) by the musculoskeletal skier model converged in about 40 min of computational time on a single core of a workstation (Thinkstation 330, 3.5 GHz E-2146 CPU). The speed of the skier was about 14 m/s and the duration of the turning maneuver was 1.5 s. Root mean squared differences between the measured joint angles and the joint angles obtained by the musculoskeletal skier model ranged from 0.75 to 2.77 deg. The primary activated muscle groups were the lateral and dorsal trunk muscles, the vasti, hamstrings and glutei of the inner leg as well as the glutei, vasti, soleus and hamstrings of the outer leg. Anterior cruciate ligament (ACL) forces peaked when the skier passed the gate at the fall line and amounted to 87 N on the outer left leg. The main contribution to the loading of the ACL was due to an external abduction moment acting on the knee joint. Sagittal plane contributions were low due to consistently high knee flexion (> 58 deg) and substantial coactivation of the hamstrings.

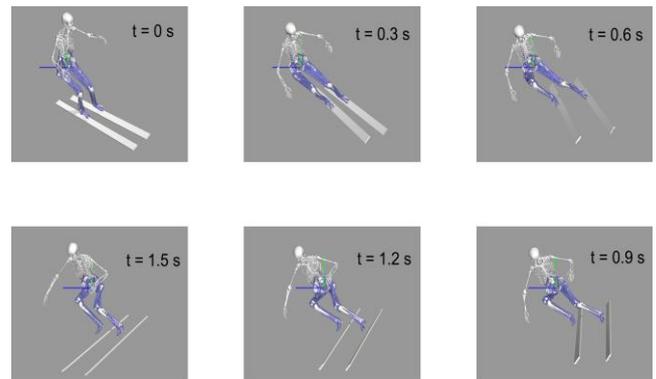

Figure 1: Musculoskeletal skier model visualized in OpenSim

## Conclusions

A novel three-dimensional musculoskeletal model of an alpine skier was developed and applied to investigate muscle and knee ligament forces during a turning maneuver. In future research the model will be applied to study the effect to equipment, injury prone situations and predictive simulations.

# Anatomical Predictors of sagittal hip kinematics during deep squat in adolescent males with and without CAM deformity

Dalia Al Otti<sup>1</sup>, Stijn Ghijssels<sup>1</sup>, Filip Staes<sup>2</sup>, Lennart Scheys<sup>1</sup>

<sup>1</sup>Institute for Orthopaedic Research and Training, Department of Development and Regeneration, KU Leuven/University Hospitals Leuven, Leuven, Belgium; <sup>2</sup>Research Group for Musculoskeletal Rehabilitation, Department of Rehabilitation Sciences, KU Leuven, Belgium;.

## Summary

The aim of this ongoing study is to investigate the spinopelvic parameters and movement patterns of highly active adolescent males with and without CAM deformity during 2 deep squat tasks. Preliminary results show that subjects with CAM exhibit altered sagittal pelvic and hip kinematics in a manner similar to adults with symptomatic FAI.

## Introduction

CAM-type Femoroacetabular Impingement (FAI) is a motion related disorder of the coxo-femoral joint characterized with groin pain. The aetiology of CAM-FAI is still unclear, specifically in relation to possible biomechanical factors influencing CAM-formation during final skeletal maturation.

Previous studies have demonstrated significant difference in certain spinopelvic parameters as well as the execution of movements like stair climbing and squats between FAI adult subjects and healthy controls [1]. However, there has been no similar investigations on adolescent males subjects. Nevertheless, research identifies this specific age population as most prone to developing cam deformity and subsequently FAI in adulthood [2]. Therefore, a multidimensional biomechanical exploration of movement execution and its association with radiological spinopelvic parameters as aimed for in this study is imperative.

## Methods

Recruitment is currently ongoing for this study in collaboration with a local elite soccer school. Players are included if they train for a minimum of 12 hrs/week and subsequent physical screening ruled out current pain or injury.

All subjects undergo a hip radiographic examination that consists of a modified Dunn view scan and a low-dose bi-planar x-ray scan) during deep squatting. Therefrom following parameters are extracted: alpha angle ( $>55^\circ$  = CAM present), pelvic incidence, pelvic tilt, and sacral slope.

Fig. 1: Image (a) shows an EOS® scan in deep squat, image (b) shows the squat standardization method used, and image (c) shows the constructed kinematics skeletal model.

This is followed by a 3D kinematic analysis captured with 12–infrared camera system (Vicon, UK). Each participant is asked to perform, in triplicate, (1) a free deep squat at their own pace followed with (2) a standardized deep squat in which the ankle’s plantar flexion and excessive trunk flexion where controlled for. Resulting data is exported to Visual3D software (C-motion, USA) for skeletal model computation and subsequent analysis of hip flexion and pelvic anteversion.

## Results and Discussions

Statistical significance was set to ( $p < 0.05$ ) for all tests. The currently available cohort consists of 11 subjects (age=  $15 \pm 2$  years). Peak hip flexion and pelvic anteversion during standardized squat were found to be significantly different between the CAM and no CAM Groups. A Pearson’s correlation test furthermore revealed a negative relationship between pelvic incidence and hip flexion during both free ( $r = -.66$ ) and standardized squats ( $r = -.62$ ). Additionally, alpha angle was positively correlated with both the peak hip flexion during the descend phase of the standardized squat ( $r = .68$ ) and anteversion values at the peak depth of the standardized squat ( $r = .75$ ).

Table. 1: The results of the 4 primary outcome parameters and their respective independent t-test p-values for the 2 study groups.

Group	n	Alpha Angle	Pelvic Incidence	Peak Hip Flexion (standard squat)	Peak Pelvic Anteversion (Standard squat)
CAM	5	64.5±5.3	47.3±3.8	109 ±8.2	30 ±6.5
No CAM	6	47.6±3.4	53±8.7	95 ± 7.7	18 ± 7.9
Significance	-	.000*	.193	.032*	.043*

\* Significance less than 0.05

## Conclusions

Our preliminary results show that adolescent males with asymptomatic CAM exhibit significantly higher sagittal ROM of the hip and the pelvic compared to controls during a standardized deep squat. The high correlation between alpha angle and anteversion at peak depth of the standardized squat points to inability of subjects with larger CAMs to retrovert their pelvic adequately at high hip flexion. Interestingly, this altered pattern of movement has been previously reported in symptomatic adults with FAI as a mechanism of excessive anterior femoral head coverage that can lead to impingement [3].

# Frontal plane knee control with regard to leg dominance in female adolescent competitive handball players during a Drop Vertical Jump

Sabrina Erdrich

SNL<sub>H</sub> – Sports Neuromechanics Lab Heidelberg, Heidelberg, Germany

Email: [erdrich@snlh.de](mailto:erdrich@snlh.de)

## Summary

Dynamic knee valgus is considered a risk factor for anterior cruciate ligament (ACL) injuries in team handball. The study demonstrates the magnitude of this biomechanical risk factor in healthy female adolescent handball players with respect to leg dominance, highlighting the potential higher injury risk for the non-dominant side. The results may help to optimize preventive training strategies.

## Introduction

Females have a distinct higher risk to injure their ACL than males in the same sports [1]. It has also been shown that in ski and soccer sports females are more likely to injure their non-dominant side compared to their male counterparts, who seem to more frequently injure their dominant side (defined as the kicking leg) [2,3]. There is no such evidence in team handball sports. Faulty biomechanics might give a hint for one side being at higher risk than the other. The purpose of this study was to define the extent of 2D dynamic knee valgus with respect to leg dominance, during the stretch-shortening-cycle (SSC) from a two-legged Drop Vertical Jump (DVJ) at the start of the season in female handball players.

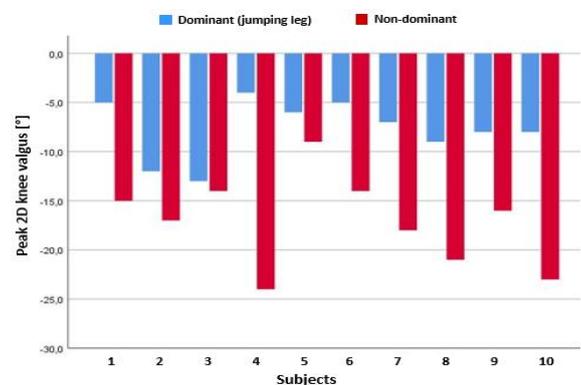

## Methods

10 competitive female handball players ( $16,5 \pm 0,8$  yrs;  $171,9 \pm 5,7$  cm;  $65,5 \pm 8,4$  kg;  $10,3 \pm 2,6$  yrs experience;  $94,0 \pm 8,1$  KOOS sports/recreational Score; Baden League Level) took part in this preseason cross-sectional study. Subjects performed a DVJ from a 37 cm box (feet 35 cm apart [1]), placed under a basket to create an overhead goal, which has been shown to increase performance. Two rectangles (60 x 40 cm) were marked with a colored tape in front of the box (the midpoint being 60 cm away from the leading edge of the box) in order to simulate two force plates. To define knee alignment 8 colored 1 x 1 cm tape stripes were placed bilaterally at predefined anatomical landmarks: Anterior superior iliac spine (ASIS), mid patella, ankle joint center and proximal thigh 30 cm above the knee marker in line with the ASIS and patella marker [4]. Subjects performed 3-5 practice trials, before 2 trials were recorded. Tests were conducted barefoot to avoid variability of the performance due to different shoe materials and to be able to observe foot landing strategies for subsequent analysis. A trial was successful when the SSC and the landing were in the marked area and the subject landed stable on both feet. A digital camera (Fujifilm, model X-T10, 60 Hz) placed in the frontal plane (4,50 m ahead of the box, at 1,30 m height) captured the movement. Recorded videos were processed using Kinovea Software (Version 0.8.15, Kinovea Open

Source Project). Peak knee valgus was defined as knee valgus at the deepest point of the eccentric phase by assessing the player's navel height during the movement. For further analysis the worse valgus angle of the two trials was used. The dominant leg was defined as the jumping leg. Due to normally distributed data side-to-side differences were compared using paired t-tests ( $\alpha = .05$ ).

## Results and Discussion

All players demonstrated dynamic knee valgus during the SSC of the DVJ (Fig. 1).

**Figure 1:** Peak 2D knee valgus angles during the SSC from a Drop Vertical Jump with arm swing (dominant vs. non-dominant side).

Throughout the group frontal plane knee control was more deficient on the non-dominant side ( $-17.1 \pm 4.6^\circ$ ) compared to the dominant side ( $-7.7 \pm 3.0^\circ$ ) ( $p < .001$ ). The consistency of the side-to-side valgus pattern supports the approach to define the dominant leg as the jumping leg in team handball, as it shows better neuromuscular control for the selected parameter.

## Conclusions

The magnitude of faulty frontal plane knee control in healthy adolescent competitive female handball players at the start of the season underlines the need for targeted ACL injury prevention training for this population. Due to the results the non-dominant side seems to be at distinct higher injury risk; this should be considered in preventive training concepts. Further research with bigger sample sizes is needed to substantiate these findings.

## Effects of 4-week Transcranial Direct Current Stimulation Combined with Foot Core Exercise on Foot Muscle Strength and Ankle Kinesthesia

Songlin Xiao, Xini Zhang, Baofeng Wang, Changxiao Yu, Weijie Fu\*

Key Laboratory of Exercise and Health Sciences of Ministry of Education, Shanghai University of Sport, Shanghai, China

\*corresponding author: fuweijie@sus.edu.cn

### Summary

This study aims to investigate the effects of transcranial direct current stimulation (tDCS) combined with foot core exercise on foot muscle strength and ankle kinesthesia. Thirty participants randomly assigned to either anodal tDCS (a-tDCS) or sham tDCS (s-tDCS) combined with foot core exercise group, received twelve sessional tDCS combined with foot core exercise over four weeks. The results showed that compared to the pre-intervention and s-tDCS, a-tDCS combined with foot core exercise can significantly decrease the passive kinesthesia threshold of ankle eversion and increase toe flexor strength ( $p < 0.05$ ), which suggested that a-tDCS combined with foot core exercise can effectively improve the physical performances of the foot and ankle.

### Introduction

Currently, the tDCS is a safe noninvasive approach for modulating the excitability of brain regions. Our preliminary study showed that single-session a-tDCS may potentially improve the physical performances of the foot and ankle [1]. However, to date, there has been little research on exploring the long-term effect of tDCS alone, particularly combined with physical training. Therefore, this study aims to determine the effects of 4-week tDCS combined with foot core exercise on foot muscle strength and ankle kinesthesia.

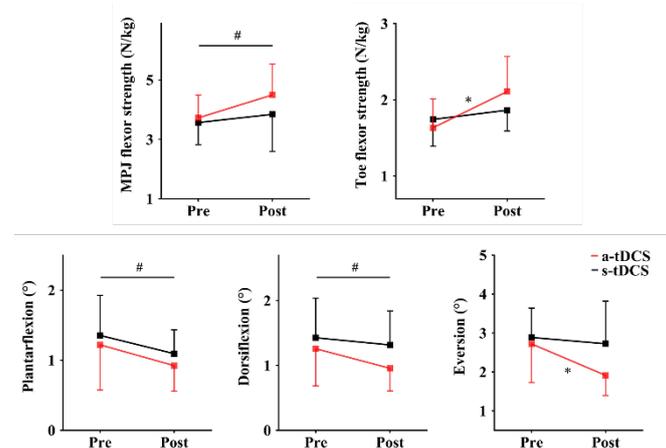

### Methods

In this double-blinded sham-controlled study, thirty healthy participants were randomly evenly assigned to two groups (i.e., a-tDCS or s-tDCS combined with foot core exercise). Each group received a 4-week intervention protocol over twelve sessions, which applied tDCS during performing foot core exercise. A-tDCS was applied over sensorimotor regions with an electric current intensity of 2 mA for 20 min using 4 × 1 ring electrodes, while s-tDCS followed the same protocols except that active stimulation remained on for only 30 s before the beginning and end of stimulation. Foot core exercise included short foot exercise, towel curling training, toe spread training, and balance board training. Two-way repeated-measures analysis of variance was used to examine the effects of tDCS combined with foot core exercise on metatarsophalangeal joint (MPJ) flexor strength, toe flexor strength, and the passive kinesthesia threshold of ankle joint.

### Results and Discussion

A significant intervention by time interaction effect for the passive kinesthesia threshold of ankle eversion and toe flexor strength was observed ( $p < 0.05$ ). Post-hoc analysis showed that compared to pre-intervention and s-tDCS, a-tDCS combined with foot core exercise can significantly increase

the toe flexor strength and decrease the passive kinesthesia threshold of ankle eversion (Figure 1).

**Figure 1:** Comparisons of foot muscle strength and the passive kinesthesia thresholds of ankle joint before and after intervention between a-tDCS and s-tDCS groups. MPJ, metatarsophalangeal joint; # indicates significant differences between pre- and post-intervention regardless of groups; \* indicates significant differences between pre- and post-intervention in a-tDCS group;  $p < 0.05$ .

A significant time effect was observed for MPJ flexor strength, toe flexor strength, the passive kinesthesia thresholds of ankle plantarflexion, dorsiflexion, and eversion (Figure 1).

Four-week foot core exercise combined with a-tDCS or s-tDCS can enhance foot muscle strength and ankle sensory function. Moreover, a-tDCS combined with foot core exercise can induce a more positive improvement in toe flexor strength and ankle eversion kinesthesia than s-tDCS. Similarly, a previous study found that multi-session a-tDCS can activate the cortical sensorimotor regions and promote the effects of physical training on the physical performances of the foot and ankle [2].

### Conclusions

The findings of this study suggested that tDCS, especially a-tDCS, combined with foot core exercise can sufficiently improve toe flexor strength and passive ankle kinesthesia.

# THE VALIDITY OF THE GPS-BASED ACCELEROMETER TO MEASURE FOOT STANCE CHARACTERISTICS DURING RUNNING.

Michael Lawson<sup>1,2</sup>, Robert A. Needham<sup>1</sup>, Nachiappan Chockalingham<sup>1</sup>, Roozbeh Naemi<sup>1</sup>

<sup>1</sup>Centre for Biomechanics and Rehabilitation Technologies, Staffordshire University, Stoke-on-Trent, United Kingdom

<sup>2</sup>AIK Fotboll, Solna, Sweden

Email: mike.lawson@aikfotboll.se

## Introduction

GPS technology is commonly employed within team sports to quantify work rate through derivatives of speed and distance. These sensors also contain high frequency accelerometers which provides an opportunity to gain further information into an athlete's locomotion. Accelerometers have been previously validated against a motion capture system to capture foot stance time characteristics during running mounted at the center of mass [1] and sternum [2]. The GPS sensors are mounted on the posterior aspect of upper trunk within a specially designed vest. The purpose of this study was to investigate whether the GPS-based accelerometer can accurately determine foot stance time characteristics during running at different running speeds.

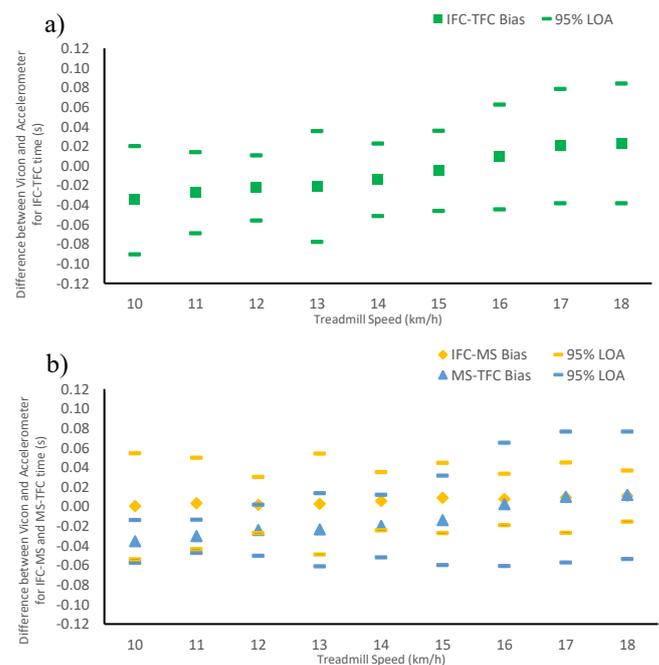

## Methods

Thirteen experienced male runners (age:  $27 \pm 3.7$  years) ran on a treadmill with 1-degree inclination for 40 seconds at 9 different speeds ranging from 10-18km/h. Participants wore an GPS sensor (STATSports Apex, Northern Ireland) containing a high frequency tri-axial accelerometer housed in an appropriately sized GPS vest and were provided with standardized running shoes (Puma Anzarun). An eighteen-camera motion capture system (VICON, Oxford, UK) recorded marker coordinate data at 100 Hz, which was filtered (4<sup>th</sup> order Butterworth, 10 Hz cutoff frequency) and analyzed in Visual3D (C-Motion Inc, MD, USA). Initial foot contact (IFC), midstance (MS) and terminal foot contact (TFC) were determined with a kinematic method [1,3]. Foot stance time characteristics from the accelerometer data (recorded at 100 Hz) were processed and analyzed in Visual3D. A zero cross over method of the Y-axis was used to determine IFC (negative to positive) and TFC (positive to negative). MS was determined as the second acceleration peak following IFC. Time between IFC and TFC was determined as stance time. Stance time and time between IFC, MS and TFC were compared between the motion capture system and accelerometer across each running speed. Mean biases, 95% limits of agreement and Hedges g effect sizes were used to quantify the level of agreement between the two systems.

## Results and Discussion

The accelerometer underestimated stance time for running speeds 10km/h (-0.03s) to 15km/h (-0.01s) and overestimated between speeds 16km/h (0.01s) to 18km/h (0.02s) (Figure 1a). The time between MS and TFC caused the stance time underestimation in the lower speeds, however, the time between IFC and MS also contributed to the overestimation in the higher speeds (figure 1b). A small effect size was noted at

15km/h (-0.26). Reasonable agreement was observed in 12km/h, 14km/h and 15km/h. The decrease in bias as speed increased in the lower speeds is similar to previous studies that investigated foot stance time with sternum mounted accelerometers [2]. This may be due to the greater center of mass vertical oscillations typically observed at lower running speeds [2] which increases noise within the accelerometer.

**Figure 1:** Bland-Altman plots of the difference between the Vicon and Accelerometer in timings between a) Stance time, b) IFC and TFC, MS and TFC. LOA= limits of agreement.

## Conclusions

The present study showed that the ability of the GPS-based accelerometer to measure foot stance characteristics is speed dependent. The highest agreement between the two systems with low bias was observed at 15km/h. At 12km/h and 14km/h there was an underestimation of stance time, however, these speeds showed reasonable limits of agreement. Therefore, this study has shown valid estimations of stance time characteristics with the GPS based accelerometer at speeds of 12km/h, 14km/h and 15km/h.

Email: matthew.slopecki@mail.mcgill.ca

### Summary

Muscle fatigue is thought to contribute to incidence rates of musculoskeletal disorders (MSD). When one muscle is fatigued, in order to accomplish a whole-body repetitive task, a person can develop compensation strategies, such as increasing motor variability (MV); however, the effects of localized muscle fatigue has only been assessed on single-joint or inter-segment variability. In the present study, we employed the uncontrolled manifold (UCM) framework to compare how fatiguing different muscles affects whole-body coordination. Shoulder fatigue caused significant increases in variance components, and a significant decrease in synergy index. This suggests that fatigue of the shoulder joint forced a greater reorganization of the motor control system, compared to other fatigue locations and no fatigue.

### Introduction

Repetitive, upper limb, fatiguing movement is a common component of workplace tasks, associated with the development of MSD. Compensation strategies exist in motor patterns after muscular fatigue [1]. Variability and multi-joint adaptations compensate against muscular fatigue, however current research has only investigated how localized muscle fatigue affects single-joint or inter-segment variability [1]. The objective of this project was to simultaneously link changes in individual joint variability to task performance to investigate the effect of different fatigue locations on motor variability, using the uncontrolled manifold framework.

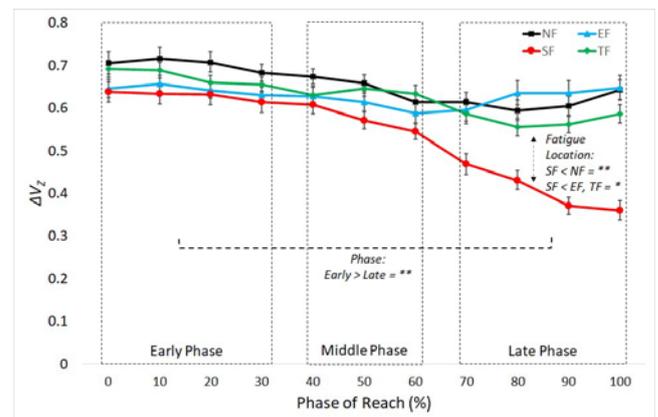

### Methods

Twelve (5m/7f) participants completed a repetitive pointing task (RPT), consisting in repetitively moving the dominant index finger between two targets (30% and 100% of maximal reach) placed at shoulder height, at rest and after maximal fatiguing protocols of the shoulder (SF), elbow (EF) and trunk (TF), as described by Yang et al. [1]. Kinematics of the trunk and upper limb were collected using a 7-camera motion capture system collecting at 120hz. A kinematic model was created following ISB recommendations [2]. A UCM framework [3] was applied to the kinematic model, linking elemental variables (degrees of freedom at a joint) to endpoint fingertip position.

Reaches were separated into Early (0 - 30%), Middle (40 - 60%) and Late (70 - 100%) phase. A mixed ANOVA determined effects (Phase, Fatigue location) on variance components ( $V_{UCM}$  and  $V_{ORT}$ ). A one-way ANOVA determined effects (Phase, Fatigue Location) on Synergy Index ( $\Delta V_z$ ) data. Post-hoc pairwise comparisons of Bonferroni were used.

### Results and Discussion

Significant main effects of Fatigue Location:  $F(3, 516) = 5.41$ ,  $p < 0.01$ ,  $partial\ n^2 = 0.03$ ; and Phase:  $F(2, 516) = 8.23$ ,  $p < 0.01$ ,  $partial\ n^2 = 0.03$ , were observed on the variance data. No interaction effects were found. Specifically, SF caused significant increases in variance components. Results of the effects of fatigue on  $\Delta V_z$  revealed significant main effects of Fatigue Location:  $F(3, 516) = 5.30$ ,  $p < 0.01$ ,  $partial\ n^2 = 0.03$ ; and Phase:  $F(2, 516) = 8.13$ ,  $p < 0.01$ ,  $partial\ n^2 = 0.03$ . No interaction effects were observed. Decreased  $\Delta V_z$  in late phase of movement was observed after SF.

**Figure 1:** Changes in  $\Delta V_z$  during phases of reach. \* indicates a significant pairwise comparison with significance set at  $P < 0.05$ . \*\* indicates a significant pairwise comparison with significance set at  $P < 0.01$ .

### Conclusions

SF, compared to other conditions, caused significant increases in  $V_{UCM}$  and  $V_{ORT}$ . A decreased  $\Delta V_z$  in the late phase of the movement was observed, which is particularly noticeable in SF (Figure 1). This shows that fatigue of the shoulder joint, compared to other fatigue locations, forced a greater degree of reorganization in the motor control system to maintain performance of the RPT, surrogated as the accurate endpoint position of the fingertip

## Impact of personality on postural control – a pilot study\*

J. Kędziołek<sup>1</sup>, M. Błażkiewicz<sup>1</sup>

<sup>1</sup>Józef Piłsudski University of Physical Education in Warsaw, Poland

Email: [justyna.kedziorek@awf.edu.pl](mailto:justyna.kedziorek@awf.edu.pl)

### Summary

Postural control is a term used to describe the way in which the central nervous system (CNS) regulates sensory information from other systems in order to produce adequate motor output to maintain a controlled, upright posture. Emotions and therefore personality type (especially fear, anxiety) can affect the strategy of body control. The aim of this study was to evaluate the impact of personality on postural control. Thirty three healthy individuals participated in this study. The Big Five Model was used in order to examine personality traits. Each participant performed in total 6 different standing tasks with eyes open and closed. Increased entropy values mean high irregularity and high complexity of the postural control system. A positive correlation was found between high values of Sample Entropy during one leg standing and Emotional Stability while negative correlation appeared between Agreeableness and Intellect.

### Introduction

Postural control includes complex work of somatosensory, vestibular and visual systems. Such complexity allows the body to perform dynamic and complex tasks. Little is known about the impact of personality on postural control. Studies have shown that poor balance management is associated with panic disorder, agoraphobia and ADHD. People with these disorders have increased levels of anxiety which occurred in high level of neuroticism according to the Big Five Model of personality. This phenomenon is observed in children who have poor balance and motor skills exhibit elevated anxiety and insular behavior [1]. The aim of this study was to examine the relationships between the postural control and the Big Five personality Model.

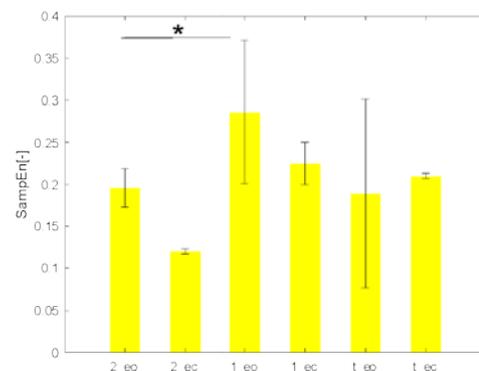

### Methods

Thirty three healthy individuals (21.94±1.64 yrs; 67.45±10.89 kg; 173.85±6.56 cm) participated in this study. Personality traits were assessed using IPIP-BFM-50 questionnaire based on the Big Five Model of personality. Participants underwent six balance measurements (each - 30sec) in the following order: both leg standing with eyes open (2eo), eyes closed (2ec), one leg standing with eyes open (1eo), eyes closed (1ec) and tandem standing with eyes open (teo) and eyes closed (tec). Center of pressure (CoP) trajectories in the anterior-posterior (AP) and medio-lateral (ML) directions were measured using the AMTI AccuSway at a sampling rate of 100 Hz. The study used Sample Entropy (SampEn) to assess CoP dynamics. The SampEn was calculated according to [2] using MatLab software. All statistical analysis was performed using Statistica software.

The Wilcoxon test was used in order to find differences between balance tasks. Pearson's correlation was used in order to find association between personality and nonlinear measure.

### Results and Discussion

A significant, positive correlation was found between SampEn (1\_ec) in ML direction and Emotional Stability ( $r = 0.345^*$ ). Moreover, a significant, negative correlation was noted between SampEn (1\_ec)\_ML and Agreeableness ( $r = -0.383^*$ ) and Intellect ( $r = -0.455^*$ ). Significant difference was found for SampEn in AP direction between 2\_eo and 1\_eo ( $p = 0.0001$ ) (Fig. 1).

**Figure 1:** Mean and standard deviation of Sample Entropy values in AP direction for all trials, where: \* - significant differences.

### Conclusions

The highest values of SampEn in AP direction during 1\_eo and 1\_ec tasks indicated a high irregularity of CoP signal. These conditions required a lot of attention and concentration, due to the small surface of support and lack of visual control. The lowest values of SampEn in AP during the 2\_ec task highlighted the ease and comfort of task execution. When the SampEn in that task increased, the extroversion in these subjects decreased. It is important to conduct study on a larger sample size to understand how some types of personalities may react to different postural tasks and connect emotions, temper with future problems like risk of falls and elevated anxiety in the elderly.

Email: [Lea-Fedia.Rissmann@rub.de](mailto:Lea-Fedia.Rissmann@rub.de)

### Summary

The aim of this study was to investigate cortical and spinal excitability during and after stretch-shortening cycles (SSCs). For this purpose, net ankle joint torque, motor-evoked potentials (MEPs), cervicomedullary motor-evoked potentials (CMEPs) and M-waves of the triceps surae muscles were obtained during and after SSCs. Preliminary data indicates enhanced torque output during and after the shortening phase of SSCs compared with pure shortening contractions (SHO), while cortical excitability was increased during and after SSCs and spinal excitability was increased during SSCs only.

### Introduction

Force, work, and power output during the shortening phase of SSCs is enhanced compared with SHO, which is called the SSC effect [4]. The SSC effect has partly been explained by residual force enhancement (rFE), which is triggered by active stretch contractions (STR) [3]. Further, STR were shown to induce long-lasting modulations in cortical and spinal excitability during an isometric-hold phase after STR [1, 2]. However, little is known about cortical and spinal excitability changes during and after the shortening phase of SSCs, which is what this study sought to assess. In line with enhanced torque output during and after SSCs compared with SHO, we expected increased cortical and similar spinal excitability during the shortening phase and similar cortical and increased spinal excitability after the shortening phase of SSCs.

### Methods

One participant laid prone on the bench of an isokinetic dynamometer (IsoMed2000, Ferstl GmbH, GER) with their right foot strapped onto a footplate attachment. Net ankle joint torque and crank arm angle were recorded at 1000 Hz. Voluntary fixed-end reference contractions (REF) were performed at +10° plantar flexion (PF) and -15° dorsiflexion (DF); voluntary STR, SHO and SSCs were all followed by isometric-hold phases at DF or PF, respectively. Stretch velocity was 40°·s<sup>-1</sup> and shortening velocity was 120°·s<sup>-1</sup>. All contractions were performed at a joint-specific 40% of maximum soleus (SOL) muscle activity level. SOL, gastrocnemii and tibialis anterior muscle activities were recorded at 5000 Hz using surface EMG. All data were synchronized using a 16-bit A/D card within a Power1401 data acquisition interface with Spike2 software (CED, Cambridge, UK). Different stimulation types were superimposed on the voluntary contractions during REF<sub>PF</sub>, SHO and SSCs. Stimulations were delivered during and 3-s after the shortening phase of SHO and SSCs and at time-matched instants during REF<sub>PF</sub>. M-waves (M<sub>max</sub>) were evoked by 1-ms single-pulse electrical tibial nerve stimulations (DS7AH, Digitimer, UK). CMEPs were obtained

after a single pulse (100-μs) stimulation of the spinal cord at the cervicomedullary junction (D185, Digitimer, UK). MEPs were evoked by a single-pulse (280-μs) magnetic stimulation of the motor cortex by positioning a double-cone coil (D-B80, MagPro Compact, MagVenture, DK) over the left vertex [1]. MEPs & CMEPs were matched to 10-30% of M<sub>max</sub> and normalized to M<sub>max</sub> obtained during the same contraction condition [2]. The SSC effect was calculated as the mean torque difference over a 150-ms window prior to stimulation during the shortening phase of SSCs relative to SHO. rFE and residual force depression (rFD) were calculated as mean torque differences between STR, SHO or SSCs relative to REF<sub>DF</sub> or REF<sub>PF</sub> at time-matched instants, respectively [1].

### Results and Discussion

Preliminary results indicate a SSC effect, as well as rFE after STR and rFD after SHO and SSCs. rFD was lower in SSCs compared with SHO. MEP/M<sub>max</sub> and CMEP/M<sub>max</sub> ratios were higher during SSCs than during SHO. These findings indicate increased cortical and spinal excitability during SSCs compared with SHO during the shortening phase. MEP/M<sub>max</sub> ratios were increased in SHO and even higher in SSCs compared with REF<sub>PF</sub>. CMEP/M<sub>max</sub> ratios were similar in REF<sub>PF</sub> and SSCs, but reduced in SHO. Larger MEP/M<sub>max</sub> ratios after SSCs than after SHO and than during REF<sub>PF</sub> indicate increased cortical excitability. Similar CMEP/M<sub>max</sub> ratios during REF<sub>PF</sub> and after SSCs indicate no change in spinal excitability after the shortening phase of SSCs.

### Conclusions

Our preliminary results suggest that stretch-induced rFE was not completely abolished during the shortening phase of SSCs as indicated by the reduced rFD after SSCs relative to after SHO. Furthermore, the SSC effect and reduced rFD were accompanied by increased cortical and spinal excitability during the shortening phase and increased cortical excitability after the shortening phase of SSCs, respectively. Increased cortical and spinal excitability might be evoked by the preceding stretch phase during SSCs and could potentially explain enhanced muscle performance during and after SSCs.

## Inter-individual Variation in Coordination and Control of Countermovement Jumps

Stuart A. McErlain-Naylor<sup>1</sup>, Robert A. Needham<sup>2</sup>

<sup>1</sup>School of Health and Sports Sciences, University of Suffolk, Ipswich, UK

<sup>2</sup>Centre for Biomechanics and Rehabilitation Technologies, Staffordshire University, Stoke-on-Trent, UK

Email: s.mcerlain-naylor@uos.ac.uk

### Summary

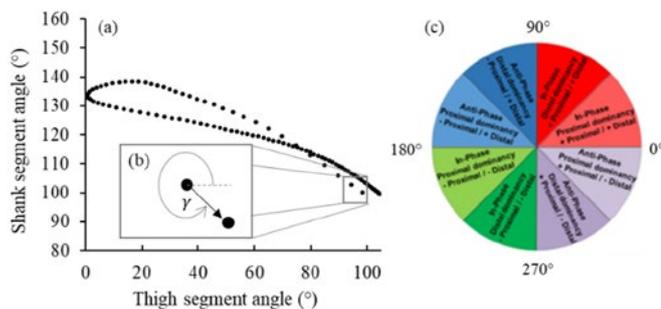

A modified vector coding technique was used to quantify coordination and control during countermovement jumps by 16 males. Previously reported group-level coordination patterns were confirmed, although substantial inter-individual variation existed. Patterns of thigh-shank coordination and control were observed corresponding to a ‘deep’ or ‘shallow’ countermovement strategy, each used successfully within the cohort.

### Introduction

Coordination patterns during countermovement jumps (CMJ) have previously been described at the group level [1]. Thigh-shank segment coupling showed a general anti-phase and thigh dominated coordination pattern during both the eccentric and concentric phases, except at the transition where an in-phase and shank dominated coordination pattern was observed. However, inter-individual variation in these coordination and control strategies is yet to be explored.

### Methods

Sixteen males each performed three maximal CMJs, with segmental kinematics recoded via 3D motion capture. For each participant’s highest jump, a modified vector coding technique [2] was used to quantify inter-segmental coordination (Figure 1). Readers are directed elsewhere for further information on vector coding, coordination pattern classification, and associated data visualisations [2].

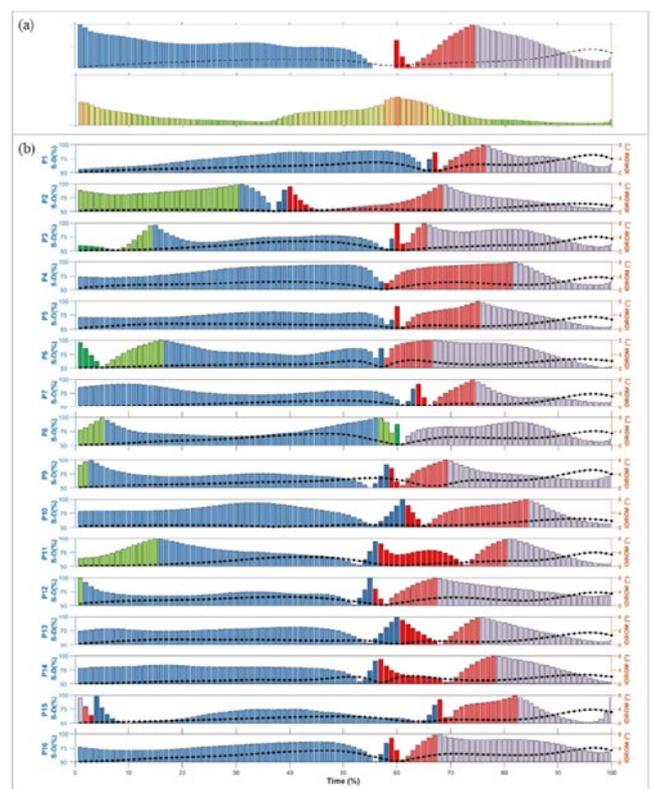

**Figure 1:** (a) angle–angle plot representing thigh and shank segment angles during a CMJ; (b) expanded view of one coupling angle that is assigned to a coordination pattern classification (c) [2].

### Results and Discussion

At the group level, previous results [1] were confirmed (Figure 2a): an anti-phase and thigh dominated thigh-shank coordination pattern during both the eccentric and concentric phases, except at the transition where an in-phase coordination pattern was again observed. Inter-individual variation was greatest at movement initiation and transition between

concentric and eccentric phases. Coupling angle mapping and profiling techniques highlighted patterns of thigh-shank coordination and control corresponding to a ‘deep’ (greater inter-data point range of motion, early anti-phase coordination) or ‘shallow’ (lesser range of motion, early in-phase coordination) countermovement strategy (Figure 2b). Both strategies were used successfully within the cohort (*e.g.*, by P1 and P2, respectively). Analysis of alternative segment couples will also be presented and discussed.

**Figure 2:** Coupling angle mapping (coordination pattern classification: colour-scale, Figure 1c), segmental dominance (bar height, 50-100%) and dominant segment inter-data point range of motion (IDP-ROM: dotted line, 0-8°) profiling of thigh-shank coordination in the sagittal plane: (a) group means (top) and inter-individual coordination variability (bottom); (b) individual participants ordered from highest to lowest jump height.

### Conclusions

Group-level analysis of CMJ coordination and control masks important inter-individual variation in movement strategies.

# Pain-induced Adjustments in Motor Unit Discharge Depend on Contraction Speed

Eduardo Martinez-Valdes<sup>1</sup>, Francesco Negro<sup>2</sup>, Michail Arvanitidis<sup>1</sup>, Dario Farina<sup>3</sup>, Deborah Falla<sup>1</sup>

Email: [e.a.martinezvaldes@bham.ac.uk](mailto:e.a.martinezvaldes@bham.ac.uk)

## Summary

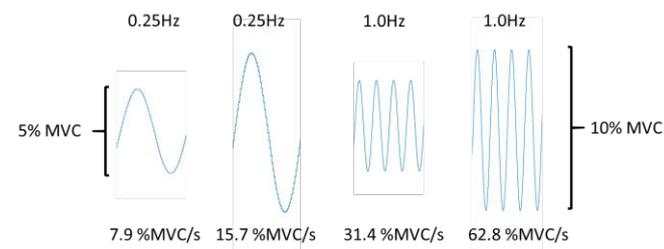

Variations in the proportion of low-and high-threshold motor units recruited during contractions at diverse speeds can induce different effects in the firing behavior of motor units in response to pain. Here we show that that pain reduces motor unit discharge rate and prolongs the neuromechanical delay (NMD) at slow contraction speeds only. This new evidence supports the presence of differential nociceptive inhibitory inputs across the MU pool, which allow exerting fast submaximal contractions in response to pain.

## Introduction

At high forces, the discharge rates of low-and high-threshold motor units are influenced in a different way by muscle pain [1]. These differential effects may be particularly important for performing contractions at different speeds since the proportion of low and high-threshold motor units recruited varies with contraction velocity [2]. Therefore, we investigated whether motor unit discharge and recruitment strategies are differentially affected by pain depending on their recruitment threshold, across a range of contraction speeds.

## Methods

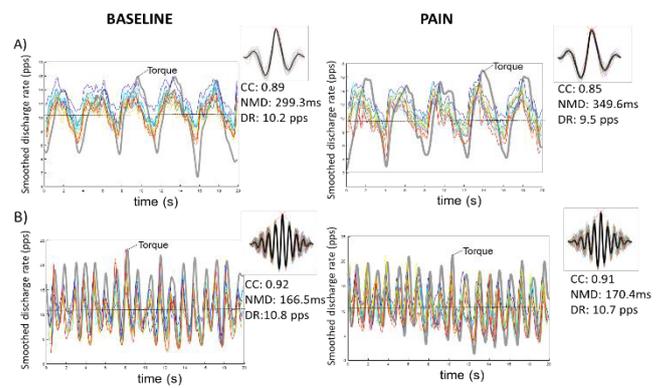

Fifteen participants (26 (3) years, 9 men) performed ankle-dorsiflexion sinusoidal-isometric contractions at two frequencies (0.25Hz and 1Hz) and two modulation amplitudes [5% and 10% of the maximum voluntary contraction (MVC)] with a mean target torque of 20%MVC (Figure 1). High-density surface electromyography recordings from the tibialis anterior muscle were decomposed with convolutive blind-source separation and the same motor units were tracked across painful (intramuscular hypertonic saline injection) and non-painful (baseline, isotonic saline, post-pain) conditions. Mean discharge rate, recruitment threshold and the delay between the cumulative spike train and the resultant torque output (NMD, [3]) were assessed.

**Figure 1:** Sinusoidal torque targets representing different contraction speeds.

## Results and Discussion

Mean discharge rate decreased significantly during pain at slow contraction speeds only (0.25 Hz,  $p=0.04$ ). Moreover, NMD only increased during pain at slow contraction speeds (0.25 Hz,  $p=0.03$ ). Recruitment threshold increased significantly with contraction speed ( $p=0.01$ ) but was not affected by pain. Results from a representative participant can be seen in **Figure 2**.

**Figure 2:** Representative results from one participant. Sinusoidal contractions were performed at 20% MVC with 10% amplitude modulation at a frequency of 0.25Hz (A) and 1Hz (B) during baseline (left) and painful (right) conditions. Smoothed discharge rates (DR, low pass filtered at 2Hz), torque profiles and results from the cross correlation (CC) between the cumulative spike train and torque can be seen for each of the contractions. An increase in neuromechanical delay (NMD) and decrease in discharge rate can be seen for the painful condition at low contraction speeds only (A). At high speed contractions (B), both the NMD and DR were similar between baseline and the painful condition.

## Conclusions

The firing behaviour of motor units in response to muscle pain is dependent on contraction speed. The preserved firing frequency and NMD at faster contraction speeds suggests that higher threshold motor units compensate for the decline in firing frequency of low threshold motor units when a low force is exerted (20% MVC). Such a mechanism allows for the execution of fast submaximal tasks to be maintained despite the presence of pain, but could increase fatigability and persistence of symptoms in the long term.

## Anthropometric adiposity measures, not body mass index, relate to measures of trip-related fall risk in older adults

Noah J. Rosenblatt<sup>1</sup>, Michael L. Madigan<sup>2</sup>

<sup>1</sup>Center for Lower Extremity Ambulatory Research, Rosalind Franklin University of Medicine and Science, North Chicago, USA

<sup>2</sup>Department of Industrial and Systems Engineering, Virginia Tech, Blacksburg, USA

Email: [noah.rosenblatt@rosalindfranklin.edu](mailto:noah.rosenblatt@rosalindfranklin.edu)

### Summary

We investigated the effects of anthropometric adiposity measures (AAM) on trip-related gait kinematics and kinematics following a lab-induced trip in community-dwelling older adults. We recruited N=55 adults  $\geq 65$  years of age, with obese and normal-weight body mass index (BMI) and collected trip-risk measures based on motion of the toe during gait, trip-recovery measures reflecting trunk and step control after a lab-induced trip, and AAM. Trip-risk measures were significantly associated with waist-to-hip circumference ratio (WHR) and thigh circumference, but not BMI. Participants with obese WHR had significantly more variable minimum toe clearance (MTC) than non-obese. Trip-recovery measures were significantly associated with hip circumference, thigh circumference, fat mass index (FMI), and total fat, but not BMI. Participants with obese FMI had impaired trunk control relative to non-obese following a trip. Central obesity and overall adiposity may more closely relate to trip-induced falls risk than BMI.

### Introduction

Obesity increases fall risk in older adults and trip-related falls are the lead fall-cause in older adults. Thus obesity-related increased fall-risk could reflect more frequent tripping and/or impaired recovery responses after tripping. Indeed, older adults with obese BMI have lower MTC (Garman et al 2015) and impaired kinematics of trip-recovery compared to those with normal-weight BMI (Rosenblatt et al 2012). However, dichotomizing obesity based on BMI may poorly indicate excessive fat. When assessing obesity-related health conditions it is recommend to combine BMI with other obesity measures, a concept that may extend to falls. We investigated the effects of AAM on trip-related fall risk. We hypothesized that measures of trip-risk and trip-recovery would: 1) associate with AAM other than BMI; 2) be less favourable in obese vs. non-obese older adults, characterized by AAM other than BMI.

### Methods

28 community-dwelling older adults with normal-weight BMI and 27 with obese BMI participated. We calculated the following AAM using a tape measure, scale, and DEXA scan: waist, hip and thigh circumference; BMI; WHR; index of central obesity (waist circumference/height); percent leg, trunk, and total fat; and FMI (fat mass/height<sup>2</sup>). Participants donned a safety harness then walked along an 8 m walkway 10-20 times. During the last pass, an obstacle unexpectedly rose from the walkway to obstruct the swinging limb and induce a trip. From motion capture markers we derived three measures of trip-risk: median and interquartile range (IQR) of MTC and the probability of tripping as per Byju et al

(2016), and four trip-recovery measures: trunk flexion angle and angular velocity ( $\theta$  and  $\omega$ , respectively); anterioposterior distance between the toe marker on the stepping limb and the center of mass ( $COM_{dist}$ ), and recovery step time. For  $HI$ , we separately ran principal component (PC) analysis on the set of trip-risk then trip-recovery measures. For each included PC, we calculated PC scores and correlated them with AAM. To address  $H2$ , we grouped participants according to the AAM that most strongly correlated with a given PC score and had an established obesity cut off, then ran between-group comparison for measures that loaded on the PC.

### Results and Discussion

We induced a trip in 47 participants, and 80% used a lowering strategy. A single PC explained 83% of the variance in trip-risk measures, all of which strongly loaded on the PC. WHR ( $r=0.29$ ) and thigh circumference ( $r=0.31$ ) were significantly associated with PC scores, while BMI was not. When grouping participants based on WHR, obese participants exhibited a significantly higher MTC-IQR than non-obese (Cohen's  $d=0.64$ ). Two PCs explained 80% of the variance in trip-recovery measures, with  $\theta$ ,  $\omega$  and  $COM_{dist}$  strongly loading on the first PC (PC1). Hip circumference ( $\rho=0.40$ ), thigh circumference ( $r=0.43$ ), FMI ( $\rho=0.34$ ), and total fat ( $r=0.33$ ) were significantly associated with PC1 scores, while BMI was not. When grouping participants based on FMI, obese participants exhibited less favorable  $\omega$  ( $d=0.84$ ; Figure 1) than non-obese. Only step time loaded on PC2, but PC2 scores were not associated with any AAM. While biomechanics studies traditionally use BMI when assessing the effects of obesity on fall risk, alternative should be considered. Indeed, a 2020 study by Meng et al found android to gynoid fat ratio provided better insight into postural control than BMI. Similarly, fall-risk is elevated in adults  $\geq 50$  years of age with central obesity but not with obese BMI (Cho et al 2018).

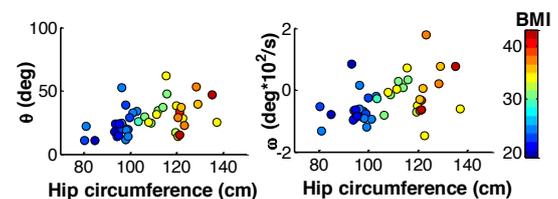

Figure 1: Scatters of trunk control measures and hip circumference.

### Conclusions

Central obesity (WHR above established thresholds) and greater adiposity (high FMI) affect trip-related fall risk in older adults, perhaps more strongly than increased BMI.

### Summary

Balance during feet-in-place standing can be maintained by the ankle mechanism and the counter-rotation mechanism. A balance board limits the effectiveness of the ankle mechanism. However, preliminary results of this study on four young adults revealed that the contribution of the counter-rotation mechanism to the CoM acceleration was limited compared to the contribution of the ankle mechanism. The participants kept their head relatively stable compared to the balance board rotations, which could be preferable to keep the field view constant. It could be that trunk rotations are used to regulate the orientation of the head in space, rather than to control CoM accelerations.

### Introduction

Balance control, defined as controlling the Center of Mass (CoM) within the base of support (BoS) during standing, can be achieved by applying ankle moments to shift the center of pressure (CoP) within the BoS ('ankle mechanism') [1], or by changing the angular momentum of segments around the CoM, e.g. arm and trunk movement ('counter-rotation mechanism') [1]. This study aims to reveal the influence of standing on a balance board, which reduces the effectiveness of the ankle mechanism, on the relative contribution of both mechanisms to balance control.

### Methods

Children (6-9y), young adults (18-24y) and non-falling older adults (65-80y) performed trials of 16 seconds of standing on uniaxial balance boards varying in height (15,17 and 19 cm), creating an unstable support in the sagittal (AP) or in the frontal plane (ML). A greater height will create a larger

mechanical perturbation by reducing the effectiveness of the ankle mechanism [2]. This abstract contains preliminary results of four young adults (2 males, 2 females, mean age; 21.1 years old) standing on the highest ML balance board. Full body kinematics (16 segments, 48 markers, using SIMI 3D-motion analysis system (GmbH)) and kinetics (using the imbedded AMTI force plate) were recorded. The contributions of the ankle mechanism and counter-rotation mechanism to the CoM acceleration, as described by Hof (2007) [1] were calculated for the ML direction.

### Results and Discussion

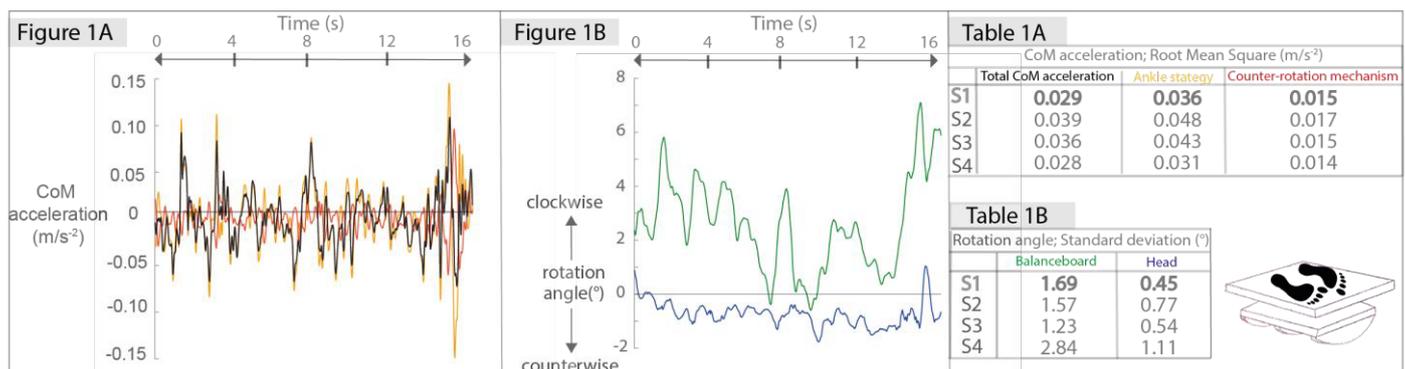

The contribution of the counter-rotation mechanism to CoM acceleration was limited (Figure 1A and Table 1A). Participants did not aim to keep the balance board horizontal. The amplitude of the rotations angles was greater for the balance board than the head (Figure 1B and Table 1B). This suggests that people attempt to stabilize the head in space. Keeping the head aligned may conflict with using the counter-rotation mechanism in regulating the CoM acceleration. In future work we will assess age differences in the use of the balance control mechanisms.

### Conclusions

The ankle mechanism contributed the most to CoM acceleration. Participants tended to limit head rotation. It could be that trunk rotations regulate the orientation of the head in space, rather than CoM acceleration.

Email: [pieter.meyns@uhasselt.be](mailto:pieter.meyns@uhasselt.be)

### Summary

Children with bilateral spastic cerebral palsy (CPc) experience poor postural control including affected reactive standing balance control and steady-state gait stability. We examined to what extent reactive gait stability is affected in CPc compared to typically developing children (TDc) and whether 6-weeks home-based videogame-based balance training (VGBT) can improve reactive gait stability in CPc. Reactive gait stability was assessed using medio-lateral and backward margins of stability during a perturbed step during treadmill walking and the recovery step after perturbation in 17 CPc and 9 TDc. We found that reactive gait stability was affected in CPc compared to TDc in medio-lateral and antero-posterior direction. However, no improvements were found in reactive gait stability after VGBT in CPc.

### Introduction

CPc experience poor postural control due to sensorimotor disorders resulting from non-progressive brain lesions [1]. They show affected reactive standing balance control [2] and steady-state gait stability [3]. However, it is unclear to what extent reactive gait stability is affected in CPc compared to TDc. Previous work suggested a transfer from standing VGBT to steady-state gait stability in CPc [4]. Therefore, we investigated to what extent reactive gait stability is affected in CPc compared to TDc, and whether VGBT can improve reactive gait stability in CPc.

### Methods

In our registered trial (NTR6034), 17 CPc and 9 TDc were included. Inclusion-criteria of CPc were: bilateral spastic CP, GMFCS-level II (i.e. walking without assistive devices, with difficulty on uneven surfaces), no surgical interventions <12 months nor Botulinum Toxin A-injections <6 months. CPc performed 6 weeks home-based VGBT using the X-box One (Microsoft). Kinect games focusing on balance (tennis, football, bowling) were used 5x/week, 30min/session. Pre-VGBT (CPc & TDc) and post-VGBT (CPc), participants performed split-belt treadmill walking at preferred speeds including slip perturbations. At right foot contact, the right belt speed accelerated and then decelerated back to normal speed to induce a slip-like perturbation. Ten perturbations were unpredictably elicited. A perturbation was followed by approximately 10 unperturbed strides. Total body (Plug-In-Gait) kinematics were collected using a 10-camera Vicon motion-capture system at 120 Hz. Medio-lateral and backward margins of stability (ML-MoS, BW-MoS) were calculated as the position of the extrapolated center of mass (XCoM) relative to the lateral malleolus and heel of the

leading foot, respectively[5]. XCoM was defined as CoM, plus its velocity times a factor:  $\sqrt{(\text{CoM height}/\text{acceleration of gravity})}$ . Negative ML-MoS results in deviation from straight walking, and negative BW-MoS in interruption of forward progression. MoS was calculated for the perturbed step and the next step. Additionally, MoS variability (sdMoS) was determined. Mann-Whitney tests were performed to assess baseline differences between CPc and TDc. Wilcoxon signed-rank tests were performed to assess the effect of intervention in CPc.

### Results and Discussion

Reactive gait stability was less in CPc compared to TDc in medio-lateral and antero-posterior direction. The perturbed step and step afterward showed higher ML-MoS (Figure 1) and lower BW-MoS than TDc. This suggests a protective strategy of increasing ML gait stability with reduced forward progression when perturbed. Variability of reactive gait stability appeared similar between the groups. Contrary to preliminary findings in steady-state gait stability [4], no improvements were found in reactive gait stability after VGBT, except for a counter-intuitive increase in variability of BW-MoS of the perturbed step. It should be investigated whether task-specific reactive gait training can improve reactive gait stability in CPc.

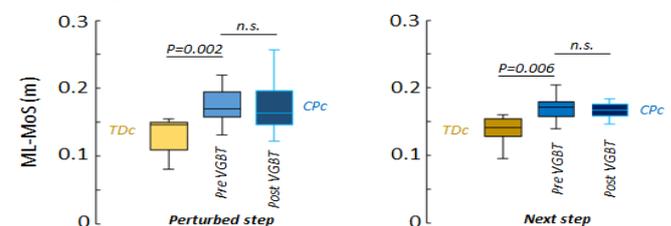

Figure 1: ML-MoS in CPc (blue) and TDc (orange).

### Conclusions

Reactive gait stability is affected in CPc. VGBT while standing does not improve reactive gait stability in CPc.

## Summary

Among persons with lower limb loss, wearable sensors determined that intact limb hip, knee, and ankle joint motions contribute to increased postural sway, supporting the use of a triple inverted pendulum model.

## Introduction

Persons with lower limb loss often rely on the intact limb, exhibit impaired balance and a high incidence of fall-related injury [1]. Postural sway (i.e., balance) is typically explained by double or single inverted pendulum models of the hip and/or ankle, neglecting contributions of the knee joint. However, recent work suggests knee joint motion influence and work in concert with the hip and ankle to stabilize the center of mass (COM) kinematics [2]. Yet, the extent to which ankle, knee, and hip motion contributes to postural sway in persons with limb loss is unknown. This study used a triple inverted pendulum model to determine the contributions of lower limb joint motion to standing postural sway using wearable sensors. We expected combinations of hip, knee, and ankle motions would predict sway parameters.

## Methods

Forty-two participants with unilateral lower limb loss (30 transtibial, 12 transfemoral; 25m/17f, 35±8yrs, BMI: 27.3±5.2kg/m<sup>2</sup>) stood quietly for 30s on a firm surface, with eyes open and eyes closed, while wearing 4 accelerometers on the sacrum, thigh, shank, and foot of the intact limb (128Hz, Opal Gen2, APDM Inc, Portland, OR). Triaxial accelerations were transformed to inertial anterior-posterior components, from which 3 sway parameters were computed [3]: ellipse area (EA), root-mean-square (RMS), and jerk. A state space model with a causal Kalman filter calculated hip, knee, and ankle joint flexion-extension angles and ranges of motion (ROM; max-min joint excursion). Multiple linear regression predicted postural sway parameters from the intact lower limb joint ROMs, with BMI and amputation level as covariates ( $p < 0.05$ ).

## Results and Discussion

With eyes open, hip ROM predicted sway EA, whereas hip

and knee ROM predicted sway RMS, and hip (2.8±1.9°), knee (2.1±1.5°), and ankle (1.5±0.9°) ROM predicted sway jerk (Table 1; EA: .04±.03 m<sup>2</sup>, RMS: .08±.04, jerk: 1.8±1.5 m/s<sup>3</sup>). With eyes closed, hip ROM (3.6±2.1°) persisted as the predictor of sway EA (.06±.06 m<sup>2</sup>); no other lower limb joint motions (knee: 3.2±2.5°, ankle: 2.1±1.4°) influenced other sway parameters in this condition. As hip motion increased, sway parameters also increased, regardless of visual condition. Consistent with our hypothesis, and the suggested use of a triple inverted pendulum model, knee and ankle joints have negative and positive relationships to sway parameters, respectively. Thus, increasing intact-side hip flexion, knee extension, and ankle plantarflexion ROM increased COM postural sway during quiet standing with limb loss. Given the increased dependence on vision for postural control among persons with lower limb loss [4], the lack of relationship between sagittal lower limb joint motion and postural sway with eyes closed is surprising, but may be explained by motions and coordination strategies in other planes, segments, and prosthetic limb control.

## Conclusions

Motions from all intact lower limb joints contribute to postural sway in persons with lower limb loss during quiet standing, with eyes open, supporting the use of a triple inverted pendulum model of balance. Improving coordination of the biarticular muscles of the intact hip and knee may have important implications for balance control.

### Summary

Gait was unexpectedly perturbed by rapid acceleration-deceleration once per trial at mid-stance of the unaffected leg during a randomly selected gait cycle. The initial perturbation was determined as the percentage of participant's maximum walking speed and increased or decreased in each trial, based on success or failure of recovery. Participants had fewer falls and more recoveries and had a higher recoverable perturbation. The protocol was found to be feasible in stroke survivors with moderate gait deficits.

### Introduction

Stroke survivors show a high risk of falls with unexpected external perturbations during walking [1]. Fear of falling is one of the problems that stroke survivors encounter daily. Regaining balance after stroke is thus imperative. Assessment of gait may be key to use as a fall risk prediction tool [2]. Despite the number of studies that focus on gait stability, ways to quantify dynamic stability of human gait are still not fully clear [3]. Thus, the purpose of this work is to develop treadmill-based midstance gait-perturbation for a poststroke population.

### Methods

Twelve participants were randomly assigned to one of the three intervention groups: clinical physical therapy, reactive standing slip, and active video gaming. Reactive balance was tested by a progressive perturbation protocol on the R-Mill treadmill before and after the 10 weekly intervention sessions.

The protocol consisted of a maximum of fifteen 90-second walking trials, each trial with three 30-second periods: pre-perturbation, perturbation, and recovery. The perturbation was induced by increasing the treadmill belt speed to a specified perturbation magnitude for 0.25 seconds, then returning it to its previous speed. All speed changes were done at a constant acceleration of 15 m/s<sup>2</sup>.

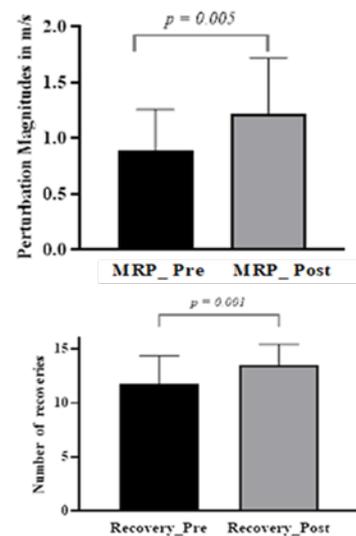

These belt speed perturbations, which induce a forward fall, were applied once per trial at mid-stance of the unaffected leg, during a randomly preselected gait cycle within the perturbation period.

Average stance time was determined from vertical force data from gait cycles prior to the perturbation and used to calculate the half stance time (mid-stance) after the randomly selected heel-strike event; this mid-stance was the point at which the perturbation was induced. A stepwise progression based on

trial outcome was followed to modulate the perturbation magnitude for subsequent trials.

### Results and Discussion

We were able to implement an individualized, treadmill-based, midstance gait-perturbation protocol for reactive balance assessment. Participants demonstrated improvements from pre-intervention to post-intervention in trial outcomes (fall vs. recover), and maximum recoverable perturbation (MRP) in Figure 1. Compared to the pre-session, there were fewer falls at post-testing and more recoveries and had a higher MRP.

**Figure 1:** Comparing pre to post tests for maximum recoverable perturbation magnitudes and recoveries.

### Conclusions

The capability to induce a perturbation at mid-stance, during a randomly selected gait cycle, within a given perturbation period, in a research laboratory setting has potential in assessing balance control among stroke survivors and in providing a more consistent test across- subjects and within-subjects.

### Summary

Locomotor adaptation and savings are hypothesized to underlie locomotor learning and are often studied through split-belt walking. We studied locomotor savings of split-belt adaptation after three weeks in healthy human adults. Fourteen participants adapted to split-belt walking for ten minutes upon first exposure and completed the same protocol again after three weeks, without any training in between. Measures of spatiotemporal asymmetry were used to assess adaptation. We applied Singular Spectrum Analysis, a non-parametric approach, to quantify adaptation and washout trends. Participants exhibited savings after three weeks in both adaptation and washout phase. Collectively, our results demonstrated locomotor savings of split-belt adaptation within ten minutes of total adaptation time and were more prominent in the spatial domain than the temporal domain.

### Introduction

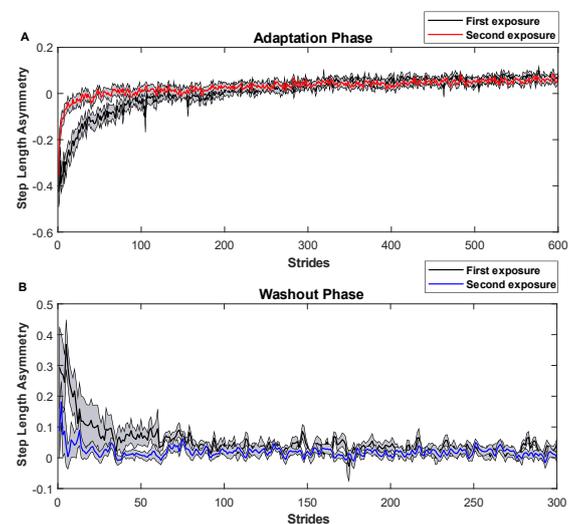

Locomotor adaptation is the ability to continually adjust one's locomotion pattern which aids in humans to move through their surroundings. Short term locomotor adaptation and savings have been studied experimentally using a split-belt treadmill [1]. We assessed the long-term savings of split-belt adaptation by re-exposure to split-belt adaptation after three weeks in able-bodied participants. Furthermore, step length's spatial and temporal characteristics have been studied and spatial information was reported to exhibit savings [1], therefore, we expected greater savings to be present in spatial (Step Length) rather than temporal (Double Support and Swing Time) gait asymmetry parameters.

### Methods

Fourteen healthy young adults completed the same split-belt treadmill protocol during first exposure and then second exposure after three-weeks. During the Split-belt protocol participants walked five minutes fast tied-belt baseline ( $1.5 \text{ m s}^{-1}$ ), five minutes slow tied-belt baseline ( $0.5 \text{ m s}^{-1}$ ), ten minutes split-belt adaptation ( $1.5: 0.5 \text{ m s}^{-1}$ ), and five minutes slow tied-belt washout ( $0.5 \text{ m s}^{-1}$ ) [2]. Step Length Asymmetry (SLA) and Double Support Asymmetry (DSA) were calculated from the force plates embedded in the treadmill. Singular Spectrum Analysis (SSA) was used to extract trend parameters like adaptation volume (i.e., total amount of adaptation during adaptation phase) and shape (i.e., percentage of total adaptation volume) of SLA and DSA to quantify adaptation and magnitude of savings [3]. Statistical non parametric test (paired Wilcoxon-signed rank test) was used to compare first and second exposure.

### Results and Discussion

One-sample Wilcoxon signed rank test indicated adaptation in SLA volume ( $M = 0.413$ ,  $SD = 0.133$ ,  $V = 105$ ,  $p < 0.001$ ), SLA shape ( $M = 0.638$ ,  $SD = 0.180$ ,  $V = 105$ ,  $p < 0.001$ ), DSA volume ( $M = -0.095$ ,  $SD = 0.127$ ,  $V = 14$ ,  $p = 0.013$ ). Paired Wilcoxon signed rank test showed long term savings in SLA volume ( $V = 105$ ,  $p < 0.001$ ) and DSA volume ( $MI = -0.095$ ,  $SD1 = 0.127$ ,  $M2 = -0.042$ ,  $SD2 = 0.065$ ,  $V = 30$ ,  $p = 0.172$ ) in adaptation phase.

**Figure 1:** Group-averaged results (N=14) of Split-belt adaptation. Group averaged SLA - A (adaptation phase), B (washout phase).

### Conclusions

We found locomotor savings within 10 minutes of split-belt adaptation after three-weeks of washout period in healthy adults. Also, savings of locomotor adaptation were more prominent in spatial gait parameters than temporal gait parameters.

### Summary

We introduced a reflex-based model to perform forward dynamics with ground contact information in a range of walking speeds without known motion beforehand. The model successfully predicted normal walking at different speeds. The model can also generate stable gait kinematics and predict ground reaction force (GRF). It has potential applicability in predicting GRFs in patient populations for eventual use in assistive device control aimed at achieving a more normal walking pattern.

### Introduction

A neuromechanical simulation consists of a control model that represent the central nervous system and a musculoskeletal model that represents the body. Movements such as walking can be forward-simulated in control and musculoskeletal models based on physical laws. A reflex-based controller [1] can generate muscle activations during gait. The two lower limbs have separate stance and swing reflexes, which are selected based on ground contact sensing. The reflex outputs depend on the dynamic interplay between legged mechanics and the ground. As resulting GRFs are unknown, a recurrent dynamic network was introduced to approximate the GRFs.

### Methods

In an OpenSim [2] musculoskeletal model, we used an optimization control framework (CMA-ES) [3] to implement the reflex-based controller [1]. The 3D musculoskeletal model consists of seven segments connected with eight rotational joints and is actuated by 22 muscles. Each foot segment has three contact spheres that can dynamically interact with the ground. We first developed a reward function that the optimization aimed to maximize during a specified time interval. The reward was designed so that the total reward was high when the musculoskeletal model walked at desired velocities with minimum effort.

After the optimization, we trained a recurrent dynamic network to map the joint kinematics to the GRF. Then we predicted the GRFs with new joint kinematics using the trained network. The predicted GRF was then fed back to the input of the controller to drive the forward simulation.

### Results and Discussion

Realistic joint kinematics were produced over a range of desired walking velocities between 1.1m/s and 1.8m/s. All simulations produced a stable gait pattern at all walking speeds with the reflex-based controller using predicted GRFs. Peak extensions in the hip and the ankle increased

with increasing walking speed. Knee kinematics were more realistic with higher walking speeds than with lower.

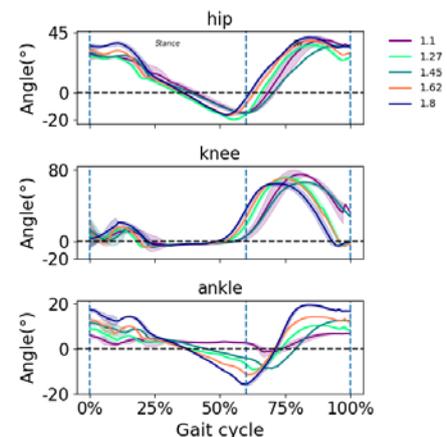

Figure 1: Kinematics of simulated walking over a range of speeds.

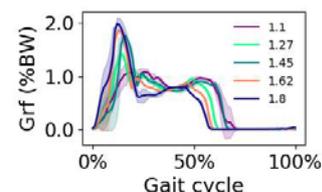

Figure 2: Predicted GRF over a range of speeds.

### Conclusions

The neuromechanical model and optimization framework presented based on a reflex-based controller simulated reasonable walking kinematics over a range of desired speeds without any experimental data. It can also predict GRFs associated with the simulated joint kinematics to control the model. It has potential applicability in predicting GRFs in patient populations whose kinematics can be reasonably well predicted with the reflex-based model, which can be useful in designing control algorithms in assistive devices that aim to achieve more normal walking patterns.

### Summary

The aim of this work was to analyze how PD affects the motor plan. We hypothesized that the EMG sequence can be considered as a motor program. To be able to address and quantify the motor control abnormalities will allow us to identify how the PD disrupts normal control processes.

### Introduction

Parkinson's disease (PD) is the second most prevalent neurodegenerative disorder affecting people worldwide. Gait disorder is one of the cardinal features of PD and might be affected by a modified pattern of motor unit activation and rigidity [1]. State of the art showed that basal ganglia dysfunction affects not only the automatic maintenance of the movement [2] but also each component of the motor plan in terms of timing. For a voluntary movement of a given amplitude and speed, a motor program is meant to specify the muscles to be used and their relative spatio-temporal parameters of activation [3].

### Methods

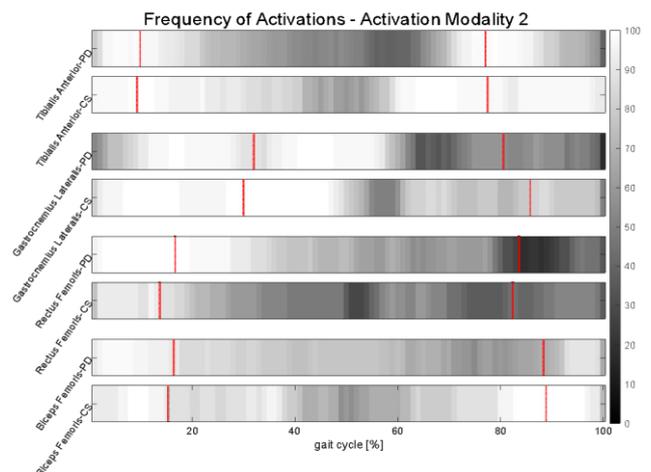

The data of eighteen PD subjects (age  $65.6 \pm 10.5$  years, BMI  $26.5 \pm 3.5$  kg/m<sup>2</sup>) and ten controls subjects ((CS) age  $62 \pm 6.5$  years, BMI  $26.4 \pm 3.7$  kg/m<sup>2</sup>), have been acquired at the Human Movement Bioengineering Laboratory (10m walkway) of the Department of Information Engineering at the University of Padova (Italy). Data from an 8-channels EMG system (1000Hz, BTS, Italy) were collected to record the electrical activity of four lower limb muscles bilaterally: Tibialis Anterior, Gastrocnemius Lateralis (GL), Rectus Femoris and Biceps Femoris. The EMG signals were band pass filtered with a double 5th order Butterworth filter and full wave rectified. The cut-off frequencies varied between 15 and 20 Hz for high pass filter, and between 450 and 495 Hz for low pass filter. A double-threshold statistical detector [4] was applied for activation detection. Peak of the envelope (PoE) and its position (PPoE) per each accepted burst were extracted together with burst duration. Subjects were then grouped per activation modality types.

### Results and Discussion

The most representative activation modalities, i.e., 1, 2 and 3 bursts, were reported in Table 1. In Figure 1 is reported the distribution of the activations over the gait cycle for each group of participants and each muscle for the two-activations modality. Red bars represent the PPoE for each burst. Greatest in between group differences were appreciated in the GL.

**Table 1:** Frequency of activation modalities in percentage of the total amount of trials for each group.

	TA		BF		RF		GL	
	CS	PD	CS	PD	CS	PD	CS	PD
1	10.3	7.2	23.2	21.3	25.5	43.9	43.1	59.8
2	63.8	61.9	44.6	51.1	45.5	41.8	48.3	37.1
3	17.2	21.6	26.8	19.1	23.6	9.9	5.1	2.1

**Figure 1:** Activation frequency. Red vertical bars indicate PPoE for the second modality.

### Conclusions

We propose a representation to characterize PD's motor control for lower limb muscles. PD subjects displayed a different motor plan during walking. The objective assessment of a different motor control strategy could be useful for planning interventions aiming at improving the walking pattern of PD's subjects.

### Summary

Stroke may cause different gait abnormalities, such as knee hyperextension and stiff-knee gait. This study used predictive simulation to investigate how the weakening and strengthening of the knee extensor muscles affect the gait pattern of a post-stroke patient. The prediction result showed impairments similar to those observed in the gait obtained by the inverse dynamics. While the predictive simulation of muscle weakening corrected the stiff-knee gait, the gait prediction of muscle strengthening decreased the knee hyperextension exhibited in the gait pattern of the patient.

### Introduction

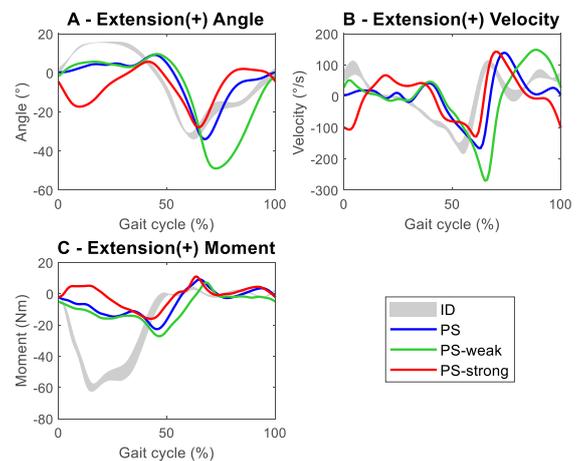

Individuals who suffered stroke may present impaired gait. Knee hyperextension and stiff-knee gait (SKG) are deviations commonly exhibited by this population, but these gait patterns could have different causes [1]. Understanding how to improve these impairments may support the rehabilitation. Predictive simulation was used in order to investigate the cause-effect relationship between changes in the musculoskeletal system and the observed gait abnormalities in a typical post-stroke patient. In a simplified approach, the purpose of this study was to predict the effects of the weakening and strengthening of the knee extensor muscles on pathological gait, and to investigate whether the specific changes could improve the gait pattern of the patient.

### Methods

The gait analysis was performed for a female patient (age: 46 years; height: 1.60 m; mass: 63.8 kg) walking overground at a self-selected gait speed ( $0.55 \pm 0.04$  m/s). Inverse dynamics (ID) results were obtained using a scaled lower body model (gait2392) and the tools available in OpenSim (v. 3.3). The 3D musculoskeletal model used for predictive simulations (PS) was based on the one used in ID. The PS was formulated as an optimal control problem [2]. The observed speed in the gait analysis was imposed. Personalized muscle-tendon parameters (optimal fiber length, maximal isometric force and tendon slack length) were used for PS. An optimal control problem was solved using the ID joint moments to estimate the personalized muscle-tendon parameters [2]. With this parameter set, it was possible to predict a pathological gait without directly relying on the kinematics and kinetics of the collected gait data. In order to investigate the effect of muscle weakening (PS-weak), maximal isometric force of the knee extensor muscles in PS was decreased by 50%. Similarly, muscle strengthening (PS-strong) was predicted by increasing maximal isometric force by 50%.

### Results and Discussion

The knee hyperextension and SKG observed in the ID were predicted, but PS resulted in less knee extension during the stance phase than the ID (Fig. 1A). PS-weak increased knee hyperextension and corrected the SKG, while the opposite was observed for PS-strong (Fig. 1A). These results indicate that weak knee extensor muscles is related to knee hyperextension in this patient, as also reported by Mulroy et al. [3]. The decreased peak of knee flexion in the swing phase was accompanied by low knee flexion velocity (Fig. 1B), which has been identified as a cause of SKG [4]. The change of dominance from knee flexion to extension moment in early stance phase in PS-strong (Fig. 1C) allowed knee flexion, which corrected knee hyperextension.

**Figure 1:** Knee extension (A) angle, (B) velocity and (C) moment for inverse dynamics, predictive simulation, knee extensor muscle weakening and knee extensor muscle strengthening results.

### Conclusions

The alteration of the knee extensor muscle strength predicted improvements in the post-stroke gait and identified possible causes of the knee hyperextension and SKG. Future studies may investigate other gait abnormalities and should include more patients in the analysis.

## Crack patterns around an osteon simulated with the phase field method for fracture

Anna Gustafsson<sup>1</sup>, Hanna Isaksson<sup>1</sup>

<sup>1</sup>Department of Biomedical Engineering, Lund University, Lund, Sweden

Email: [anna.gustafsson@bme.lth.se](mailto:anna.gustafsson@bme.lth.se)

### Summary

The microstructure is key for good fracture resistance in cortical bone. In this study we evaluate the potential of using the phase field method to simulate crack growth around an osteon and compare the results to our previous extended finite element models. We show that the phase field models can capture realistic crack patterns in cortical bone, such as crack deflections along cement lines. In future studies, the phase field method will be a valuable tool for elucidating the underlying reasons for bone fragility in osteoporotic patients.

### Introduction

Cortical bone tissue is a composite material (Fig. 1A) with good fracture resistance in healthy conditions. Potent toughening mechanisms arise when cracks interact with the microstructure. Although local fracture properties cannot be quantified experimentally, indentation tests suggest that osteons have slightly higher fracture toughness than the surrounding matrix [1].

We have shown using the extended finite element method (XFEM) how weak cement line interfaces can deflect cracks that approach an osteon [2]. However, the osteon fracture properties did not influence the crack patterns in our XFEM models [2]. The phase field method is a new promising method for modelling fracture [3], not yet applied in biomechanics. The aim of this study is therefore two-fold: 1) to evaluate the potential of using the phase field method to simulate crack growth in cortical bone at the microscale and 2) to analyze if the fracture energy of the osteon affects the crack pattern.

### Methods

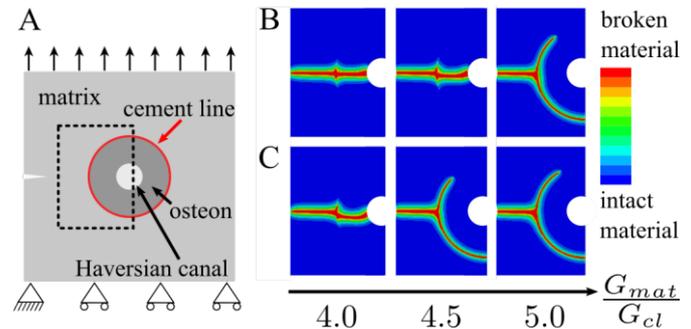

We adopted a phase field model for fracture previously applied on wood [4]. The same osteon geometry as in [2] was used with material parameters given in table 1. The fracture energy  $G_{cl}$  in the cement line was compensated following [4] to account for energy dissipation in the surrounding materials from the regularized phase field crack. The model was loaded quasi-statically in tension (Fig. 1A) and crack patterns were evaluated for interface fracture energies 4-5 times lower than the matrix. The fracture toughness of the osteon was assumed to be equal to or 20% higher than the matrix.

**Table 1: Material parameters [2].**

	Matrix (mat)	Osteon (ost)	Cement line (cl)
E (GPa)	15	12	18
$\nu$	0.3	0.3	0.3
G (N/mm)	0.4	0.4 (0.48)	0.1-0.08

### Results and Discussion

The phase field models predicted similar crack patterns as seen in our XFEM models [2], where weak interfaces deflected cracks and hindered them from growing through the osteons. Crack deflections occurred for interfaces approximately 5 times weaker than the matrix.

**Figure 1:** A) Finite element model. Crack patterns inside the dotted region are shown for B)  $G_{ost}=0.4$  N/mm, and C)  $G_{ost}=0.48$  N/mm, for different cement line fracture energies.

Increased fracture energy in the osteon further promoted crack deflection in the cement line (Fig. 1B and C). This is reasonable, as it indicates that osteons also, in combination with cement lines, play a role in protecting the Haversian canals from damage. This effect was not captured by the XFEM models [2].

### Conclusions

To capture the competition between crack deflection and crack penetration at the osteon boundary is key for understanding the relationship between microstructure and tissue fracture toughness in cortical bone. This preliminary study shows that the phase field method is a suitable candidate for analyzing such relationship. Future studies should focus on simulating damage in more realistic bone geometries to elucidate the underlying reasons for bone fragility in osteoporotic patients.

### Summary

Human body models (HBMs) are becoming an indispensable tool to assess safety for current and future transportation systems. In this study, a framework for the design of open-source VIVA+ HBM lineup is presented. A workflow was developed where a single model serves as the baseline model, while all the other models in the lineup (other anthropometric design points and postures) are closely linked derivatives. Such an approach facilitates continuous integration for efficient model development, where the model development is focused on the baseline HBM while all the other models concurrently receive updates.

### Introduction

Recent trends in automobile injuries indicate that safety should be evaluated for a wider population [1,2]. Finite element (FE) HBMs are well suited for performing virtual safety evaluations at multiple anthropometric design points and for various road users. Traditionally, however, developing and maintaining a lineup of HBMs require considerable modeling effort.

### Methods

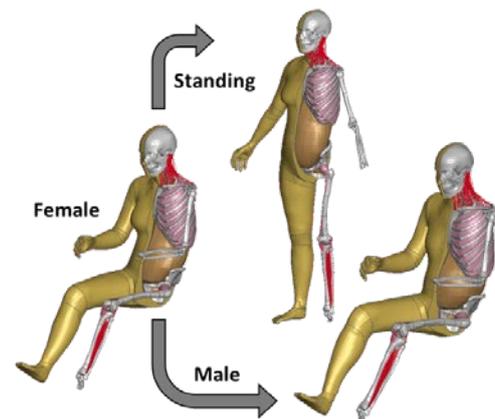

The goal for the VIVA+ HBM framework was to have one model as the baseline model and rest of the models in the lineup defined as closely linked derivatives. Such a workflow was implemented by having a common FE mesh for all the models in the lineup and by using mesh morphing to obtain the new geometry for specific anthropometries or postures [3]. In addition, material properties not affected by mesh morphing, were parametrized for easy adjustment.

As the first step, the FE mesh for an average female was developed on a statistical average geometry to serve as the baseline. This mesh was defined using hexahedral elements with seamless mesh flow about the joints, so that the mesh can accommodate large changes in joint angles to represent different postures. Models of different anthropometry and postures were then derived from the baseline model using mesh morphing.

### Results and Discussion

Figure 1 shows the outcome of generating standing female and seated average male HBMs from the baseline VIVA+ seated female HBM. The only differences between the models are the node coordinates of the mesh. With this approach, the models benefit from having consistent definitions between them and enables more reliable comparisons of the outcomes between the models.

This workflow enables continuous integration for the models at two levels. First, it allows all the model development to be focused on the baseline model. All the changes are continuously relayed to all the derivative models in the VIVA+ lineup. This establishes a strong link between all the models and helps to keep all the models consistent with minimal effort.

**Figure 1:** Derivative standing and male models from the baseline average female VIVA+ model.

Second, as the best practice in the development of digital products today, this workflow for HBMs enables frequent releases with smaller updates rather than a bigger release with many updates. With this framework, new features or model improvements can be released regularly, with the updates available on all the models in the VIVA+ lineup. We also see this as an important aspect of open-source sustainability, where a VIVA+ contributor needs to make an update only on the baseline model and the changes are reflected on all the derivative models.

### Conclusions

In this work, we demonstrated a workflow for establishing continuous integration for a lineup of HBMs, which is critical for sustainability of open-source and collaborative model development.

## A Penalty Contact Implementation on a Highly Parallelisable Cartesian Mesh Finite Element Solver

Frederik Trommer<sup>2</sup>, Pinaki Bhattacharya<sup>1</sup>

<sup>1</sup>Insigneo Institute for in silico Medicine, University of Sheffield, United Kingdom

<sup>2</sup>Department of Mechanical Engineering, University of Sheffield, United Kingdom

Email: fntrommer1@sheffield.ac.uk

### Summary

Elastic-elastic penalty contact was implemented in the highly parallelizable voxel based micro finite element solver ParOSol. Displacements for a simple contact problem were predicted and were found comparable to a commercial solver. This serves as an intermediate step towards implementing in ParOSol a novel contact formulation which has been shown to reduce errors associated with the jagged voxel surface.

### Introduction

Micro finite element analysis (uFE) is a validated tool for non-invasively quantifying bone mechanics using high resolution computed tomography (CT) images. MicroFE solvers for Cartesian mesh (or voxel) models, such as ParOSol [1], can efficiently solve problems with billions of degrees of freedom. As yet, such solvers do not accurately compute contact induced stresses due to the artificially jagged Cartesian mesh surface. The novel simulated smoothed surface, sliding contact (SS-SC) formulation [2] addressed this by simulating a smooth surface within a penalty contact approach, resulting in a reduction of errors associated with contact from 42% to 2%. The usability of the SS-SC formulation is limited by the fact that it is currently implemented in an in-house FE solver. As an intermediate step towards implementing the SS-SC formulation in the highly parallelized octree-based multigrid ParOSol solver, the present study implements the standard penalty contact formulation in ParOSol.

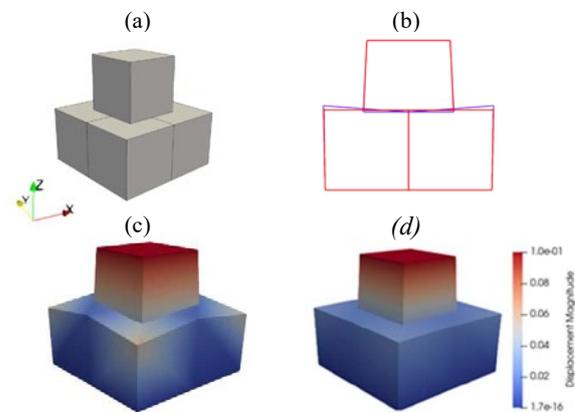

### Methods

The disjoint deformable bodies involved in contact are initially aligned along the same Cartesian grid. Initial rigid-body transformations orient these bodies such that contact is incipient. An incremental solution strategy is implemented to capture intermediate contact states leading to the final state of deformation and/or load. Within each increment, contact iterations are performed to solve the nonlinear contact boundary conditions. Specifically, in each iteration, the global stiffness matrix and the global load vector are updated by contributions from the tangent contact stiffness and the contact reaction forces. These contributions are computed based on [3]. The implementation was used to analyse the problem of two linear elastic, homogeneous and isotropic bodies (A and B) with hard, frictionless contact interaction (Figure 1). The nine nodes on the bottom plane of body B (comprising four voxels) are fixed in all dimensions; the 4 nodes on the top of body A, comprising a single voxel, are restricted in x and y directions; body A is displaced in -z direction onto body B such that they penetrate by 10% of the

voxel size. Two equally weighted master–slave pairs were defined with the opposing surfaces of A and B as master and slave respectively and vice versa. Model prediction is verified against an identical formulation in the commercial FEA solver Abaqus v6.14.

### Results and Discussion

Figure 1 compares the predictions from ParOSol and Abaqus for the displacement of the bodies.

**Figure 1:** a) Model geometry in reference configuration. b) Outlines of the solutions at a central cross section, blue: Abaqus, red: ParOSol. Magnitude of contact induced displacements predicted by c) Abaqus and d) ParOSol.

### Conclusions

The implemented penalty contact formulation converged, and predicted deformations comparable to a commercial solver. The solution obtained by Abaqus shows more overclosure and a larger bulge in body B, probably owing to numerical artifacts due to the small size and the constrained nature of the problem. Future implementations will engage the multigrid cycles in the solution process and include a simulated smooth surface definition, thus improving the prediction of surface interactions and integrating the SS-SC formulation more completely into ParOSol.

## Computational fluid dynamics in cerebral aneurysm.

A. Brambila Solórzano<sup>1</sup>, C. Escobar del Pozo<sup>2</sup>

<sup>1</sup>Termofluids Department, Faculty of Engineering, UNAM, México City, México

<sup>2</sup>Faculty of Mechanical and Electrical Engineering, Universidad de Colima, Colima, México

### Summary

A methodology for the study of fluid dynamics in intracranial aneurysms was developed to try to understand the pathophysiology of the disease. Besides, this methodology can help doctors in making clinical decisions on which aneurysms to operate, since the risk of rupture and postoperative complications are comparable.

### Introduction

The incidence of intracranial aneurysms is extremely high: 2-5% of the adult population are affected. Fortunately, the majority remain asymptomatic and, the risk of rupture is very low: 0.1-1% [1]. The rupture of an aneurysm and its consequent subarachnoid hemorrhage has a mortality rate of 45% with significant neurological residues in half of the survivors [2]. Aneurysm detection has increased due to advances in imaging, the decision of which aneurysms to treat should not be taken lightly because the risk of rupture and the risk of the clinical procedure are comparable. Hemodynamics is one of the most accepted factors in the development of intracranial aneurysms. The aim of this work is developing a methodology to analyze fluid dynamics, pressure, and shear stress in intracranial aneurysm in order to help the doctors to choose the best treatment.

### Methods

It is necessary to know the exact geometry of each patient's aneurysm to perform the fluid dynamics study. This is done by obtaining digital subtraction angiography (DSA) and reconstruct the geometry of the artery and aneurysm with the software 3D Slicer. Geometry preprocessing and simulation is done with open-source software.

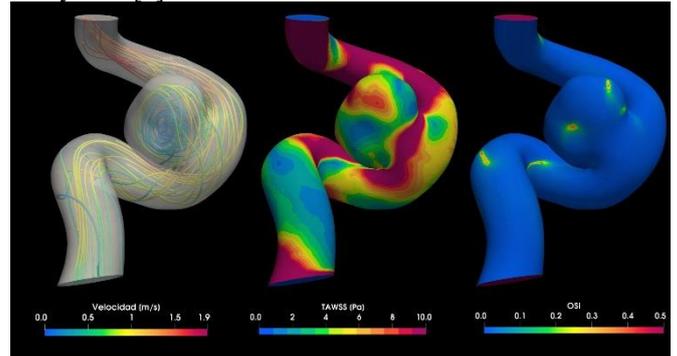

OpenFOAM software is used to solve the fluid dynamics simulation. This software uses the finite volume method (FVM) to solve the discretized equations and store the value of the variables in the computational nodes.

Blood is modeled as Newtonian fluid with viscosity  $\mu = 0.0035 \text{ Pa}\cdot\text{s}$  and constant density  $\rho = 1050 \text{ kg/m}^3$ . The boundary conditions are as follows: a pulsatile flow with a mean Reynolds of 400 was imposed at the inlet, a pressure of 0 pascals was imposed at the outlet, and a no-slip boundary condition was used on the wall, that was considered rigid.

### Results and Discussion

Complex flow patterns were observed within the aneurysm, especially in the dome of the aneurysm where recirculation zones are formed. The fluid remains stagnant for a certain

time, increasing the residence time of the particles on the endothelium. Besides, these recirculation zones cause low values of shear stress throughout the cardiac cycle, which favors destructive cell remodeling, since a shear stress greater than 0.5 pa is needed to maintain the integrity of the artery wall [3].

**Figure 1:** Hemodynamics in intracranial aneurysm in middle cerebral artery.

Also, results were obtained from some indices proposed by other authors to quantify the development of aneurysms, such as the shear stress gradient (WSSG), the oscillatory shear index (OSI), time-average shear stress (TAWSS), number of oscillatory gradient (GON), as well as relative residence time (RRT). These parameters show potential areas that can be affected that lead to a destructive remodeling of the arterial wall.

### Conclusions

Areas with low values of shear stress and high oscillatory shear index have been linked to risk areas where the aneurysm could grow or even rupture. The methodology used allows access to these values of shear stress and the different indices used in the literature through open-source software. Computational fluid dynamics can be used as a support tool for clinical decision making in intracranial aneurysms.

## Causal interactions between limbs walking with imposed leg constraints

Genevieve K.R. Williams<sup>1</sup>, Domenico Vicinanza<sup>1</sup>, Attias, Michael<sup>3</sup>, Stéphane Armand<sup>3</sup>,

<sup>1</sup>Faculty of Sport and Health Sciences, University of Exeter, Exeter, UK; <sup>2</sup>Faculty of Science and Engineering, Anglia Ruskin University, Cambridge, UK; <sup>3</sup>Laboratory of Kinesiology Willy Taillard, Geneva University Hospitals and University of Geneva, Geneva, Switzerland; email: [g.k.r.williams@exeter.ac.uk](mailto:g.k.r.williams@exeter.ac.uk)

### Summary

To provide new insights into motor control underpinning human walking we quantify the causal interaction of the leg motions during walking with bi and unilateral constraints induced by a passive exoskeleton emulating gastrocnemius contractures. Normal walking was characterised by a high mutual drive of each leg to the other. The effect of bilateral emulated contractures on one leg was a reduced drive of each leg to the other. With unilateral emulated contracture, the mechanically constrained leg strongly drives the free leg. Redundancy is used to support causal interactions where optimal walking may be driven by the most constrained leg.

### Introduction

Walking is a fundamental human action that underpins daily activities throughout the lifespan. In satisfying walking, the human biomechanical system is redundant and adaptable when faced with neurological or musculoskeletal impairments.

Examining causal interactions based on nonlinear dynamics approach provides a framework to determine the extent to which one part of the biomechanical system drives another. Appreciating the nature and strength of drive of one limb to another in gait, in particular when that gait is impaired, unveils novel information on the motor control solution.

Contractures of the lower limbs are a common impairment resulting from conditions such as spinal cord injury, brain injury, or muscular dystrophy. Associated gait adaptations have been demonstrated in Armand and Attias (2019; [pegs.unige.ch](http://pegs.unige.ch)), with the aim to provide important understanding of the mechanisms underpinning characteristics of pathological gait, as well as the biomechanical solution to walking in their presence. The aim of this paper was to explore the causal drive of the legs during walking when contractures were emulated by a passive exoskeleton to the gastrocnemius.

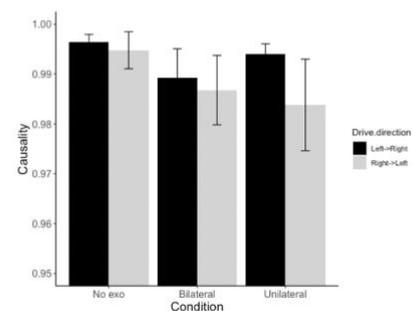

### Methods

Data acquired during the protocol reported in Attias et al. studies [1] were used for this study. Nine healthy participants (age:  $27 \pm 5.7$  years; height:  $1.70 \pm 0.09$  m; weight  $66.3 \pm 7.8$ kg) wore a passive exoskeleton to replicate the contractures of the gastrocnemius with 34 reflective markers according to the conventional gait model. Participants walked along a 10-meter walkway at a self-selected speed. Marker trajectories were recorded and computed with a 12-camera motion analysis system (Vicon Peak Mx3, Oxford, UK, 100 Hz). The three experimental conditions were normal walking,

contractures both legs (bilateral exoskeleton), contracture on the left leg only (unilateral exoskeleton). Causality based on CCM was calculated to assess the driving strength of each leg to the other using the multispatialCCM library in R-Studio [2].

### Results and Discussion

During normal walking there was the strongest mutual drive of each leg to the other, suggesting that the leg-leg system is able to influence itself bilaterally and a strong coupling exists. With bilateral exoskeleton the drive of each leg to the other reduces (significantly compared to normal walking,  $p = 0.003$  left to right, and  $p = 0.000$  right to left), indicating a mutual decrease in the legs ability to drive each other. In the unilateral exoskeleton condition, the left leg strongly drives the right, but the drive of the right leg to the left leg is reduced compared to normal walking ( $p = 0.000$  right to left).

**Figure 1:** Causal drive of the left to the right leg (black) and right to left leg (grey) across the three experimental conditions.

This nontrivial finding suggests the system uses redundancy in free parts of the system to be driven by the constrained limb, exploiting a degenerate technique that can be used to compensate for the constrained leg. The motor control solution is then defined by the optimal solution in light of the constraints imposed, and adaptability and exploiting redundancy is key to supporting functionality.

### Conclusions

Optimal walking gait may be driven by the most constrained leg, and while less resembling ‘healthy’ walking kinematics, may provide a more optimal motor control solution.

## Summary

Three-dimensional kinematics and kinetics were collected from fifteen participants who performed over-ground walking at a constant speed, as well as a low, moderate and maximal walking acceleration. During accelerative walking, ankle coordination was substantially altered by timing of torque onset and peak, rate of torque development and peak torque magnitude. These results have implications for clinical rehabilitation, as well as robotic and powered assistive devices, where adaptations in ankle coordination may facilitate functional accelerative gait.

## Introduction

Changes in joint coordination (joint movement patterns and torque development) are generally examined at a constant speed, despite accelerative gait comprising a large portion of locomotion. Previous research has demonstrated that during accelerative walking, increased net work about the ankle was due to muscles contracting to store energy in the tendon, compared to constant speed walking where energy was stored from external sources [1]. Therefore, acceleration likely requires more than simply increasing torque about the ankle, as timing of torque production will also play an important role.

However, previous work has only examined a single acceleration magnitude and temporal characteristics of torque development were not explored. Therefore, it is unknown how ankle coordination is altered as acceleration increases. We hypothesised that an increase in net work about the ankle, intended to increase walking acceleration, would not be due to solely increasing torque magnitude, and instead would also be a product of temporal adjustments to the ankle torque profile.

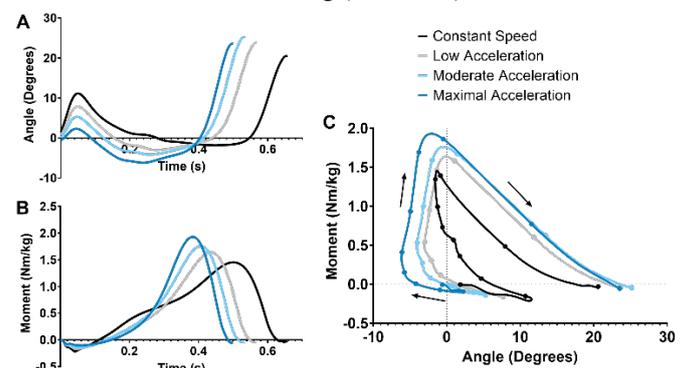

## Methods

Fifteen participants ( $27 \pm 4$  years,  $175 \pm 9$  cm,  $70 \pm 11$  kg) performed over-ground walking at a constant speed, as well as a low, moderate and maximal walking acceleration. Participants walked over an in-ground force plate for eight successful trials; defined as approaching the plate at a constant speed, striking the plate with the entire right foot and then performing constant or accelerative gait for three steps. Three-dimensional kinematic (200 Hz) and kinetic data (1000 Hz) were recorded in ODIN (Codamotion) and processed in Visual3D (C-Motion) to calculate ankle joint angle, moment and work. Statistical analysis was performed using linear mixed modelling, where the outcome variable was analysed with acceleration magnitude as a fixed effect and participant as a random effect.

## Results and Discussion

Net work about the ankle increased 0.384 J/kg as acceleration increased from 0–100% ( $P < 0.001$ ) due to an increased

maximal moment (Fig. 1B,  $P < 0.001$ ), combined with an increased time between heel strike and start of plantar flexion moment (Fig 1B,  $P < 0.001$ ), and a decreased time between the start and peak plantar flexion moment (Fig. 1B,  $P < 0.001$ ). Thus, onset of plantar flexion moment was delayed as acceleration increased, which when combined with a shorter time to produce maximal torque, resulted in a 5.55 Nm/s increase in rate of torque development from constant speed to maximal accelerative walking ( $P < 0.001$ ).

**Figure 1:** Mean ankle joint angle (A) and moment (B) for each walking condition (plantar flexion = positive). Dots on moment-angle curve (C) represent 10% portions of stance. Heel-strike to toe-off occurs in a clockwise direction as indicated by arrows.

During acceleration, there appears to be a period where dorsiflexion occurs without any change in torque (Fig. 1C), followed by a rapid increase in ankle torque without any change in ankle angle. These results demonstrate that ankle coordination is significantly altered as walking acceleration increases, which may have a range of implications in the treatment of neuromuscular disorders and the development of powered exoskeletal and prosthetic devices. Currently powered assistive devices are commonly controlled by altering peak torque based on a set time delay after heel strike [2]. These results support previous work that has highlighted the importance of adapting timing of torque onset and peak, magnitude of peak torque and rate of torque development in the design and application of assistive devices [3].

## Conclusions

Timing, magnitude and rate of torque development during acceleration is altered compared to constant speed walking, which has implications for clinical, robotic and rehabilitation applications.

## Initiation of arch recoil is asynchronous with the windlass mechanism in walking

Email: [l.welte@queensu.ca](mailto:l.welte@queensu.ca)

### Summary

The arch of the foot stretches and recoils in response to an applied load. In walking and running, it is unclear whether a reduction in applied force, or the windlass mechanism is responsible for arch recoil. We used high-speed x-ray and ground reaction forces to assess the timing of the load on the foot, the initiation of the windlass mechanism, as well as peak ankle and arch dorsiflexion. We found that the onset of arch recoil in walking is much later than the initiation of the windlass mechanism. Instead, load on the arch and/or arch-ankle coupling may play a larger role in initiating arch recoil than the windlass mechanism.

### Introduction

The arch of the foot is mobile in both walking and running. In general, the arch moves in a spring-like manner [1], flattening in response to load and recoiling when the load is released. However, the windlass mechanism, whereby metatarsal-phalangeal joint (MTPJ) dorsiflexion raises the arch, is also credited with enabling arch recoil in walking and running [2]. While the windlass mechanism statically raises the arch [3], it is unknown whether it initiates arch recoil in propulsion, or if the arch recoils simply because forces on it are declining.

Recently, we showed that arch mobility enables ankle motion in running propulsion [4]. The propulsive phase is well modelled by a rebounding mass-spring system, which is theoretically in sync with the arch's recoil. However, arch recoil and ankle power are substantial in walking [5], despite more inverted-pendulum and less spring-like behavior. Using biplanar x-ray, we compare the timing of arch recoil and ankle dorsiflexion to peak loads in walking and running to understand how the arch-spring contributes to propulsion and to measure windlass mechanism timing relative to arch recoil.

### Methods

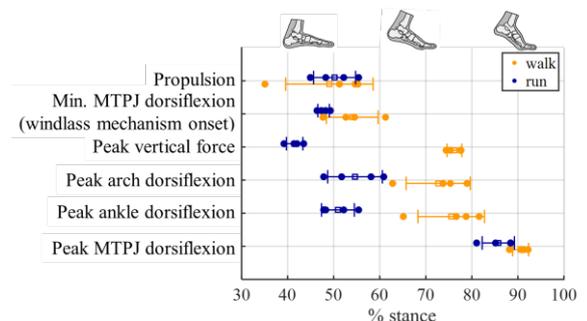

Four participants walked and ran in minimal shoes over force plates while a high-speed biplanar x-ray system captured their foot and ankle motion. CT-generated models were used to semi-automatically measure the position and orientation of medial arch bones, toe and tibia [6]. Each bone had an inertial co-ordinate system. The dorsiflexion axes of the talus and tibia aligned with a cylinder fit to the tibial and talar domes.

“Propulsion” was the instant after the anterior-posterior force became anterior. Tait-Bryan YZX angles measured the rotation of the talus to the tibia (ankle), the first metatarsal to the calcaneus (arch) and the MTPJ (as an indication of an engaged windlass mechanism). The timing and magnitude of peak ankle, arch, and MTPJ dorsiflexion were measured in walking and running.

### Results and Discussion

MTPJ dorsiflexion and propulsion occur simultaneously (Figure 1). In running, they coincide with the start of arch recoil; in walking, the arch flattens for the first half of propulsion before it recoils. Peak arch and ankle dorsiflexion are simultaneous: in running, these maxima are synchronized with propulsion; in walking, they are aligned later in stance with the second vertical ground reaction force peak.

Additionally, peak arch dorsiflexion was similar between walking and running (diff =  $2 \pm 2^\circ$ ), while peak ankle dorsiflexion was higher in running (diff =  $11 \pm 3^\circ$ ). When visualizing the bone motion at peak ankle dorsiflexion in running, the tibia appeared close to its end range of motion on the talus, substantially more anterior than in walking.

**Figure 1:** The timing in % stance of peak ankle, arch and toe dorsiflexion in walking and running for each participant, as well as the windlass mechanism onset, the transition to propulsion from the anterior-posterior force and the peak vertical force.

### Conclusions

The synchronized onset of ankle plantarflexion, arch recoil and the windlass mechanism in running supports the arch's contribution to a spring-like propulsion. In walking, our results suggest that the windlass mechanism does not initiate arch recoil, as the onset of MTPJ dorsiflexion would have initiated arch plantarflexion. Instead, arch recoil seems to be initiated by the vertical load on the arch and may be related to peak ankle dorsiflexion. The arch and ankle dorsiflexion peaks occur simultaneously in walking and running, despite different peak ankle dorsiflexion, and position of the tibia on the articular surface of the talus. The arch and ankle appear to be intricately linked in propulsive function.

## A comparison of multisegment foot kinematics between younger and older adults during walking

Nayeli Marcial<sup>1</sup>, Victoria Chester<sup>1</sup>, Usha Kuruganti<sup>1</sup>

<sup>1</sup>Andrew and Marjorie McCain Human Performance Laboratory, University of New Brunswick, Fredericton, Canada

Email: [nayeli.marcial@unb.ca](mailto:nayeli.marcial@unb.ca)

### Summary

Older adults exhibit different gait patterns compared to younger adults [1]. The aim of the study was to examine age-related differences in multisegment foot (MSF) kinematics during walking. Results indicate that older adults, when compared to younger adults, show significant differences in MSF kinematics, such as decreased range of motion (ROM) of the midfoot relative to the calcaneus and reduced joint mobility of the midfoot when walking. Examining age-related MSF kinematic differences may lead to a greater understanding of typical and atypical foot mechanics and function in older adults.

### Introduction

During gait, the foot and ankle have important roles such as attenuating shock at impact, providing stability and support of the lower limb, and aiding in forward propulsion of the body [2]. It is plausible that changes in foot function may result in impaired movement patterns which is known to increase with age. However, the interrelationship between age-related differences in foot mechanics and physical function are not clear [1]. The use of MSF models could provide insight about the functional significance of motion occurring within the foot as well as alterations due to age. Only a few studies have used an MSF model to determine the age-related differences in foot kinematics during walking [1-4] and further research is warranted. The purpose of this study was to compare MSF kinematics between younger and older adults during walking at a self-selected speed.

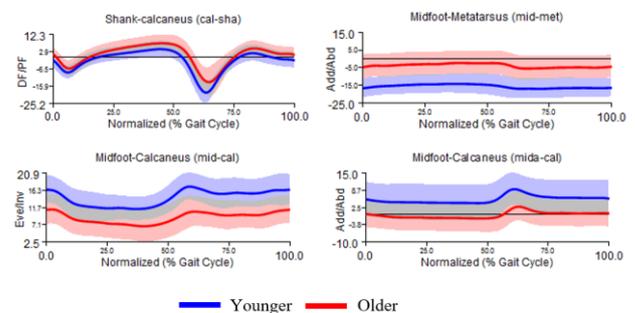

### Methods

Sixteen young participants (8 males, 8 females, mean age 23.62±3.73 years, mean weight 69.1±16.4 kg, mean height 1.71±0.12 m) and fifteen older participants (8 males, 7 females, mean age 71.64±5.94 years, mean weight 82.9±16. kg, mean height 1.71±0.12 m) with no known lower-extremity disease/disorder/injuries were recruited. A12-camera Vicon T160 motion capture system (Oxford Metrics Group Ltd., UK), sampling at 100 Hz, was used to track thirty-six retro-reflective markers (9 mm diameter) were placed on the medial and lateral tibia and anatomical landmarks of the foot using a modified version of a 5-segment MSF model used [5]. Three-dimensional relative angles and planar angles of the foot segments were computed. Significant group differences ( $p < 0.05$ ) in range of motion, mean max and min peak relative angles between foot segments, and time of occurrence of these peaks were analyzed using a one-way ANOVA or if indicated, Kruskal-Wallis test. Statistical analyses were completed using R Studio (RStudio 2018, RStudio, Inc., USA).

### Results and Discussion

The results suggest that older adults demonstrate significantly different MSF kinematics compared to younger adults during gait (Figure 1). These age-related differences included decreased mean peak plantarflexion (PF) of the calcaneus-shank angle (older:  $-13.3 \pm 6.52^\circ$ ,

younger:  $-5.31 \pm 17.08^\circ$ ) with a delay to peak onset (older:  $66.49 \pm 18.19\%$ ; younger:  $56.49 \pm 18.19\%$  gait cycle). A decreased ROM was also evident for the older group ( $-21.10^\circ \pm 1.97^\circ$ ) compared to younger ( $-22.23^\circ \pm 1.42^\circ$ ). The older group had reduced mean max eversion of the midfoot-calcaneus angle (older:  $12.47 \pm 5.02^\circ$ ; younger:  $18.10 \pm 3.95^\circ$ ). The ROM was thereby slightly decreased (older:  $5.85^\circ \pm 0.18^\circ$ , younger:  $7.19^\circ \pm 0.37^\circ$ ), whereas the time to max peak eversion was decreased (older:  $28.68 \pm 27.98\%$ , younger:  $28.68 \pm 27.98\%$  gait cycle) of the midfoot-calcaneus. Moreover, the older group had reduced mean max adduction of the midfoot-calcaneus (older:  $3.59 \pm 6.19^\circ$ ; younger:  $9.93 \pm 6.37^\circ$ ), as well as decreased ROM ( $5.20 \pm 0.45^\circ$ , younger:  $5.83 \pm 0.27^\circ$ ). Further, the older group had increased time to min peak adduction (older:  $36.46 \pm 16.56\%$ , younger:  $33.26 \pm 16.26\%$  gait cycle) and time to max peak adduction (older:  $59.96 \pm 8.29\%$  younger:  $59.49 \pm 5.24\%$  gait cycle) of the mid-cal angle. Additionally, the older group had reduced mean peak abduction of the metatarsus-midfoot angle (older:  $-2.46 \pm 7.84^\circ$ , younger:  $-13.23 \pm 6.06^\circ$ ), but there were no differences in the ROM. Further, the older group had increased time to min peak abduction (older:  $36.92 \pm 27.63\%$ , younger:  $30.36 \pm 27.14\%$  gait cycle) and time to max peak abduction (older:  $42.14 \pm 16.86$ , younger:  $37.66 \pm 12.54\%$  gait cycle) of the met-mid angle. These findings suggest a less propulsive gait pattern and reduced mobility of the foot, especially the midfoot.

**Figure 1.** Mean cal-sha, mid-cal and met-mid angles of younger and older adults (solid line with standard deviation band).

### Conclusion

MSF analyses will improve our understanding of foot mechanics and function in younger and older adults. Further, such data could aid in distinguishing between typical and atypical gait patterns in older adults. Future studies should include a larger sample size and range of walking speeds to corroborate these findings.

### Summary

This study investigated lower extremity joint extensor moment angular impulse ( $I_{joint}$ ) during the walk to run transition (WRT) and run to walk transition (RWT) processes. We found  $I_{ankle}$  and  $I_{knee}$  contributed to more than 80% of the total lower extremity support moment impulse. Additionally, gait transitions significantly change  $I_{knee}$  after the transition step.

### Introduction

Walking and running have different whole-body center of mass dynamic patterns [1]. The transition between the walking inverted pendulum and the running spring mass paradigm is primarily determined and modulated by lower extremity kinetic factors [2]. Both the WRT and RWT require lower extremity extensor muscles to support the body moving forward. Joint level moment angular impulse represents the joint moment effect over time and it is regarded as the end-effect of muscle functions in human locomotion [2,3].

This study aimed to investigate lower extremity joint extensor moment angular impulse ( $I_{joint}$ ) during the WRT and RWT processes. Since joint kinetic parameters are known to increase with locomotion speed, we hypothesized that  $I_{joint}$  would increase during the WRT and decrease during the RWT.

### Methods

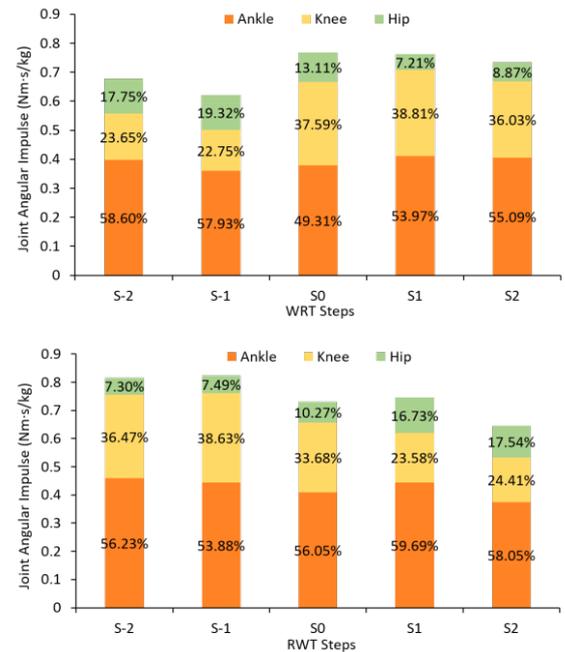

Ten healthy subjects ( $50.7 \pm 6.0$  years,  $173.4 \pm 11.4$  cm,  $69.7 \pm 14.9$  kg) participated in this study. Subjects were asked to complete treadmill WRT (1.8 – 2.4 m/s) and RWT (2.4 – 1.8 m/s) protocols, with acceleration and deceleration set to  $0.1 \text{ m/s}^2$  and  $-0.1 \text{ m/s}^2$ , respectively. We selected five steps for data analysis: transition step (S0); two steps before transition (S–2, S–1); two steps after transition (S1, S2).

Stance phase joint extensor moment angular impulse ( $I_{joint}$ ) was calculated as the sum of all stance phase extensor joint moment integrated over time within each joint [3]. Total lower extremity joint support moment impulse ( $I_{total}$ ) was calculated as the sum of  $I_{ankle}$ ,  $I_{knee}$  and  $I_{hip}$  during stance phase.  $I_{joint}$  was examined for differences between joints and steps via the 2-way ANOVAs (joint  $\times$  step) for WRT and RWT in SPSS (V22.0, IBM, Armonk, NY).  $I_{total}$  was examined using a 1-way ANOVA to compare between the five steps tested during WRT and RWT, respectively.

### Results and Discussion

$I_{ankle}$  was higher than  $I_{hip}$  at all steps during both WRT and RWT. Within  $I_{knee}$ , we found significant differences between

steps before and after transition: S–2 was lower than S1 and S2, and S–1 was lower than S1 during WRT; during RWT,  $I_{knee}$  at S1 was lower than S–2 and S–1 (Figure 1).

**Figure 1:** Joint extensor moment angular impulse in WRT (top) and RWT (bottom) steps.

$I_{ankle}$  contributed to around 50% of  $I_{total}$  among all steps during both transitions. This indicates ankle plantar flexor moment would compensate for the changeable stance time length, and this would be helpful to maintain a relatively consistent  $I_{ankle}$  output during both transitions. Future assistive device design should consider the ankle plantar flexor moment compensatory mechanism in response to the change of locomotion tasks, speeds and stance time.

### Conclusions

Both the  $I_{ankle}$  and  $I_{knee}$  played more dominant roles to support the body during both WRT and RWT processes. Gait transitions significantly change  $I_{knee}$  after the transition step.

## Posture (slouched versus erect sitting) affects upper limb maximal voluntary contraction levels: preliminary results

A. Tomezzoli<sup>1</sup>, B. Fréchède<sup>1</sup>, S. Duprey<sup>1</sup>

<sup>1</sup>LBMC UMR\_T9406, Univ Lyon, Univ Claude Bernard Lyon 1, Univ Gustave Eiffel, IFSTTAR, F69622, Lyon, France  
Email: [aurelie.tomezzoli@univ-eiffel.fr](mailto:aurelie.tomezzoli@univ-eiffel.fr)

### Summary

A slouched, versus erect sitting posture, is known to affect shoulder abduction isometric maximal voluntary contraction (MVC) levels. This study investigated the impact of 2 sitting postures on shoulder abduction, elbow flexion and wrist flexion MVCs. Fourteen participants (3 men, 11 women, 23.7±4.6 years) were randomly placed in a slouched or erect sitting posture, using oral instructions and light touch. Isometric MVCs were measured by a uniaxial load cell. The maximal of 3 MVCs was extracted for each joint (0-20° wrist flexion, 90° elbow flexion and 90° shoulder abduction in the scapula plane) in each posture, and then compared w.r.t posture using t-tests. In the erect posture, mean isometric MVC was 13.1% higher ( $p<0.01$ ) for wrist flexion, 14.1% ( $p<0.01$ ) for elbow flexion and 11.7% (NS) for shoulder abduction.

### Introduction

Upper limb musculoskeletal disorders are a major public health issue. Biomechanical parameters and individual susceptibility are some of the risk factors for these diseases [1]. Besides, a slouched, versus erect sitting posture, decreases individual functional capacities for shoulder abduction isometric maximal voluntary contraction (MVC) [2]. Thus, posture modifications might be a key to limit musculoskeletal disorders' occurrence.

The goal of this study was to assess the impact of two sitting postures (erect vs slouched) on wrist, elbow and shoulder isometric MVCs. Preliminary results are reported here.

### Methods

Fourteen participants (3 men, 11 women, 23.7±4.6 years) were recruited after ethical endorsement (CPP N°2020-A00573-36). Their spinal curvatures were increased or decreased using oral instructions and light touch, to reach erect or slouched stable, easily maintained postures, in a random order. Wrist flexion MVC was measured at 0-20° of wrist flexion, with 90° of elbow flexion and 10° of shoulder abduction, forearm supine. Elbow flexion MVC was measured at 90° of elbow flexion, with 10° of shoulder abduction. Shoulder abduction MVC was measured at 90° of abduction in the scapula plane, *i.e.* 45° of flexion. Upper limb and trunk stabilization were performed manually and using an armrest. The participants were asked to maintain their posture and keep their eyesight horizontal while they pulled a flat foam-padded device connected to a 500N TME F480TC uniaxial load cell by a wire rope (Figure 1). Recorded oral encouragements provided guidance for a two second progressive rise, then for a three second sustained maximal contraction. Three trials, separated by a minimal one-minute rest, were performed in each posture for each

joint. If between trials maximal difference exceeded 25%, a 4th trial was performed and the most divergent trial was considered unrepresentative of the posture and thus discarded.

Raw data were smoothed using a 4th order Butterworth filter with a cutoff frequency of 1 Hz. The maximal value of each set of three trials was extracted. Finally, the effect of posture was assessed using paired t-tests, after variable transformation to insure their normal distribution.

Figure 1: Elbow isometric MVC measurement device.

### Results and Discussion

In the erect posture, mean isometric MVC was 13.1% ( $p<0.01$ ) higher for wrist flexion, 14.1% ( $p<0.01$ ) for elbow flexion and 11.7% (NS) for shoulder abduction.

Posture seems to be one of the most important explanatory factors for MVC intra-individual variability, after tiredness and pain [3]. Postural induced scapula position modifications [2] might explain its impact on MVCs. The effect size found by Kebaetse for shoulder abduction MVC was higher (16.2% instead of 11.7% here) [2], which could be explained by the degree of arm rotation or spinal posture characteristics.

### Conclusions

Posture seems to modify individual upper limb functional capacities, which had already been reported for shoulder capacities. The present study expands this result to wrist and elbow joints. Thus, posture could impact the risk of musculoskeletal disorders as well as athletic performances for the whole upper limb.

### Summary

Forest machine operators are exposed to a variety of musculoskeletal stressors including repetitive strain injury, back and shoulder pain, and discomfort. This study examined the effects of operator skill level and operating settings on muscle activity of the upper body while operating a tree harvesting simulator. The results of this study showed that there were differences in upper limb muscle activity due to operating settings. In addition, novice participants demonstrated greater muscle activity than experienced operators suggesting differences due to experience. The results of this study may help to better understand the muscular demands of this type of work and develop improved work protocols.

### Introduction

The integration of machinery has reduced the risk of manual material handling within the tree harvesting industry. While the operation of mechanized harvester machines does not require large force contractions, the continuous and repetitive nature of the work can result in muscular discomfort and fatigue. The workload in the upper extremities of the workers operating forestry machines for long hours has been associated with discomfort and pain. [1, 2].

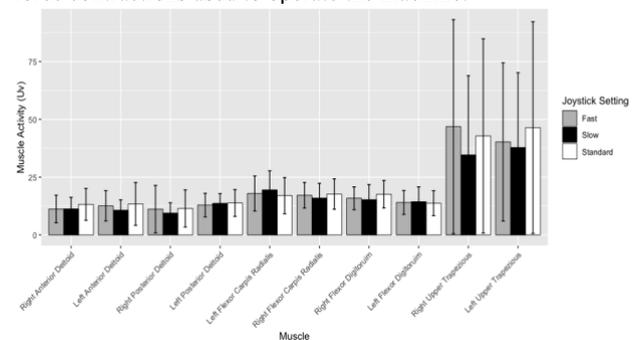

### Methods

Fifty-four (n=54) individuals participated in the study (49 males, 5 females) and were categorized as novice (Age: 29.4 ± 7.4; Weight (kg): 76.9 ± 12.5; Height (m): 1.8 ± 0.1), experienced (Age: 34.7 ± 10.2; Weight (kg): 93.8 ± 16.3; Height (m): 1.8 ± 0.7) or advanced (Age: 37.9 ± 11.2; Weight (kg): 101.8 ± 11.7; Height (m): 1.8 ± 0.1). Novice participants were recruited by word of mouth and experienced/advanced operators were recruited from a forestry company. Muscle activity was monitored using bipolar surface electromyography (EMG) placed over the flexor digitorum (FD), flexor carpi radialis (FCR), anterior deltoid (AD), upper trapezius (UT), and posterior deltoid (PT) muscle groups. EMG were acquired wirelessly (Due-Pro, OT Bioelettronica, Turin, Italy). Participants used a Ponssee tree harvesting simulator to simulate cutting trees. Participants started by completing an orientation using a standard crane speed. Then, participants were asked to cut 15 trees in 15 minutes using three randomized crane speeds; slow, standard and fast. Furthermore, the experienced and advanced operators completed an additional trial using a sensitive joystick setting. The sensitive joystick mimicked a challenging condition that more experienced operators would typically face when harvesting trees. The EMG amplitude of each signal was normalized to the individual's maximum isometric voluntary contraction. Muscle activity amplitude was estimated using the Root Mean Square (RMS) value. Median frequency (MF) was calculated at the beginning (after 1 minute) and end of the Simulator trial (~15 minutes) and compared to estimate fatigue. Statistical analysis of variance (ANOVA) and pairwise t-tests were conducted to test for significant differences in mean RMS and MF percent changes across the various operating and joystick settings. All of the statistical tests were compared for significance using a p-value less than the alpha value, set at 0.05

### Results and Discussion

Figure 1 presents the mean RMS EMG data across muscles for the three crane speeds for novice participants. During the slow speed condition novice participants demonstrated significantly lower mean

RMS of the left PT using the fast speed (12.8 mV). Similarly, novice participants also showed significantly less mean RMS of their right forearms with the slow speed (16.4 mV (FCR); 15.3 mV (FD)) than the standard speed setting (17.7 mV; (FCR) 17.6 mV (FD)). In contrast, novice participants showed significantly greater mean RMS of their left forearms with the slow speed (14.9 mV (FCR); 19.4 mV (FD)) than the standard speed setting (13.7 mV; (FCR) 17.0 mV (FD)). While operating the sensitive joystick, experienced participants demonstrated significantly higher mean RMS in their right AD (14.4 mV) and lower mean RMS in both the left (12.8 mV), and right (21.6 mV) FCR, than using the standard speed (11.8 mV (AD); 23.6 mV (Right FCR); 12.5mV (Left FCR)). While there were differences detected in EMG amplitude, no significant differences were detected in the MF between the beginning and the end of the trial for any condition. Previous research [3] has shown decreases in the MF after 4 hours of Simulator use suggesting fatigue. The lack of significant differences in the MF in this study may be due to the shorter duration of the simulator operation (15 minutes) and the low force contractions used to operate the machine.

**Figure 1:** Mean RMS (uV) across all speed settings of novice participants

### Conclusions

Ergonomic field studies of this industry are lacking as it is difficult to obtain comprehensive data while operators are cutting trees in the woods. Forest machine simulators provide an opportunity to further study this population. Overall, increases in muscle activity were found in all participants, however the regions affected varied according to skill level. The lack of significant differences in the frequency data suggests that future research should include longer testing to be more reflective of a typical work shift. The present findings suggest that there are differences in the muscles recruited during harvester operations depending on the skill level of the operator. The information will help employers to develop more focused training for operators using controls that minimize muscle requirements and develop skill.

### Acknowledgments

We would like to acknowledge JDI Woodlands for provision of the simulator and Mr. Andre Cyr for his valuable insight

## Beyond Euler/Cardan analysis: true glenohumeral axial rotation during arm elevation and rotation

Klevis Aliaj<sup>1,2</sup>, Heath B. Henninger<sup>1,2</sup>

<sup>1</sup>Department of Orthopaedics, University of Utah, Salt Lake City, Utah, United States of America

<sup>2</sup>Department of Biomedical Engineering, University of Utah, Salt Lake City, Utah, United States of America

Email: klevis.aliaj@utah.edu

### Summary

Based on Euler/Cardan analysis, prior investigations have reported up to 80° of glenohumeral (GH) external rotation during arm elevation, varying by plane of elevation (PoE) [1, 2]. This (apparent) axial rotation incorrectly quantifies the rotation around the humerus' longitudinal axis because it assumes a sequence-specific path [3]. In this investigation, (true) axial rotation was computed by following the actual humeral path. True GH axial rotation was not different than 0° during arm elevation and does not vary by PoE. Clinicians want to understand the physically motivated true axial rotation [4], and thus it should be reported in kinematic analyses.

### Introduction

Euler/Cardan analyses report up to 80° of GH external rotation during arm elevation, which is dependent on the PoE [1, 2]. However, this (apparent) axial rotation assumes a sequence-specific path for the humerus. Clinicians want to understand the physically motivated (true) axial rotation, and rely on laboratory analyses to inform their understanding of underlying shoulder biomechanics. This is critical for the GH joint since its motion cannot be visually ascertained in common clinical settings. True GH axial rotation has not been previously measured *in vivo*, and its difference from apparent axial rotation is unknown. We hypothesized that true GH axial rotation was 0° and did not vary by PoE during arm elevation.

### Methods

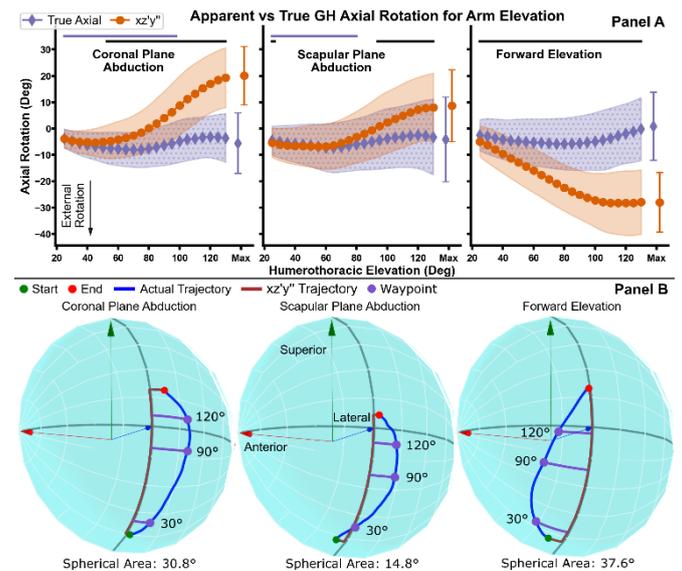

This analysis was performed on kinematic data previously collected for healthy shoulder kinematics [5]. Humerus and scapula motions were imaged at 100 Hz using a custom biplane fluoroscopy system in 20 healthy subjects (10M/10F; 42±17 yrs; right-hand dominant) while performing coronal, scapular and forward elevations, and external rotation in adduction, and in 90° of abduction. Model-based markerless tracking was utilized to ascertain 3D bone kinematics.

Apparent axial rotation was computed using the  $xz'y''$  and  $yx'y''$  sequences. True GH axial rotation was computed by projecting GH angular velocity onto the humerus' longitudinal axis and integrating the resulting scalar value from the start of the motion to each timepoint [3]. One-dimensional statistical parametric mapping was utilized to: compare apparent vs. true GH axial rotation and GH axial rotation vs. 0°; and detect differences in axial rotation by PoE.

### Results and Discussion

In contrast to apparent GH axial rotation, true axial rotation does not differ by PoE and is not different than 0° during arm elevation at higher elevation angles (Fig. 1A, one Euler sequence shown for clarity). The signed spherical area

between the sequence-specified and actual humeral trajectory – which does not represent an actual rotation around the humerus' longitudinal axis – accounts for the difference between apparent and true axial rotation (Fig. 1B). Euler/Cardan analysis misrepresents axial rotation leading prior studies to measure substantial GH axial rotation and differences between PoEs during arm elevation.

**Figure 1:** **A:** The solid purple line indicates true axial rotation  $\neq 0^\circ$  and solid black line indicates true  $\neq$  apparent axial rotation. **B:** The spherical area between the actual (blue) and sequence-specified (brown) humeral trajectory quantifies differences between true and apparent axial rotation in **A**.

### Conclusions

Clinically relevant quantification of axial rotation is important because biomechanics literature informs clinical understanding of shoulder biomechanics – especially for the GH joint since its motion cannot be visually ascertained. Clinicians can more reliably interpret the physically motivated true axial rotation (i.e. there is minimal humeral rotation during thump up arm elevation). True axial rotation should be reported in future studies of shoulder kinematics.

# Biomechanics during controlled forward descents on outstretched arms in response to Fall Arrest Strategy Training (FAST) in older men and women

Pifko, J.<sup>1</sup>, Arnold, C.<sup>2</sup>, Farthing, J.P.<sup>1</sup>, Lanovaz, J.<sup>1</sup>

<sup>1</sup>College of Kinesiology, University of Saskatchewan, Saskatchewan, SK, Canada

## Summary

Upper body injuries commonly arise from forward falls in older adults. Research examining sex-related differences and the effect of training to improve capacity to reduce injury risk during simulated forward fall arrest biomechanics in older adults is lacking. We assessed 55 older adults (29 women) who completed three testing sessions evaluating biomechanics during a controlled forward descent on outstretched hands before and after Fall Arrest Strategy Training (FAST). Upper extremity loading and energy absorption requirements were reduced after the intervention. Older men had different descent mechanics compared to older women, but both groups responded similarly to FAST.

## Introduction

More than 50 percent of injuries from falls in older adults occur in the upper body. Reaching hands forward is a common reaction to protect the body from injury during a forward fall [1]. One option to mitigate fall injury risk is to improve fall arrest capacity with an exercise intervention program. While women have been the focus of most fall prevention studies, injuries such as head trauma can occur equally between sexes [2]. Sex-related biomechanical changes after fall injury prevention programs in older adults is unknown. Our purpose was to quantify fall arrest capacity in older men and women in response to a unique intervention program.

## Methods

Older adults completed three testing sessions: Baseline, Pre (after a 12-week control), and Post (after 12 weeks of FAST). FAST was led by two physical therapists for 45 minutes twice per week and focused on goals to improve upper extremity (UE) strength, reaction time, and movement time in combination with fall prevention goals – balance, strength, function, and mobility.

In the testing sessions, participants completed forward descents similar to the downward portion of a push-up at a body lean of 60° from horizontal using a custom apparatus [3]. Initially, participants had 90° shoulder flexion, elbows extended, and hands shoulder-width apart. A neutral spine with extended knees, feet together, and ankles in 90° dorsiflexion were used throughout the descent. Participants descended to a target of 90° elbow flexion in approximately 1.5 s following a metronome. Three trials were captured and averaged for each participant.

Bilateral force platforms (OR6-7, AMTI, Watertown, MA, fs=2000Hz) recorded hand reaction forces while a motion capture system (VICON, Centennial, CO, fs=200Hz) collected bilateral 3D UE kinematics. Outcome variables included elbow range of motion (eROM), maximum ground reaction forces (mxGRF), peak elbow moment (eMOM; normalized to height and body weight), elbow stiffness (eSTF), and overall energy absorption (OE; normalized to height and body weight) [4]. Independent *t*-tests compared sex demographics and separate 3 x 2 (time x sex) mixed-design ANOVAs with repeated measures examined outcome variables.

## Results

Seventy-eight participants were enrolled in the study, and 55 older adults (29 women) completed all testing sessions. There was no significant age difference between sexes ( $\bar{x}_M=73.5\pm 8.2$  years,  $\bar{x}_W=69.7\pm 6.9$  years, range=60-93 years,  $p=0.062$ ). Older men were significantly taller and heavier than older women, although body mass index was similar (M:28.7±3.6m<sup>2</sup>kg<sup>-1</sup>, W:27.8±5.5m<sup>2</sup>kg<sup>-1</sup>,  $p=0.447$ ). FAST attendance between sexes was similar (M:82.5±13.6%, W:81.2±14.4%,  $p=0.722$ ).

No sex or time effects were seen for eROM (Table 1). mxGRF showed a main effect of time ( $p<0.001$ , Base-Post, Pre-Post) and sex (M>W,  $p=0.007$ ). Sex main effects were seen for eMOM (M>W,  $p<0.001$ ) and eSTF (M>W,  $p=0.009$ ). A time main effect was found for OE ( $p=0.018$ , Pre-Post).

## Discussion and Conclusion

After the FAST program, participants shifted load distribution away from their UE during the descent movement and subsequently reduced UE OE demands. While older men applied higher forces and had higher eMOM and eSTF than older women, the intervention had similar effects on the controlled forward descent biomechanics.

Email: gkuntze@ucalgary.ca

### Summary

This study examined differences in upper and middle trapezius activation and scapular kinematics in response to changes in axillary crutch fit. Longer than standard fit crutches led to greater scapula upward rotation and greater activation intensity of the upper and middle trapezius. Shorter than standard fit crutches led to greater scapular downward rotation but no differences in EMG intensity.

### Introduction

Crutches that are too long or too short may affect motion of the shoulder complex, contributing to injury of muscles, tendons, ligaments and nerves [1]. There is a knowledge gap regarding the effects of axillary crutch length on the kinematics of the shoulder complex and activity of associated muscles. This study examined the effects of longer and shorter than standard fit crutches on scapular kinematics and activation intensities of the upper and middle trapezius.

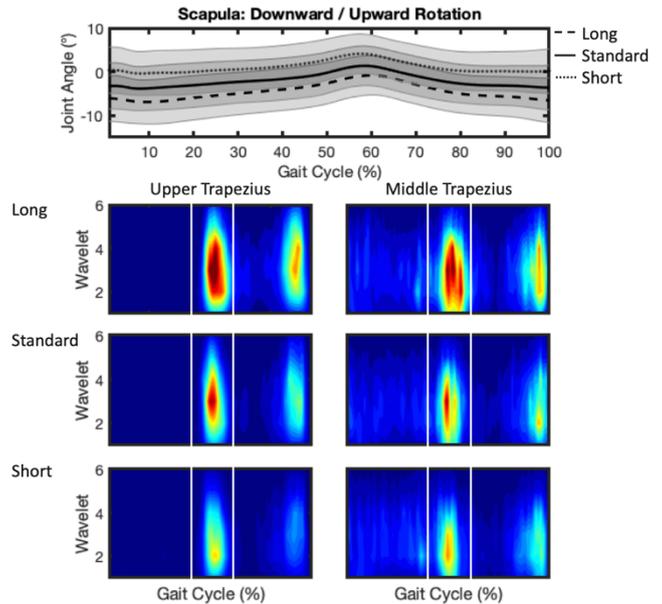

### Methods

Nine men participated in axillary crutch-assisted gait ( $1.40 \pm 0.07 \text{ ms}^{-1}$ ) using crutches that were 5cm longer and shorter than a standard fit (REB18-1045). Scapular kinematics (Motion Analysis, USA, 240 Hz) and upper and middle trapezius electromyography (EMG, Biovision, Germany, 2400 Hz) were recorded. Segment angles were computed in Visual3D (C-Motion, USA) and EMG data were processed in Matlab (MathWorks, USA) using a wavelet approach [2]. Long and short condition EMG intensities were normalized to the total intensity (TI) of the standard condition, where  $TI = \text{sum of intensities across wavelets and time}$ . EMG TIs of the first activation peak (Figure 1) were computed. Statistical analyses of maximum scapular rotation angles, and upper and middle trapezius TIs were performed in SPSS (IBM, USA) using Wilcoxon Signed Tanks Tests ( $\alpha=0.05$ ).

### Results and Discussion

Longer than standard crutches resulted in greater scapular upward rotation ( $p=0.008$ ) and greater TI of upper ( $p=0.028$ ) and middle trapezius ( $p=0.008$ ) (Table 1). Shorter than

standard fit crutches resulted in greater downward rotation of the scapula ( $p=0.008$ ). TIs did not differ between short and standard fit conditions ( $p>0.05$ ).

**Figure 1:** Effects of crutch fit on scapula rotation (°) and trapezius EMG intensities (red=high, blue=low). Vertical white lines indicate the period of interest for total EMG intensity analysis.

### Conclusions

Longer crutches increased scapular upward rotation and caused greater trapezius muscle activation intensities. These findings may be relevant to individuals with conditions including rheumatoid arthritis, Ehlers-Danlos syndrome, hemophilia and paraplegia, who may have a limited capacity to compensate for the greater mechanical and neuromuscular demands of crutches that are too long [1].

## Age-Related Changes to Triceps Surae Muscle-Subtendon Interaction Dynamics During Walking

William H. Clark<sup>1</sup> and Jason R. Franz<sup>2</sup>

<sup>1</sup>Department of Ecology and Evolutionary Biology, Brown University, Providence, RI, USA

<sup>2</sup>Joint Department of Biomedical Engineering, UNC Chapel Hill and NC State University, Chapel Hill, NC, USA

### Summary

Ankle moment and power generation is largely governed by the interaction between the triceps surae muscles (i.e., gastrocnemius and soleus) and the Achilles subtendons (i.e., distinct bundles of tendon fascicles arising from each muscle). Here, we investigated the interaction between triceps surae muscle and subtendon behaviour as a determinant for reduced ankle push-off in older adults. Our findings suggest that the capacity for sliding between subtendons facilitates independent muscle actuation in young adults but restricts that actuation in older adults. The resultant disruption in contractile behavior may contribute to hallmark reductions in push-off intensity during walking in older adults.

### Introduction

The gastrocnemius (GAS) and soleus (SOL) muscles of the triceps surae undergo different fascicle kinematics and contribute differently to powering locomotion [1]. These differences may be facilitated by the Achilles tendon (AT), which is comprised of distinct bundles of tendon fascicles (“subtendons”) that originate from each muscle. Evidence of non-uniform displacement patterns within the AT suggests that sliding between subtendons may facilitate independent muscle actuation. Yet, in older adults, we have observed more uniform AT tissue displacements that correlate with reduced ankle moment generation during walking [2]. Here, we investigated differences in GAS vs. SOL muscle behavior as a determinant of reduced ankle moment generation. First, we hypothesized that, compared to young, older adults would have more uniform AT tissue displacements that would be accompanied by smaller differences between GAS and SOL muscle length-change. Second, we hypothesized that differences between GAS and SOL muscle length-change would correlate with peak ankle moment generation.

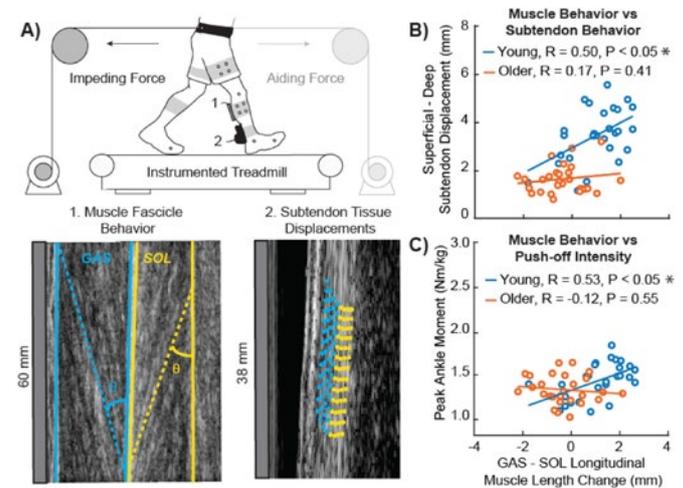

### Methods

9 young (24±4 yrs, 4F) and 9 older (74±4 yrs, 3F) adults walked on a treadmill for 1 min each at 1.2 m/s with and without: (1) a 5% body weight horizontal aiding force (decrease ankle moment) and (2) a 5% body weight horizontal impeding force (increase ankle moment), as shown in Fig. 1A. A 60 mm ultrasound transducer recorded cine B-mode images through the right medial GAS and SOL at 76 fps. Simultaneously, a 38 mm ultrasound transducer recorded ultrasound radiofrequency data of the right leg free AT at 155 fps enabling synchronized assessment of two equally sized tendon depths – superficial (GAS) and deep (SOL). Post collection, we quantified time series of GAS and SOL fascicle lengths [3] and subtendon displacements [4], averaged across 2 strides per condition. We report stance-phase differences in

longitudinal muscle length change (i.e., GAS-SOL) and AT non-uniformity (i.e., superficial-deep). Mixed factorial ANOVAs tested for the effect of age and condition (1.2 m/s, aiding, and impeding) on peak ankle moment, GAS-SOL longitudinal muscle length change, and AT non-uniformity.

### Results and Discussion

In support of our hypotheses, older adults walked with 49% more uniform AT tissue displacements ( $P < 0.05$ ) that were accompanied by 17% smaller differences between GAS and SOL muscle length-change ( $P < 0.05$ ). Only young adult muscle-level behavior correlated with AT non-uniformity and peak ankle moment generation (Fig. 1B-C).

**Figure 1:** (A) Depiction of experimental protocol. Muscle behavior correlated with subtendon behavior (B) and peak ankle moment (C) in young, but not older adults. \*significant ( $P \leq 0.05$ ) correlation.

### Conclusions

Our findings suggest that the capacity for sliding between subtendons facilitates independent triceps surae muscle actuation in young adults but restricts that actuation in older adults. The resultant disruption in muscle contractile behavior may contribute to hallmark reductions in push-off intensity (e.g., ankle moment) during walking in older adults.

## Regional variability of shear wave velocity is different between passive and active muscle

Allison B. Wang<sup>\*1,4</sup>, Kristen L. Jakubowski<sup>\*1,2,4</sup>, Eric J. Perreault<sup>1-4</sup>, Sabrina S.M. Lee<sup>2</sup>

### Summary

Quantifying regional stress and material properties in passive and active muscle is useful for understanding force transmission and muscle contraction dynamics. However, directly measuring stress and material properties *in vivo* remains a challenge. Shear wave velocity (SWV) is sensitive to muscle material properties and stress and has been shown to be sensitive to regional heterogeneity in the biceps brachii under passive loading. However, it is unknown if similar regional variations exist in the highly compartmentalized tibialis anterior (TA) and if these variations change under active contractions. We investigated SWV across the proximal, belly, and deep regions of the TA under passive and active loading. We found regional variations in SWV under passive loading but none during active contractions. More studies are needed to determine if similar regional variability exists in other compartmentalized muscles. Studies using SWV should control for regional variability when investigating passive muscles.

### Introduction

An individual muscle can have different compartments with distinct fiber architecture, fiber types, and innervation patterns. Strain within individual compartments is different under passive [1] and active loading [2]. These differences may be linked to regional variations in material properties and stress within the muscle. Heterogeneity in stress and material properties can influence muscle contraction dynamics and force transmission. However, current methods cannot make direct measurements of stress and material properties *in vivo*. Shear wave velocity (SWV) is a promising measurement as it is sensitive to differences in material properties and stress [3]. Previously, we have used SWV to detect heterogeneity within the bicep brachii muscle under passive conditions. However, it is unclear if these regional variations also occur in highly compartmentalized muscles, like the tibialis anterior (TA) where there is evidence of regional strain heterogeneity [4]. It is also unclear how the regional variations differ between active and passive loading where the stress inducing mechanism is vastly different. Therefore, we aim to investigate if SWV is different between compartments (proximal, belly, and deep) of the TA during passive and active loading. We hypothesize that, due to strain variability, SWV will vary across the proximal, belly, and deep regions of the TA.

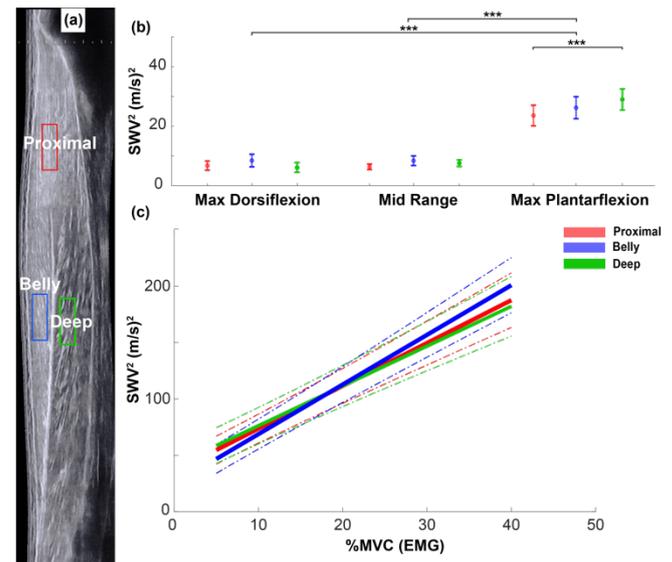

### Methods

Eight healthy young adults participated in the study. Shear wave ultrasound data (SuperSonic Imagine) was measured at the proximal, belly, and deep regions of the muscle (Fig. 1a) at several ankle angles (passive condition: maximum dorsiflexion and plantarflexion, and at the midrange of ankle range of motion; active condition: midrange ankle angle). Torque and electromyography (EMG) data were simultaneously collected with the EMG as visual feedback during the active trials. Participants performed isometric contractions of the TA by actively dorsiflexing at different levels of activation (5 – 40% maximum voluntary

contractions in 5% increments). SWV<sup>2</sup> is reported as it has been shown to be linearly related to changes in shear modulus and stress [3]. Linear mixed-effects models were used for statistical analyses.

### Results and Discussion

Under passive conditions, SWV<sup>2</sup> increased with TA lengthening ( $p < 0.001$ ), but the effect varied across different regions ( $p < 0.001$ ; Fig. 1b). At the longest length, SWV<sup>2</sup> in the deep region was 5.5 m<sup>2</sup>/s<sup>2</sup> greater than in the proximal region ( $p < 0.05$ ). Under active conditions, SWV<sup>2</sup> increased linearly with muscle activation ( $p < 0.001$ ), but the relationship between SWV<sup>2</sup> and activation was not different across regions ( $p = 0.14$ ; Fig. 1c). During active conditions, inter-subject variability was much higher than passive conditions. The different patterns of regional variations between passive and active muscle may be related to different regional variations in stress or material properties between passive lengthening and active contractions.

**Figure 1:** (a) Different regions within the tibialis anterior where SWV measurements were taken. Regional difference of shear wave velocity under passive lengthening (b) and active contraction (c).

### Conclusions

We found regional variations of SWV<sup>2</sup> in the TA under passive loading, but not during active contractions. When using SWV<sup>2</sup> in the TA under passive loading, the imaging region needs to be considered. More studies are needed to determine if results are similar for other muscles that have a compartmental design.

## Is there passive force-mediated enhancement of active force in skeletal muscles?

E.K. Moo<sup>1,2</sup>, R. K. Korhonen<sup>2</sup>, and W. Herzog<sup>1</sup>

<sup>1</sup>University of Calgary, Calgary, Canada, <sup>2</sup>University of Eastern Finland, Kuopio, Finland,  
Email: ekmo@ucalgary.ca

### Summary

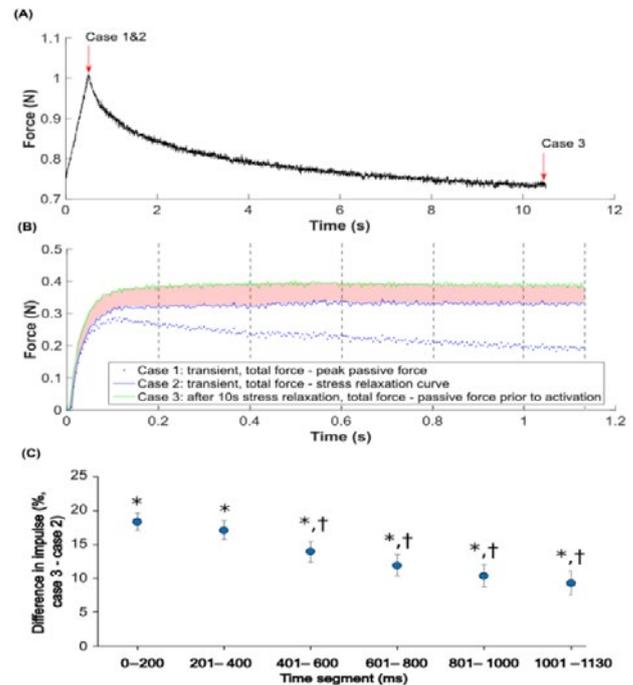

Aside from the regular Calcium ( $\text{Ca}^{2+}$ )-dependent mechanism, active force production in skeletal muscle is also mediated by passive force, especially at high load. We wanted to quantify the amount of additional force that can be attributed to this force-mediated mechanism, by activating the muscle-tendon unit (MTU) of the mouse tibialis anterior that was held at a constant length but was activated at different levels of force. We found a result opposite to that expected; i.e., the active force generated at high passive force was lower than that produced at low passive force. Further research is needed to understand the influence of passive force on active force production.

### Introduction

Skeletal muscle contraction has been thought to mainly involve  $\text{Ca}^{2+}$ -dependent series of events in which  $\text{Ca}^{2+}$  binds to troponin C to expose myosin-binding sites on actin, which in turn allows for the formation and cycling of cross bridges. Recent studies show that active force production is enhanced by passive force, especially at high loads [1-3]. This force-mediated mechanism acts through ‘awakening’ super-relaxed cross bridges by force, thus increasing the total number of cross-bridges for increased production of active force. However, the amount of additional force contributed by the ‘force-awakened’ cross bridges remains unclear. Therefore, the goal of this study was to quantify the active force produced by intact MTU that was stretched to the same length but activated at different levels of force. We posited that MTU activated at higher force generates higher active force in a manner consistent with the literature [1-3].

### Methods

Intact MTU of tibialis anterior muscles of 8-10 week-old male C57/BL6 mice ( $N = 7$ ) were stretched to long length (4 mm longer than resting length, 36 – 40% strain) corresponding to the descending limb of the active force-length curve using a custom-built miniature dynamometer. At the target length, the MTU was activated isometrically for 1.13s either instantaneously or following 10s of stress relaxation. The MTU was allowed to recover at the resting length for 3 min between trials. In separate trials, the MTU was stretched to the target length and held isometrically without activation to measure the stress relaxation of the passive force. Muscle force was recorded by a force transducer. For trials where activation was triggered instantaneously at the target length, the active force was derived either by subtracting the peak passive force from the total measured force (case 1, Fig. 1B, blue dotted curve) or by subtracting the stress-relaxation curve spanning the activation duration from the total force curve (case 2, Fig. 1B, blue solid curve). The active force resulting from activation following 10s relaxation was determined by subtracting the passive force prior to activation from the total measured force (case 3, Fig. 1B, green solid curve). The active force was divided into six time segments (Fig. 1B, vertical dotted lines), and force impulses for case 2 and case 3 were compared for each time segment.

**Figure 1:** (A) Stress relaxation when the MTU was held passively at the target length for 10s, (B) active force produced when the MTU was activated either instantaneously (left arrow in (A), blue curve, case 1&2), or following 10s of stress relaxation (right arrow in (A), green curve, case 3). (C) Difference in impulse between active forces derived for case 2 and case 3 (red shaded area in (B)), for time segments indicated in (B). \* denotes significant difference from zero, and † indicates significant difference compared to 0-200ms and 201-400ms time segments, as well as among each other. Error bars:  $\pm 1$  standard error of the mean.

### Results and Discussion

The ratio of active to passive force was  $0.16 \pm 0.10$  at the target MTU length. Following 10s stress relaxation, the passive force dropped by approximately 30% (Fig. 1A). The force impulses generated by the MTU activated following stress relaxation (case 3) were 9 – 18% higher than those when the MTU was activated at peak passive force (Fig. 1C, case 2) at all time points. This difference in force impulse decreased with activation time (Fig. 1C), which coincided with the decay of passive force with time (Fig. 1A).

### Conclusions

We found that, at the same MTU length, the active force produced at high passive force was lower than that produced at low passive force, leading to the rejection of our hypothesis. Further research is needed for understanding the force-mediated production of active force.

### 3D Soleus Model Predicts Regional Muscle Displacements that are Consistent with Dynamic MRI Measures

Katherine R. Knaus<sup>1</sup>, Remziye Erdogan<sup>1</sup>, Geoffrey G. Handsfield<sup>2</sup>, Silvia S. Blemker<sup>1</sup>

<sup>1</sup>Department of Biomedical Engineering, University of Virginia, Charlottesville, VA, USA

<sup>2</sup> Auckland Bioengineering Institute, Auckland, NZ; Email: ker4e@virginia.edu

#### Summary

The soleus muscle's aponeurosis morphology is complex, and its effects on mechanical output are poorly understood. We developed a finite element model (FEM) of 3D soleus architecture that allows for examination of the effects of aponeurosis morphology and we validated the model by comparison with dynamic MRI. The model predicts regional variations in muscle displacements that are consistent with measurements from cine DENSE (Displacement Encoding with Stimulated Echoes) magnetic resonance imaging (MRI).

#### Introduction

The soleus muscle plays an important role in walking by generating plantarflexion (PF) power. Knowledge of soleus function is currently limited by understanding of the role of this muscle's complex structure. The soleus has an internal anterior aponeurosis (AA) attached to the tibia and fibula that splits the muscle into compartments [1]. Fascicles in the posterior compartment (PC) insert onto the posterior aponeurosis (PA) which is continuous with the Achilles at the muscle-tendon-junction (MTJ), while fascicles in the anterior compartment (AC) insert onto the median septum (MS) that protrudes from the PA and interdigitates with the AA [1]. While the aponeurosis morphology is well described, the effects of this morphology on the behavior of fascicles within the compartments is not well understood. Our goals were to (i) create an FEM representing these 3D structures to examine morphologic effects and (ii) verify model-predicted tissue displacement by comparing to *in vivo* soleus displacements.

#### Methods

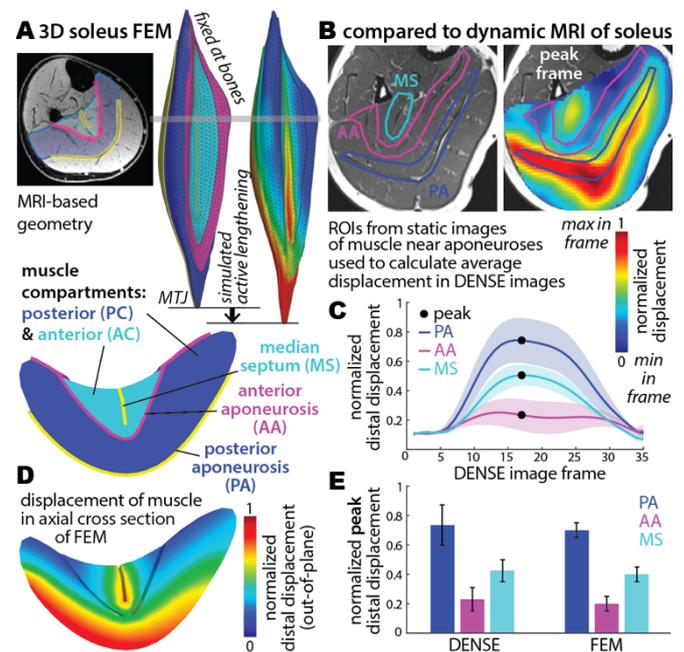

A 3D model of the soleus muscle was created with AC, PC, AA, PA, and MS structures using MRI segmentation of the lower limb of one subject (22 years, 191 cm, 88.4 kg). Model geometry was meshed into tetrahedral elements and fiber directions were assigned to each element. Muscle fascicles originated on the AA surface and inserted onto the PA surface. Muscle and aponeurosis were transversely isotropic materials. To simulate active lengthening, the soleus was activated to 75% while the PA at the MTJ was displaced 20 mm distally and the attachments of the AA to bones were fixed (Fig 1A).

Static images were collected for eight subjects (24±3 years, 175±13 cm, 66±12 kg) in an axial plane (resolution 0.49 x 0.49 mm<sup>2</sup>) at approximately one third of the soleus muscle's length as they lay prone and plantarflexed. Cine DENSE images were acquired in the same plane as subjects repeated ankle motion using a non-ferrous exercise device so that rotation of inertial disks resulted in active lengthening of PF muscles [2]. Time-varying out-of-plane tissue displacement was determined in DENSE images (Fig 1C). Average muscle displacement near each aponeurosis was found in regions of interest (ROI) defined in static images and normalized by the

range in the peak frame (Fig 1B). Displacements in FEM axial plane (Fig 1D) were compared to DENSE results (Fig 1E).

#### Results and Discussion

The FEM predicted that the greatest average axial plane distal displacement was located near the PA and MS while the least displacement was located near the AA (Fig 1D,E). All 8 subjects showed behavior similar to the model; tissue in the PA ROI had the greatest normalized displacement, followed by the MS and AA (Fig 1C,E), so differential displacement was positive in both compartments. Nonuniform displacement indicates motion of both the PA and MS relative to the AA which will affect the fascicle kinematics in the PC and AC.

**Fig 1:** A) MRI-based soleus FEM predictions and B) DENSE MRI measurements from 8 subjects of E) differential tissue displacement during active lengthening in muscle regions near the aponeuroses.

#### Conclusions

FE simulations predict soleus muscle tissue displacements that depend on aponeurosis structure. Dynamic MRI reveals similar patterns of *in vivo* tissue displacement that correspond with static images of aponeurosis morphology. The FEM enables us to investigate effects of aponeurosis morphology and material properties on regional muscle displacement.

## Does increasing passive force at the start of activation increase the total isometric force of muscles?

Siwoo Jeong<sup>1</sup>, Kiisa C. Nishikawa<sup>1</sup>

<sup>1</sup>Department of Biological Sciences, Northern Arizona University, Flagstaff, AZ, USA

Email: Kiisa.Nishikawa@nau.edu

### Summary

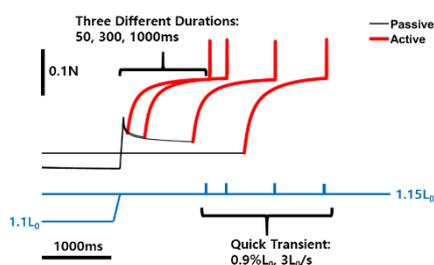

The total isometric force of a muscle has been regarded as the sum of the passive and active force. However, recent studies have suggested that the passive titin-based force might change upon activation if N2A titin binds to actin. If the titin-based force changes upon muscle activation, then the passive component of total force might not be constant. To test this hypothesis, a passive stretch and hold was performed to increase passive force, then maximal isometric contraction was established at three different times during the holding after stretch. We found that increasing passive force at the start of activation had no effect on total isometric force compared to normal passive tension at the same length but with no passive stretch. This finding suggests that titin-based passive force of muscles must change as a result of activation.

### Introduction

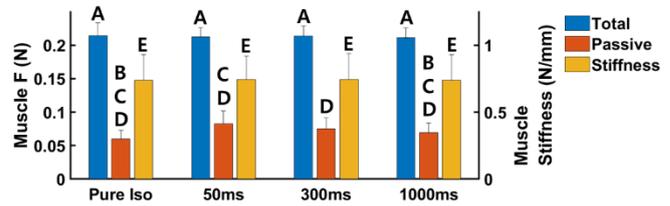

Total isometric force is assumed to represent the sum of the titin-based passive force and the active cross-bridge force [1], since titin is in parallel with cross-bridges and titin is the main source of passive tension of striated muscles [2]. However, previous research suggests that titin structure changes upon muscle activation due to Ca<sup>2+</sup>-dependent titin-actin binding [3], which might affect the titin-based passive force as well. We hypothesized that total isometric force should increase with increasing passive force at the start of activation unless titin-based passive forces change when a muscle is activated. To test this hypothesis, we activated muscles isometrically at varying times after passive stretch when the passive tension was decreasing due to stress relaxation. Our working hypothesis is that if isometric contraction starts before the increased titin force due to passive stretch has dissipated, then total isometric force should be greater than the purely isometric force unless titin structure changes.

### Methods

Six whole soleus muscles were isolated from wild-type mice. Muscles were passively stretched from 1.1L<sub>0</sub> to 1.15L<sub>0</sub> at 1L<sub>0</sub>/s and held isometrically for 50, 300 or 1000ms before activation at 1.15L<sub>0</sub>. For comparison, total isometric force was also measured at 1.15L<sub>0</sub> with no previous stretching. Instantaneous stiffness was measured in all trials

**Figure 1:** Muscle force (upper), length (lower) and measurement of instantaneous stiffness.

**Figure 2:** Mean (+1SD) total isometric force, passive force at the start of activation and instantaneous stiffness at maximal isometric force. Bars not connected by the same letter are significantly different (Bonferroni,  $p < 0.05$ ).

using a quick strain transient (0.9%L<sub>0</sub>, 3L<sub>0</sub>/s, Fig. 1). One-way repeated measures ANOVA was used to compare total isometric force, passive force and instantaneous stiffness between different hold durations and the pure isometric contraction. Bonferroni corrections were used for post-hoc comparisons to identify differences between conditions.

### Results and Discussion

Passive forces at 50 and 300ms were significantly greater than passive force with no stretching ( $p = 0.014$ , 50ms;  $p = 0.032$ , 300ms). Passive force at shorter hold duration was significantly greater than passive force at longer duration ( $p = 0.011$ , 50ms vs. 300ms;  $p = 0.006$ , 50ms vs. 1000ms;  $p = 0.017$ , 300ms vs. 1000ms), suggesting that passive force decreased as hold duration increased. Total isometric force and instantaneous stiffness did not differ significantly ( $p > 0.05$ ) regardless of passive force at the start of activation (Fig. 2).

Given the in parallel connection between cross-bridges and titin and same isometric cross-bridge force at same muscle length, total isometric force should increase with the titin-based passive force unless the titin-based force changes during muscle activation.

### Conclusions

Our results show that isometric force and stiffness were independent of the titin-based passive force at the start of activation. This finding suggests that the process of muscle activation involves more than simply adding cross-bridge force to passive force. Instead, it appears that titin force, cross-bridge force, or both are altered by muscle activation.

## Comparison of Data Reduction Techniques and their Effect on Neural Network Performance

Fabian Hoitz<sup>1,2</sup>, Vinzenz von Tscharnner<sup>1</sup>, Jennifer Baltich<sup>3</sup>, Benno Nigg<sup>1,2</sup>

<sup>1</sup>Biomedical Engineering, Schulich School of Engineering, University of Calgary, Calgary, Alberta, Canada

Email: Fabian.hoitz@ucalgary.ca

### Summary

This work compared five techniques for data reduction and their effect on the performance of a neural network that was trained for gait recognition. Layer-wise relevance propagation was found to be the best technique for data reduction and ease of functional interpretation.

### Introduction

Current trends in biomechanics include studies with large datasets [1]. While multivariate analyses (e.g., neural networks) benefit from such volumes and create astonishing results [2], functional interpretations of these extensive datasets remain challenging. It is often of interest to discern important aspects that contribute relevant information from less important aspects that are irrelevant and mostly contribute noise [3]. Data reduction techniques, such as principal component analysis (PCA), may help to isolate relevant aspects of a given dataset that would facilitate a functional interpretation without affecting the great performances of multivariate analyses.

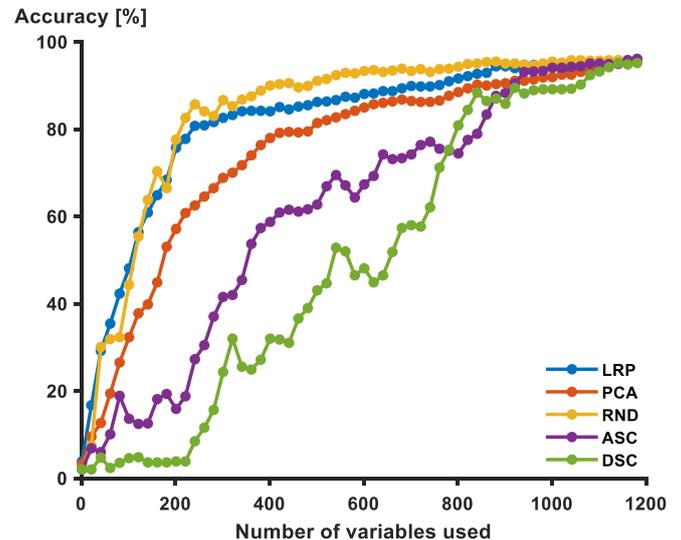

The purpose of this work was, therefore, to compare multiple data reduction techniques in their effect on the performance of a neural network that was trained for gait recognition (i.e., identify individuals based on their gait pattern).

### Methods

A neural network was trained to recognize fifty participants (12 males [mean  $\pm$  std]: 33.5  $\pm$  8.9 years, 95.6  $\pm$  27.2 kg, 179  $\pm$  6.4 cm; 38 females [mean  $\pm$  std]: 35.2  $\pm$  9.4 years, 69.8  $\pm$  13.2 kg, 164.7  $\pm$  6.3 cm) based on their gait patterns. A gait pattern consisted of 3D joint angle trajectories (Hip, Knee, and Ankle) and Ground Reaction Forces of a single step that were collected during overground running trials (3.5 m/s  $\pm$  15 %) along a 30 m indoor runway on two days that were eight weeks apart. All 1200 variables of a single gait pattern were ranked by either their relevance (derived via layer-wise relevance propagation [4]), their loading on the first principal axis (derived via PCA), their order (ascending vs. descending), or simply at random. The networks performance was then evaluated iteratively with an increasing number of variables (1-1200) according to the five ranking conditions.

### Results and Discussion

Figure 1 shows the networks accuracy as a function of the number of variables used for the gait recognition task according to the five ranking conditions. To achieve acceptable accuracies ( $\geq 80\%$ ), a minimum of 200 variables (selected via LRP or RND) was necessary.

**Figure 1:** Neural network performance as a function of the number of variables used for gait recognition in five ranking conditions: layer-wise relevance propagation (LRP), principal component analysis (PCA), random (RND), ascending (ASC), and descending (DSC).

While a random selection of variables resulted in similar performances as variables selected via layer-wise relevance propagation, their functional interpretation remains unclear. For variables selected via layer-wise relevance propagation, one can conclude that they represent those variables that are most important for a recognition of individuals by gait.

### Conclusions

Layer-wise relevance propagation may reduce large datasets to only those variables that are most vital for gait recognition.

## Summary

Advances in machine learning have facilitated extraction of 2D joint trajectories from videos of natural gait collected outside of the clinic. This work evaluates regression models for predicting parkinsonism severity in gait on the UPDRS-gait scale in previously unseen participants. Traditional linear, random forest, and ordinal logistic regression models, as well as recently introduced spatial temporal graph convolutional networks are investigated for this task. Results on a dataset of natural gait in older adults with dementia suggest regression models that use both 2D joint trajectories and engineered gait features as input outperform models that use just joint trajectories or just gait features.

## Introduction

Up to 60% of older adults with dementia develop parkinsonism when treated with antipsychotic medication. Consumer-grade cameras can unobtrusively monitor medication induced fluctuations of parkinsonism severity in gait in non-clinical settings. Recent advances in pose-tracking algorithms have facilitated extraction of trajectories of key joints in color video, presenting an opportunity to leverage deep learning models trained on 2D joint trajectories to predict clinical scores of parkinsonism severity in gait.

## Methods

Joint trajectories from 2160 natural walking bouts of 38 older adults with dementia were extracted from standard video using Alphapose. A trained annotator labelled 324 bouts from 14 participants (age:  $76.2 \pm 8.7$  years) with scores of parkinsonism on the gait criterion of the Unified Parkinson's Disease Rating Scale (UPDRS-gait). Eight gait features (cadence, number of steps, average step width, average margin of stability, the coefficient of variation of step width and time, the symmetry index of step times) were calculated from the joint trajectories [1, 2].

Linear, random forest, as well as immediate and absolute threshold variants of ordinal logistic regression were investigated for prediction of UPDRS-gait scores using these eight gait features as input. Leave-one-subject-out cross-validation (LOSOCV) was used to train models on walks from all but one participant and evaluate on the held-out participant. Model hyperparameters were tuned using 10-fold cross validation using validation sets selected from the training set.

Spatial temporal graph convolutional networks (ST-GCNs) are machine learning models that can leverage the innate spatial structure of skeleton trajectories [3]. ST-GCN models were trained to regress to UPDRS-gait scores using only joint trajectories, or both joint trajectories and gait features as input in a separate analysis. Hyperparameter tuning on three model

backbones, three temporal kernel sizes, and six dropout rates per model was performed using a LOSOCV scheme with five-fold cross-validation for each participant.

For all experiments, the macro-averaged F1-score per class on the validation set was used to select the model configuration used for evaluation on the held-out test participant.

## Results and Discussion

Table 1 presents the test set accuracy, mean absolute error, and F1-score for the top performing models using gait features, joint trajectories, or both as input. The immediate threshold ordinal logistic regression model was the top performing model on only gait features, while 10 layer ST-GCN backbones introduced in [3] achieved the highest validation macro-averaged F1-scores using joint trajectory data, with and without gait features.

**Table 1:** Test Accuracy, MAE, and F1-score for Top Models

Input Data	Accuracy	Mean Absolute Error (MAE)	Macro F1-score
Gait Features	0.406	0.766	0.333
Joint Trajectories	0.352 $\pm 0.013$	0.712 $\pm 0.036$	0.321 $\pm 0.013$
<b>Joint Trajectories + Gait Features</b>	0.411 $\pm 0.027$	0.688 $\pm 0.008$	0.372 $\pm 0.019$

## Conclusions

On a challenging dataset of natural walking bouts of older adults with dementia, regression models that combine both joint trajectories and gait features achieve better regression to parkinsonism severity in gait than models that only use gait features or joint trajectories as input.

### Summary

Ground reaction forces (GRFs) are important for understanding the biomechanics of human movement. However, the measurement of GRFs is generally limited to laboratory environments. We present a recurrent neural network (RNN) capable of predicting normal (i.e., perpendicular to surface) GRF waveforms in near real-time across a range of speeds (2.5, 3.33, and 4.17 m/s) and slopes ( $0^\circ$ ,  $\pm 5^\circ$ ,  $\pm 10^\circ$ ) using accelerometers mounted to the sacrum and foot. The average  $\pm$  SD root mean squared error (RMSE) and relative RMSE (rRMSE) between experimentally-measured GRFs and RNN predictions across 19 subjects was  $0.16 \pm 0.04$  BW and  $6.4 \pm 1.5\%$ , which is less than prior studies that predicted time-normalized vertical GRFs during level-ground running (RMSE = 0.20 BW; rRMSE = 13.9%). Our novel approach provides a technique to accurately estimate a runner's normal GRFs in a variety of outdoor environments, provide biomechanical feedback during a run, and longitudinally monitor biomechanical variables.

### Introduction

Inertial measurement units (IMUs) have been used to measure kinetic and kinematic variables outside the laboratory setting [1,2], but IMUs cannot directly measure GRFs during running. Prior work has used neural networks to predict the entire GRF waveform during the stance phase of running from IMU data [3,4]. These networks required preliminary identification of the stance phase and normalization to the duration of a step or contact time, resulting in a loss of temporal information [3,4]. Additionally, prior work predicted GRF waveforms during level-ground running, but not uphill or downhill running. A method for predicting the normal GRF waveforms using IMUs across a range of running slopes, while maintaining the temporal component, could allow researchers and clinicians to predict kinetic and kinematic variables in outdoor environments. We sought to develop an RNN to predict normal GRF waveforms across a range of slopes and speeds using data from accelerometers.

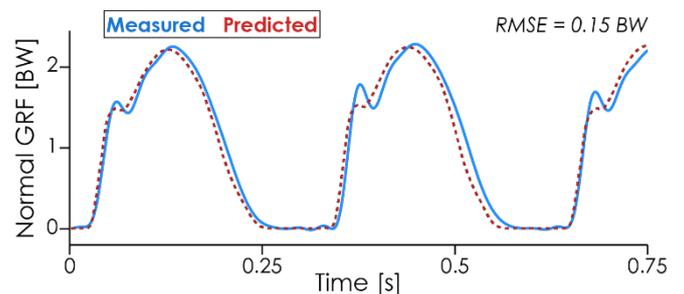

### Methods

19 subjects ran for 30-s on a force-measuring treadmill at five slopes ( $0^\circ$ ,  $\pm 5^\circ$ ,  $\pm 10^\circ$ ) and three speeds (2.5, 3.33, and 4.17 m/s) per slope. One biaxial accelerometer was adhered to the sacrum and two uniaxial accelerometers to the right shoe during all trials. Accelerometers on the shoe were used to classify foot strike patterns as rearfoot, midfoot, or forefoot [5], and sacral acceleration data were divided into overlapping 12-ms windows, allowing the RNN to iteratively predict the measured normal GRF waveform frame-by-frame. The average, SD, and range of values for each 12-ms window of

accelerometer data were included as RNN input features, along with the subject's body mass, height, slope, running speed, and percentage of a trial's steps classified as a rearfoot, midfoot, or forefoot strike. We assessed the accuracy and generalizability of the RNN using leave-one-subject-out cross validation, which provided an ensemble of RMSE and relative RMSE (rRMSE) values when comparing the normal GRF waveform predicted by the RNN to that measured by the force-measuring treadmill.

### Results and Discussion

Predictions of each subject's normal GRF waveform had an average  $\pm$  SD RMSE of  $0.16 \pm 0.04$  BW and rRMSE of  $6.4 \pm 1.5\%$  across all conditions (Figure 1). The RNN predictions had a lower RMSE during slow uphill running (2.5 m/s,  $+10^\circ$ ; RMSE =  $0.13 \pm 0.07$  BW) compared to fast downhill running (4.17 m/s,  $-10^\circ$ ; RMSE =  $0.20 \pm 0.05$  BW). RNN prediction error was less than the error of neural networks used in prior studies (RMSE = 0.21 BW; rRMSE = 13.9%), which were limited to time-normalized vertical GRF waveforms only during level-ground running [3,4].

**Figure 1:** Representative subject's experimentally-measured normal GRF waveform (solid blue line) and RNN prediction (dashed red line) at 3.33 m/s and  $0^\circ$  slope.

### Conclusions

We developed an RNN that uses accelerometer data to predict the continuous normal GRF waveform across a range of running slopes and speeds with greater accuracy than prior studies. Additionally, the RNN does not require preliminary identification of the stance phase, maintains the temporal component, can be applied to up- and downhill running, and allows for near real-time predictions of the normal GRF waveform due to the recurrent nature of the neural network.

### Summary

Force platform data were collected for sixteen youth/young adults (ages: 15-30; 14 females, 2 males; 8 matched pairs) during a single leg balance (SLB) task. Eight participants had a history of significant ankle sprain (resulting in at least 3 days of time loss and requiring medical attention) 3-15 years prior, and eight participants had no history of lower extremity injury. Discrete measurements from the force plate data were fed into three machine learning (ML) algorithms [logistic regression, support vector machine (SVM), and a random forest] to classify participants into injured versus uninjured groups. All three ML classifiers yielded prediction accuracies greater than 0.5 (Logistic regression =  $0.763 \pm 0.134$ , SVM =  $0.731 \pm 0.138$ , Random forest =  $0.644 \pm 0.133$ ). Future directions for this work will include a larger sample size and use of neural networks to examine weights used to classify participants.

### Introduction

Ankle sprain injuries are the most common injury in youth sport [1]. Literature suggests ankle sprain injuries can lead to ligament proprioceptor damage, resulting in impaired balance [2]. Although ML in biomechanics is increasingly popular, few studies have used ML to classify individuals based on kinetic parameters [3].

The objective of this project was to compare the prediction accuracies of three ML algorithms to classify individuals with and without ankle sprain history based on force platform measurements during an SLB task.

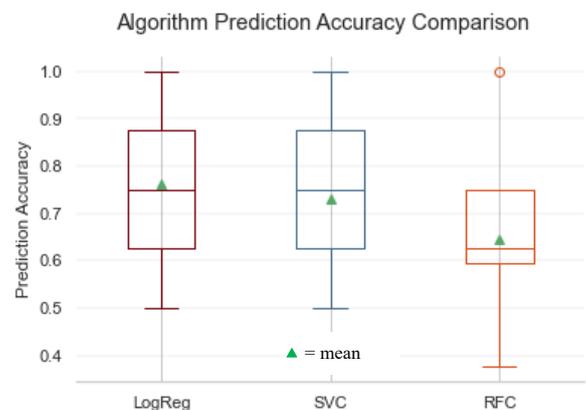

### Methods

Sixteen youth/young adults (ages: 15-30; 14 females, 2 males; 8 matched pairs) attended one testing session during which force platform data were collected during an SLB task. Eight participants had history of significant ankle sprain 3-15 years prior and eight participants had no history of lower extremity injury. For the SLB task, the participant balancing, eyes open, on each leg for 70 seconds for three trials per leg. The force platform data were used to calculate average centre of pressure (CoP) coordinates, 95% ellipse, and CoP path length. The injured leg of the previously injured group was compared to the nondominant leg of the control group.

Three machine learning algorithms were developed in Python using SciKit Learn software: logistic regression, SVM, and a random forest. CoP parameters were fed into the ML classifiers. Repeated stratified k-fold validation was used to validate the classifiers.

### Results and Discussion

Logistic regression had the 'Cs' value set to the default value of 10. This resulted in a classification accuracy of  $0.763 \pm 0.134$ . SVM was performed using a third-degree polynomial, gamma set to 0.01, and C set to 0.1 resulted in a classification accuracy of  $0.731 \pm 0.138$ . The random forest algorithm had 100 decision trees, which used Gini impurity measures and had a maximum number of 2 branches. This resulted in a classification accuracy of  $0.644 \pm 0.133$ .

**Figure 1:** Median prediction accuracies and interquartile ranges of three machine learning techniques, calculated over 20 folds.

### Conclusions

ML classifiers show potential for separating individuals with and without ankle sprain history based on kinetic differences in a single leg balance task. Logistic regression and SVM performed better than random forest. Further work is necessary in examining neural networks to determine what variables have the greatest impact on classification.

### Summary

Recent advances in markerless pose estimation algorithms enable automated analysis of human movement from digital video recordings. Human gait analysis is commonly undertaken by reporting to a laboratory equipped with a 3D motion capture system. Here, we compare spatiotemporal gait parameters and kinematics acquired by motion capture and via pose estimation of healthy human gait. We found group mean errors between motion capture and pose estimation of 0.01 s for temporal gait parameters (step time, stance time, swing time and double support time), 0.018 m for step lengths and 0.03 m s<sup>-1</sup> for gait speed; mean errors were 4.0°, 5.6° and 7.4° for sagittal plane hip, knee and ankle angles. The accuracy with which gait parameters were estimated in the current study suggest that pose estimation is a promising technique to analyze human gait.

### Introduction

Markerless pose estimation algorithms offer new possibilities for analysis of human movement outside of the laboratory. OpenPose [1] is one such algorithm that has received attention for its use in gait analysis [2]. It is of interest to clinicians and researchers to test how accurately a range of gait parameters can be estimated by applying OpenPose to digital videos of human gait. Here, we compared spatiotemporal gait parameters and kinematics obtained with sagittal plane videos of healthy human gait against simultaneously collected 3D motion capture data.

### Methods

We used a freely available dataset of over-ground walking sequences of 31 healthy adults [3]. Gait sequences were simultaneously recorded with a 3D motion capture system (100 Hz) and digital videos (25 Hz). Digital videos were obtained from left and right sagittal plane views of the walkway. We used OpenPose to track 25 body keypoints (including left and right ‘hip’, ‘knee’, ‘ankle’, ‘small toe’ and ‘big toe’) in the videos. Spatiotemporal gait parameters (step time, stance time, swing time, double support time, step length and gait speed) and sagittal plane kinematics (hip, knee and ankle angles) were independently calculated from each measurement system (3D motion capture and OpenPose views). We developed a MATLAB workflow that used the x-y image coordinates of the body keypoints from the OpenPose output to calculate gait parameters (available at <https://github.com/janstenum/GaitAnalysis-PoseEstimation>). All parameters were calculated as individual participant mean values across the walking bout. We evaluated OpenPose by

calculating errors (absolute differences) between measurement systems.

### Results and Discussion

Group mean errors (and maximal error) between motion capture and OpenPose were: 0.01 s (0.04 s) for temporal gait parameters (step time, stance time, swing time and double support time), 0.018 m (0.050 m) for step length and 0.03 m s<sup>-1</sup> (0.09 m s<sup>-1</sup>) for gait speed. Mean errors of sagittal plane kinematics across the gait cycle were: 4.0° for hip, 5.6° for knee and 7.4° for ankle angles.

Errors between motion capture and OpenPose in the current study were less than previously reported values of minimal detectable change for spatiotemporal gait parameters and sagittal plane hip and knee angles in inter-session, test-retest studies of healthy human gait [4]. This suggests that spatiotemporal gait parameters and hip and knee angles can be estimated by OpenPose with the accuracy needed to detect changes in the gait pattern in healthy humans. We found that errors between left and right OpenPose views were less than errors between OpenPose and motion capture for all gait parameters suggesting that occlusion does not affect the calculation of gait parameters with OpenPose.

We found that errors for individual steps were occasionally high for step length (range of -0.202 to 0.204 m) and that the errors were systematically affected by the participants’ position relative to the camera; however, step length errors tended to cancel out when step lengths were averaged across the bout. Videos used in this study were obtained from stationary cameras placed ~3 m from the walkway at a height of ~1.3 m with a sagittal plane view; it is unknown how the results generalize to other data collection setups. Furthermore, the current study analyzed healthy human gait; it is possible that pose estimation may differ for pathological gait.

### Conclusions

We have shown that a range of spatiotemporal gait parameters and kinematics can be estimated by OpenPose with the accuracy required to detect changes in healthy human gait [5].

Email: rsk86@drexel.edu

## Summary

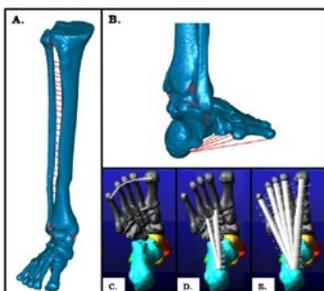

A subject specific, image-based 3D dynamic model of the foot and ankle was developed in this study based on an earlier validated model of the hindfoot. This model, able to simulate a variety of loading conditions, was used in this study to investigate the effect of body weight on arch kinematics and the plantar pressure distribution. The model was validated for this activity by comparing arch height and plantar pressure distribution against experimental data obtained from the subject from which the model was created. Excellent agreement between model and experimental results were obtained.

## Introduction

Three-dimensional (3D), subject-specific, image-based models of the foot and ankle complex can be used as both tools to better understand the biomechanics of the structure, as well as predictive planning tools for medical diagnosis. This project involves the development of a subject specific dynamic model of the foot and ankle capable of accurately reproducing its passive mechanical behavior of the foot and ankle under diverse loading conditions. The current dynamic model expands on an existing model of the hindfoot [1] by including the midfoot and forefoot and a mobile fibula with all the corresponding ligamentous constraints. The current study focuses on the validation of this new model (Fig.1) by examining changes in the foot structure during axial loading to full body weight simulating quiet standing on one foot.

## Methods

Imaging data of the geometry and orientation of the bones of the foot and ankle were obtained from Weight Bearing Computer Tomography (WBCT by CurveBeam™) scans of an individual, taken first while the subject was in the sitting position with no load applied to the scanned leg followed by a second scan with the subject in the standing position on one leg where the scanned leg was axially loaded to full body weight. A plantar pressure device (Pedar™ by NOVEL, Inc) measured the foot-to-ground pressure distribution (Fig. 2).

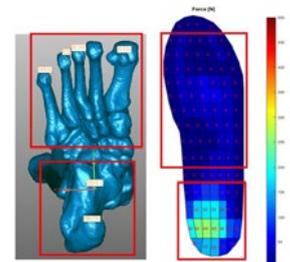

**Figure 1:** The dynamic model of the foot including elements representing: (A) the tibio-fibular ligaments, (B) the ligaments of the ankle joint complex, (C) the intermetatarsal ligaments, (D) the long-plantar ligament, (E) the plantar fascia.

The new features compared to the earlier hindfoot model [1] include the inclusion of a mobile, ligament constrained fibula, mid-foot and fore-foot bones and ligaments, and additional ligaments such as the plantar aponeurosis and long plantar ligament. The accessory sesamoids of the first metatarsal and navicular were modeled as bodies rigidly fixed to their associated bones to account for the increased areas of potential contact. The ligaments and fascia of the midfoot and forefoot spanning non-adjacent bones (e.g., the long plantar ligament) were implemented using tension-only spring elements. No a-priori kinematic constraints were applied in the model and its complex response to applied loads was exclusively the result of the ligament constraints and the bone-to-bone contact. Contact between the foot and the ground, modelled as a rigid flat surface, including static and dynamic friction allowing the foot the ability to slide on the floor. Simulations were performed starting with the foot flat on the ground in neutral position and then applying a vertical axial load to the tibia loading it slowly from zero to full body weight.

## Results and Discussion

For the validation of the model, change in arch height and pressure distribution under the foot was compared between the experimental weight bearing CT data and the dynamic model. Arch height, defined as the perpendicular distance between the center of mass of the navicular and the floor, was 6.48 mm, experimentally and 5.31 mm for the model. The cumulative pressure under the midfoot and forefoot was 27.97 kPa experimentally and 39.27 kPa from the model, and the pressure under the hindfoot was 114.02 kPa experimentally and 104.07 kPa from the model.

**Figure 2:** Comparison of the plantar pressure distribution under body weight between the model and the experimental data obtain through the Pedar™ Novel, Inc. system.

## Conclusions

A dynamic model of the foot and ankle was used to simulate the response of the foot to axial loads simulating standing. The height of the arch and the plantar pressure obtained through the model compared well to experimental data thus providing partial validation.

### Summary

Understanding passive mechanical properties of healthy muscle is required to create models that mimic human muscle properties. In this study, the passive force-length relationship of the gracilis muscle was explicitly defined based on experimentally measured passive force and sarcomere length. Our results show that the gracilis is very compliant and current muscle models overestimate the passive force of this muscle.

### Introduction

Human muscle is remarkable in its ability to produce both active and resistive forces that are necessary for mobility and stability of the human skeleton. One key aspect of muscle is its passive mechanical properties. Studies have shown that the passive mechanical properties of muscle changes due to disease, trauma and ageing. Therefore, it is important to understand the passive mechanics of healthy muscle. Passive properties of skeletal muscle vary from fibers to bundles in mouse, rabbit and human muscles. Thus, deducing passive mechanical properties of muscle from biopsy samples may be ill-advised [1]. No studies have reported on passive properties directly measured from whole human muscle.

Current predictions of whole muscle passive tension rely on models that are based on animal data obtained from a variety of species. There has been no direct experimental validation of current passive force-length models used in current musculoskeletal models that simulate human movement. Therefore, the aim of this study is to measure *in vivo* passive tension-length data for whole human muscle using a novel method. These experimental data were then compared to the standard passive force-length models from models [2, 3, 4].

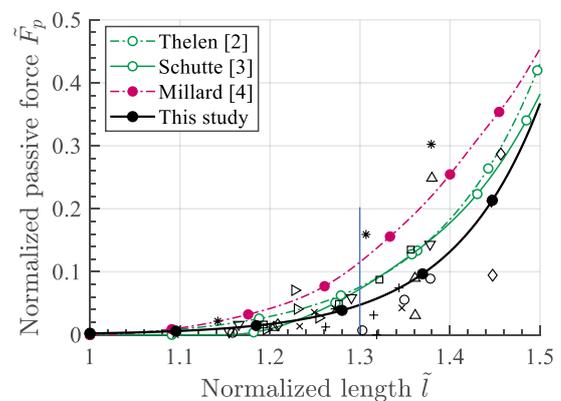

### Methods

Passive tension and sarcomere lengths were obtained from nine patients undergoing gracilis muscle transfer surgery. During surgery the leg was positioned in four joint configurations (JC) designed to gradually lengthen the gracilis muscle. *In vivo* passive tension at each JC was measured using a buckle force transducer (BFT) placed on the distal gracilis external tendon. Muscle tissue samples were clamped and excised at three of the four JC that corresponded to a knee flexion angle of 130°, 90° and 0°. The samples were formalin fixed within the clamp to determine the sarcomere length at each JC via laser diffraction. A natural exponential curve [5] was fitted to experimentally measured force-sarcomere length data to model the passive-elastic behavior of the gracilis muscle. Reported human sarcomere lengths are within a range of 70% to 130% of its optimal length [6]. For this reason,

experimental data and model predictions were compared at a normalized length of 1.3.

### Results and Discussion

The experimental data clearly demonstrate that the gracilis muscle is more compliant when compared to the current models (Figure 1). Although models based on frog fibers performed better, all models overestimated passive force.

**Figure 1:** Comparison between measured gracilis passive force-length relationship and passive force-length models. Thelen [2] and Schutte [3] models were derived from passive properties of frog fibers while Millard [4] was derived from rabbit whole muscle data. The exponential curve was fitted ( $r^2=0.95$ ) to experimental force-sarcomere length data for individuals shown by each symbol ( $n=9$ ).

The Thelen, Schutte and Millard models overestimated normalized passive force by 60%, 53% and 143% respectively.

### Conclusions

Current force-length models overestimate the passive tension of this human muscle. The gracilis appears to be very compliant compared to other human muscle however further research is needed to investigate this.

## Summary

Cerebral palsy (CP) is an upper motor neuron lesion that results in alterations in skeletal muscle structure, which have a substantial impact on muscle mechanics. In this study we investigated the whole muscle response to changes in the microstructure as a result of CP using a three-dimensional computational model. We found that when the muscle was stretched, there is a larger effect from the extracellular matrix than sarcomere length on passive stiffness. These results provide us with a deeper understanding of the influence of each change in the individual microstructural components that may occur due to CP.

## Introduction

Skeletal muscle is a complex material that has many organizational levels. It is composed of muscle fibres embedded in a background material which includes a matrix of collagen fibres, capillaries, and other cells.

The effects of structural changes resulting from CP, including the extracellular matrix (ECM) stiffness and volume fraction and sarcomere length, have been investigated through experimental studies; however, they have been found to vary between subjects and muscle groups [1]. Using a modelling approach we examined the individual contribution of different microstructural changes to muscle that may occur due to CP to passive whole muscle behaviour.

## Methods

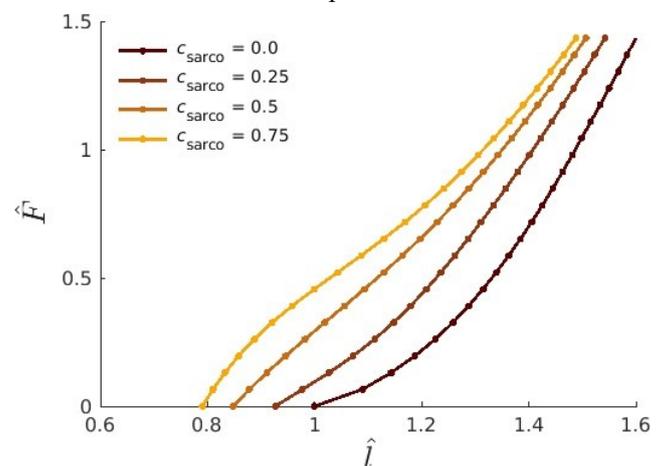

To investigate the effects of CP, we used a three-dimensional continuum model for skeletal muscle developed in [2,3]. The mathematical model consists of a fibre-reinforced nonlinearly elastic material. One-dimensional fibres are embedded within a base material, which describes contributions from the ECM and cellular components. We varied the volume fraction and stiffness of the ECM in the muscle, as well as the length of the sarcomeres. Changes in the sarcomere length led to changes in the passive force-length properties of the fibres.

To determine the effects of these different parameters on whole muscle stiffness, we conducted passive lengthening simulations. The optimal length for the sarcomeres was increased relative to healthy muscle tissue by up to 75% ( $c_{sarco}$ ). The ECM volume fraction was varied between 2% and 60% of the muscle volume, and the ECM stiffness was increased and decreased by 33% of the stiffness for healthy muscle.

## Results and Discussion

Our results showed that the nonlinear behaviour of the ECM resulted in larger contributions of the ECM to muscle stiffness at longer lengths. The sarcomere length, however, had less effect on the muscle stiffness at longer lengths (Figure 1),

which agrees with experimental findings that fibres contribute less than ECM to muscle stiffness [1]. Additionally, increases in the sarcomere passive stiffness strictly in the along-fibre direction decreased the stretch that occurred transverse to the muscle fibres. This demonstrates that the three-dimensional behaviour of muscle can be influenced by changes occurring in the muscle fibres only. Using this model we have been able to investigate the individual effects from microstructural components that can vary due to CP and develop a deeper understanding of how changes to these components may affect the muscle stiffness in patients with CP.

**Figure 1:** Plot of force normalized by maximum isometric force ( $\hat{F}$ ) against length normalized by optimal length ( $\hat{l}$ ), which demonstrates the effect of the shift ( $c_{sarco}$ ) in the sarcomere force-length relationship on whole muscle mechanics.

## Conclusions

Using our modelling approach, we were able to isolate the role of individual microstructural components in whole muscle mechanics in a way that is not possible experimentally. We found that changes in ECM properties have a greater impact on whole muscle stiffness than increases in sarcomere length. These results provide insight into the microstructural mechanisms that underlie increased whole muscle stiffness in CP.

### Summary

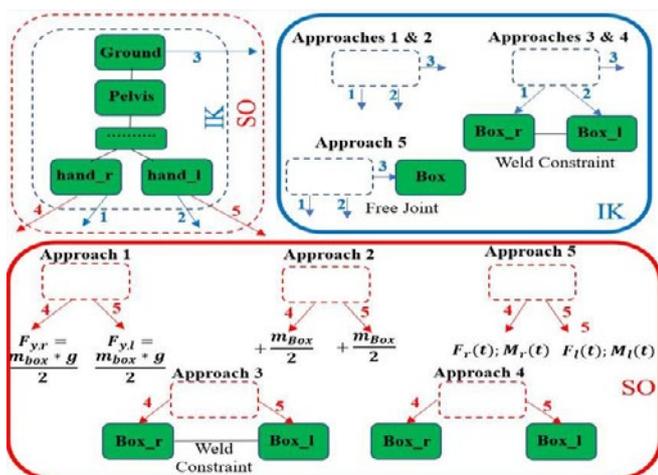

Appropriately modelling the interaction between the hands and external loads in OpenSim simulations of lifting is a difficult yet important problem. In this work, we introduce and compare five approaches of varying complexity. Approaches 1 and 2 have been employed in previously published research; Approaches 3–5 were developed as part of the current work. These modelling approaches were tested using a two-handed lifting scenario. We demonstrate that the modelling approach may result in considerably different spinal forces and, thus, must be chosen carefully in computational studies of lifting.

### Introduction

Musculoskeletal models are commonly used to estimate spinal loads using Static Optimization (SO) [1]. The external load contact forces and moments (LCF&M) acting on the hands have a substantial effect on the results of SO during lifting tasks. LCF&M are often oversimplified in computational studies of lifting and the effect of various LCF&M modelling approaches on spinal loads has not been investigated. This study explores five approaches to model LCF&M in OpenSim [2] and evaluates the effect of these modelling approaches on the predicted spinal loads for one participant during two-handed lifting tasks.

### Methods

**Experiment:** One male participant (20 yr, 185 cm, 73.9 kg) performed various symmetric stoop and squat lifting/lowering tasks with different speeds of movement and different loads in the hands. Marker data were collected for the participant and the load (Box) at 120 Hz using 10 Vicon Vantage V5 cameras. Motion cycles were cropped to begin and end when the load lifted off and returned to the floor, respectively.

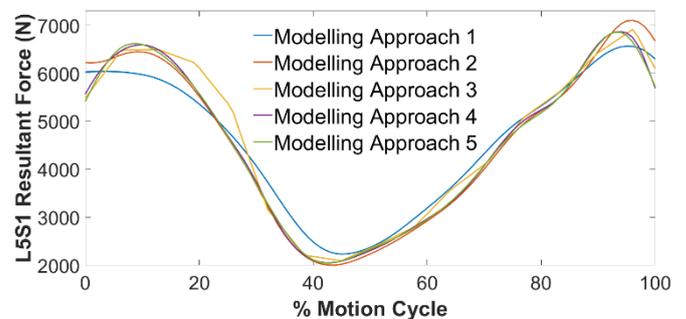

**Figure 1.** Topology of the model. Blue and red borders indicate the methods used for inverse kinematics (IK) and static optimization (SO) calculations, respectively. Green denotes OpenSim bodies.

**LCF&M Modelling Approaches:** Although the validated spine model from Bruno et al. [3] was used in this study, the presented LCF&M modelling approaches (Figure 1) are generalizable to other OpenSim lifting models. Approaches 1 and 2 do not consider the box kinematics. In Approach 1, a gravity-oriented half-load was applied to each hand; in Approach 2, the mass of each hand was increased by half of the box mass. In Approaches 3 and 4, a closed kinematic chain was formed for the IK analysis, but for Approach 4, an open-tree structure was used in SO to reduce the computational cost. In Approach 5, the kinematics of the body and box were calculated separately, and LCF&M were calculated as a function of time using an optimization procedure.

### Results and Discussion

During stoop lifting with 20 kg, the maximum difference in the maximum L5/S1 resultant force was found between Approaches 1 and 5 (582 N). When lowering the load, the difference between Approaches 1 and 2 was greater than other approaches (539 N). Modelling Approaches 3–5 suggest that, during lifting, the maximum loads on the spine do not necessarily occur at maximum upper body flexion, which corroborates *in vivo* measurements [4]. However, Approach 1 cannot capture this phenomenon because it does not consider any acceleration of the load. Nevertheless, Approach 1 has been used in many lifting studies due to the ease of application, or because the simulated tasks were static.

**Figure 2.** L5/S1 resultant forces during 20 kg stoop lifting.

### Conclusions

LCF&M modelling approaches alone can substantially affect the estimated spinal loads during lifting tasks in OpenSim models. The comprehensive evaluation of our modelling approaches during stoop and squat, three speeds of movement, and two lifting loads will be presented at the conference.

### Summary

Personalized foot progression angle (FPA) modifications effectively reduce the peak knee adduction moment (KAM), but the long-term efficacy of this intervention for medial knee osteoarthritis (OA) is not known. We conducted a randomized controlled trial comparing personalized FPA modifications to sham gait retraining. After one year, the FPA modification group had a reduced peak KAM, improved medial knee pain, and less cartilage degeneration compared to the sham group, demonstrating that FPA modifications are a promising treatment for medial knee OA.

### Introduction

FPA modifications can reduce the peak KAM, which is related to medial knee OA progression [1]. Personalizing these modifications is important to maximally reduce the KAM [2] and may improve clinical outcomes compared to uniformly-prescribed modifications [3,4]; however, the long-term efficacy of this intervention is unknown. We hypothesized that, compared to sham gait retraining, adopting a personalized FPA modification would improve pain and function, reduce the peak KAM, and slow quantitative MRI metrics of OA progression over one year.

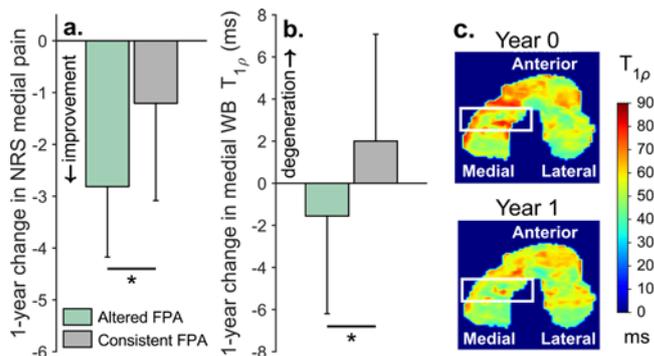

### Methods

Sixty-eight individuals with medial knee OA enrolled in this clinical trial (NCT02767570), and 49 completed it. During an initial gait analysis (year 0), participants walked naturally, then were given vibrotactile feedback instructing them to toe-in and toe-out by 5° and 10° relative to their natural FPA. Participants were randomized into an *altered FPA* group that was trained to walk with the FPA modification that maximally reduced their peak KAM, and a *consistent FPA* (sham) group that was trained to walk more consistently with their natural FPA. During six once-per-week gait retraining visits, participants received biofeedback to learn their target FPA. They were also instructed to walk with this FPA outside of the lab. Refresher gait retraining visits occurred at four, six, nine, and 12 months (year 1) post-enrollment.

MRI scans (3T) were acquired at the year 0 and year 1 visits to measure  $T_{1\rho}$  (TSL=1, 10, 30, 60 ms, FSL=500 Hz) and  $T_2$  (3D qDESS, TE1/TE2=7.54/42.38 ms) relaxation times. The femoral cartilage was segmented and registered between visits, and the average voxelwise changes in  $T_{1\rho}$  and  $T_2$  in the medial weightbearing region were computed. Changes in numeric rating scale (NRS) medial knee pain, WOMAC pain and function, KAM,  $T_{1\rho}$ , and  $T_2$  were compared between year 0 and 1 with a per-protocol analysis using t-tests ( $\alpha=0.05$ ).

### Results and Discussion

The *altered FPA* group's  $5.1\pm 20.1\%$  reduction in peak KAM at year 1 was greater than ( $p=0.003$ ) the  $4.8\pm 11.4\%$  increase in the *consistent FPA* group. The *altered FPA* group also reduced their NRS medial pain by more than the *consistent FPA* group ( $p=0.001$ , Figure 1a); however, there were no significant between-group differences in WOMAC pain ( $p=0.113$ ) or function ( $p=0.274$ ). The reduction in  $T_{1\rho}$  in the *altered* compared to the *consistent FPA* group ( $p=0.013$ , Figure 1b) suggests that offloading the medial compartment slowed or reversed the proteoglycan depletion characteristic of OA progression. There was not a significant between-group difference in  $T_2$  ( $p=0.944$ ).

**Figure 1:** The *altered FPA* group had greater improvements in NRS pain (a) and reductions in  $T_{1\rho}$  in the medial weightbearing (WB) region of the femoral cartilage (b) compared to the *consistent FPA* group ( $*p<0.05$ ).  $T_{1\rho}$  decreased over time in the medial WB region (outlined) of an *altered FPA* subject's femoral cartilage (c).

### Conclusions

For individuals with medial knee OA, personalized FPA modifications reduced joint loading, improved NRS pain, and slowed cartilage degeneration compared to sham gait retraining, but did not significantly improve function. FPA modifications may become an effective tool in the multimodal treatment of medial knee OA.

## Summary

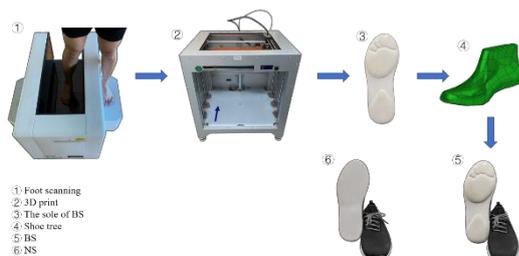

Traditionally, shoes have been used for protecting the foot and providing functional support. Normal footwear that provides stability and support functions for the foot could result in overprotection. Consequences of this may include that overprotection influences and reduces the function of lower limbs.

## Introduction

This study is motivated by an original idea of “Barefoot shoes” which has led to the creation of unstable shoes [1]. After years of evolution, the cuticle of the human foot has gradually degraded, suggesting that the protection and advancement in footwear is still of importance. Based on these necessary factors, we have designed bionic shoes (BS) by combining the functions of barefoot and shoe protection. The objective of this study was to investigate possible differences in the lower limb kinetics and kinematics based on single-leg landing (SLL) when using normal shoes (NS) and BS. We hypothesized that BS will result in higher knee joint angles, compared with NS during a SLL phase.

## Methods

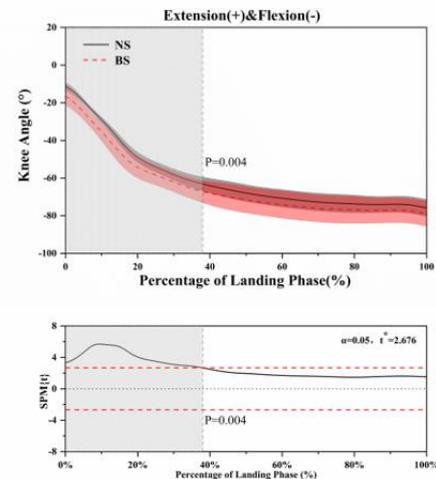

15 male subjects volunteered for the study (Age  $23.4 \pm 1.14$  years, height  $177.6 \pm 4.83$ cm, body weight (BW)  $73.6 \pm 7.02$ kg). There were two kinds of experimental shoes used in the landing experiments to detect the changes in the lower limbs whilst performing the landing task.

**Figure 1:** Illustration of shoe making procedure from initial idea to finished product.

## Results and Discussion

The statistical parametric mapping (SPM) analysis using paired t-tests in figure 2 shows the significant differences between the NS and BS during the SLL phase.

**Figure 2:** shows the kinematic differences using NS and BS in the knee angle. For the knee angle during extension and flexion, significant differences ( $p=0.004$ ) between NS and BS were found during the SLL phase.

The soft landing could increase knee flexion angles and reduce impact forces. This may provide more landing velocities over a longer time period, which could result in decreased anterior cruciate ligament injuries [2]. We can conclude that BS may reduce lower limb injuries in the knee joint when performing a drop SLL from a 40cm height.

## Conclusions

We found that when using BS to perform a SLL phase, the knee flexion angles have bigger flexion angles than those observed using NS.

### Summary

Soft tissue balancing, vital for joint stability following total knee arthroplasty (TKA), is quantified intraoperatively during passive motions; however, postoperative patient satisfaction is based on active functional outcomes. Although our cadaveric study found no correlation between intraoperative joint loads and postoperative joint kinematics, a stark difference in joint load distributions was observed between passive and active tasks, necessitating further research in quantifying postoperative joint stability.

### Introduction

Joint stability is crucial for successful functional outcomes following TKA [1]. While clinical assessment of knee joint laxity typically relies on passive manual tests, like the varus-valgus rotations at multiple flexion angles [2], the goal is to have the desired postoperative joint laxity for active motions, like walking. Soft tissue balancing, vital in TKA to achieve an optimal level of joint laxity, can be quantified intraoperatively by using instrumented tibial inserts [1]. This study aimed at correlating intraoperative joint loads and postoperative joint kinematics during laxity tests and functional tasks.

### Methods

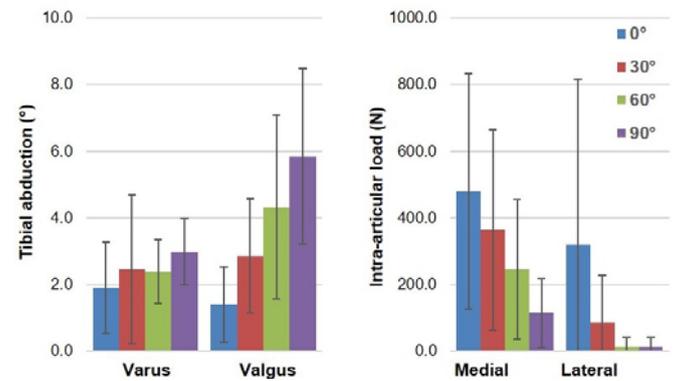

Four recipients of the European Knee Society Travelling Fellowship 2019 visiting our institution were assigned a fresh-frozen lower limb each to plan and perform posterior-stabilised TKA. An instrumented tibial insert (Verasense, Orthosensor, USA) was used to measure intraoperative joint loads at fixed flexion angles (0°-30°-60°-90°). Specimens were then subjected to varus-valgus laxity tests and mounted on a validated knee simulator [3] to perform squatting with actively loaded quadriceps. The instrumented insert captured intra-articular loads, while tibiofemoral kinematics were recorded with an optical motion capture system. The Pearson correlation test was used to assess the relationship between intraoperative intra-articular load and tibial abduction angle during laxity tests for each specimen ( $p < 0.05$ ).

### Results and Discussion

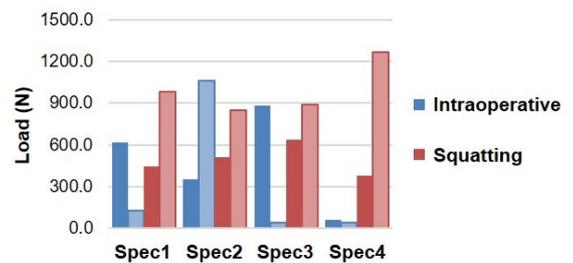

Laxity tests revealed greater stiffness in extension ( $1.7 \pm 1.2^\circ$ ) than in flexion ( $4.4 \pm 2.4^\circ$ ) for a joint moment of 10 Nm (Figure 1). A mean Pearson correlation factor ( $r$ ) of -0.63 was observed between intraoperative intra-articular load and tibial abduction angle during laxity tests ( $r_{\max} = -0.99$ ,  $p < 0.001$ ;  $r_{\min} = -0.07$ ,  $p = 0.35$ ), with statistically significant correlation observed only for one of the four specimens.

Peak intra-articular loads for intraoperative measurements were observed in extension, with the medial load higher than the lateral load for three out of the four specimens; however,

peak loads for active squatting were observed in deep flexion, with lateral loads higher for all specimens (Figure 2).

**Figure 1:** Tibial abduction during laxity tests and intraoperative joint loads at various flexion angles (Mean±SD for four specimens).

**Figure 2:** Peak loads in medial (dark) and lateral (light) compartments measured intraoperatively (blue) and during active squatting (red) for each specimen.

Despite an expected increase in varus-valgus laxity and a corresponding decrease in intra-articular loads with increasing knee flexion, no correlation was observed between the two parameters. However, intra-articular load distribution during active squatting was starkly different from the passive condition, which must be considered when assessing postoperative joint stability. A limitation of the study was that the instrumented tibial inserts were commercially calibrated only until 310N.

### Conclusions

Intraoperative joint loads and postoperative laxity kinematics were not correlated, despite following expected trends. However, the discrepancy in joint loading during passive and active motions necessitates further research to associate joint stability to intra-articular loads during functional motions.

### Summary

This study proposes a new method for the definition of anatomical reference system (ARS) for the bones of foot and ankle based on morphological and functional criteria, meant for the 3D description of the foot posture. The method shows high inter- and intra-operator precision ( $<1^\circ$  and  $<1\text{mm}$ ), providing a 3D characterization of the foot arches, which agrees with standard planar measures. Clinically sound ARS are needed to fully exploit the recent advances in the 3D description of the foot posture made possible by weight-bearing CT.

### Introduction

Establishing ARS is fundamental to report and compare measurements in clinically relevant terms [1]. So far, foot posture has been assessed radiographically [2], where only planar measures are possible, while foot motion has been investigated through gait analysis, defining ARS by external palpation of anatomical landmarks and grouping bones in rigid segments [3]. Three-dimensional scanning techniques opened the way for a deeper investigation of the foot architecture: in recent fluoroscopic studies, ARS were proposed for the hindfoot based on bone morphology [4]. A thorough definition of ARS for each bone in the foot and ankle complex is however still missing, yet necessary to fully exploit the potentiality presented by 3D investigations. Principal inertial axes may be used [5], but their clinical interpretation is often difficult. Aiming at the description of both posture and kinematics of the foot and ankle, we propose a CT-based morphological approach for the definition of ARS for every bone in the complex. To show its effectiveness, the approach is used to compare the medial-longitudinal and the transverse arches in healthy and flat feet. Inter- and intra-operator sensitivity is also addressed.

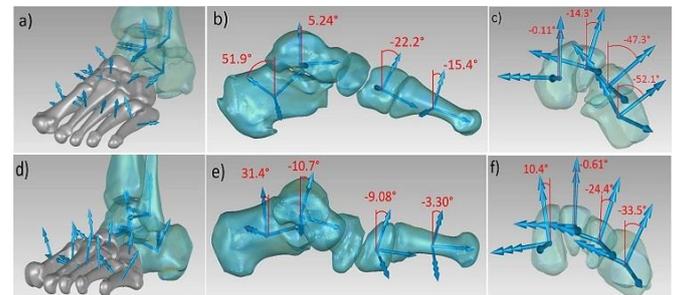

### Methods

We analyzed one healthy foot and one flatfoot. These were scanned in a Weight-Bearing CT. The 3D models of all the foot bones were reconstructed by a semi-automatic segmentation process (DICE  $> 95\%$ ). To define ARS, overall bone and joint geometry was analyzed. For the talus: z axis coincides with the axis of a truncated cone, fitted on the surface articulating with the tibia, pointing laterally; origin O is the mid-point of the cone height; x axis is the projection on the plane normal to z of the vector from O to the center of a sphere fitting the talar head, pointing anteriorly; y axis is computed accordingly. For the intermediate cuneiform: origin O is the bone centroid; x axis is the mean of the normals of plains fitting surfaces articulating with scaphoid and first metatarsus, pointing anteriorly; z axis is the mean of the normals of plains

fitting surfaces articulating with medial and lateral cuneiform, pointing laterally; y axis is computed accordingly. For the sake of conciseness, the remaining ARS are only depicted graphically (fig 1). ARS were defined three times by the same operator and once by three different operators to assess the robustness of the procedure. To describe the arches, angles were extracted from the ARS orientation using a variation of the Grood & Suntay notation (cardan sequence: z-y-x). The medial longitudinal arch is defined by the flexion angle of calcaneus, talus, medial cuneiform and first metatarsus. The transverse arch is defined by the abduction angle of medial, intermedial, lateral cuneiform and cuboid.

### Results and Discussion

The anatomical reference systems for each bone are shown in fig. 1. The inter- and intra-operator mean precision was  $0.67^\circ \pm 0.72^\circ$  and  $0.57^\circ \pm 0.82^\circ$  for rotations, and  $0.59 \pm 1.09$  and  $0.33 \pm 0.77$  mm for the translations, respectively. The proposed ARS make it possible to describe and distinguish among healthy and pathological arches (fig. 1). If the Djian-Annonier angle is computed from the proposed ARS, the amplitude of the medial longitudinal arch is  $112.7^\circ$  and  $145.7^\circ$ . Values are in line with the literature [6].

**Figure 1:** Healthy (a-c) and flat (d-e) foot. a) d) representation of the reference systems for each bone. b) e) bone angles across medial longitudinal arch. c) f) bone angles across transverse arch.

### Conclusions

The proposed ARS provide a valuable clinical description and a basis for further 3D characterization of the foot and ankle complex behavior.

### Summary

Playing-related musculoskeletal disorders (PRMD) are very common among musicians with a higher prevalence in the group of high string players (violin and viola). A commonly suggested risk factor for these injuries includes asymmetrical playing as well as muscle fatigue.

Fifteen musicians (7 with and 8 without PRMD) went through a standardized protocol that examined the influence of muscle fatigue on muscle activity patterns between and within these groups by means of surface electromyography.

Changes in muscle activity patterns were observed between and within both groups, however these changes varied significantly depending on group affiliation. In addition, the overall muscles of the right arm and the left forearm muscles showed different fatigue behavior, with the PRMD group showing stronger signs of muscular fatigue.

Based on these results, it may be possible to identify compensatory or inefficient muscle activity patterns. This can support the development of targeted management strategies.

### Introduction

Instrumentalists are exposed to numerous risk factors that can cause a PRMD [1]. Different loads during music playing can lead to an overload of the neuromusculoskeletal system. High string musicians (violin/viola) are particularly vulnerable to this due to their asymmetrical playing style. This leads to an unphysiological stress, particularly in the area of the upper extremities. The consequence can be a modification of muscle activity patterns during music performance.

The aim of this study was to investigate whether changes occur in muscle activity patterns and fatigue behavior during high string performance over a prolonged playing period, and whether this is influenced by a PRMD.

### Methods

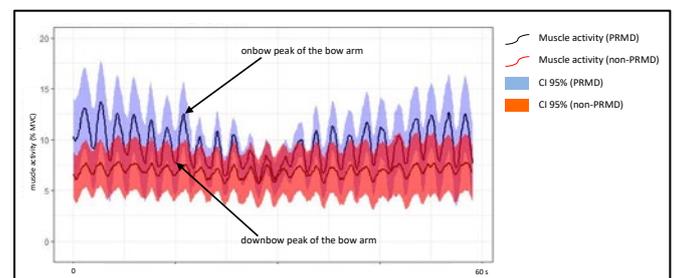

Fifteen professional or university high string musicians were recruited and then divided into a PRMD (n=7) and a non-PRMD (n=8) group. All musicians played a chromatic scale, then an individual “hard” or “heavy” piece of music for one hour, followed by a repeat of the chromatic scale. Surface electromyography (sEMG) data were recorded from 16 muscles of the arm, shoulder and trunk on both sides of the body. Primary outcome was the muscle activity measured by sEMG. Two parameters were collected, (1) the percentage of muscle activity in relation to the respective maximum strength during the time course of the chromatic scales and (2) the low frequency spectrum during the one-hour playing. Differences between and within groups as well as the low

frequency spectrum were analyzed using linear mixed models.

### Results and Discussion

Changes in muscle activity patterns were observed between the beginning and the end of the trial, however these changes varied significantly depending on whether the musicians were suffering PRMDs or were without PRMDs (fig. 1). In addition, low frequency spectrum changes were observed in the overall muscles of the right arm (p=.04) and the left forearm flexors (p=.05) following the one hour of playing in musicians with a PRMD, compared to those without a PRMD, consistent with signs of muscle fatigue.

These results are consistent with other studies that describe a modification of muscle activity [2]. A possible explanation for this modification is a redistribution of muscle activity because of pain or movement inhibition to protect the neuromusculoskeletal system [3]. The sEMG analysis strategy used in this study proved to be a suitable tool for a detailed analysis of muscle activity and provides information on differences in muscle activity between musicians with and without PRMD.

**Figure 1:** Example of changes in muscle activity pattern. Muscle activity of the right lower trapezius over time during the chromatic scale pretest. Mean muscle activity of each group including the corresponding 95% CI (shaded regions).

### Conclusions

Differences of muscle activity appear between high string musicians with and without PRMD. Based on these results, it may be possible to identify compensatory or inefficient muscle activity patterns. This can support the development of targeted management strategies for high string musicians.

## ACL injury prevention in high knee flexion conditions: a new musculoskeletal model

D. Pavan<sup>1</sup>, S. Van Rossom<sup>2</sup>, H. Hoang<sup>2</sup>, I. Jonkers<sup>2</sup>, Z. Sawacha<sup>1,3</sup>

<sup>1</sup>University of Padua, Dept. of Information Engineering, Italy;

<sup>2</sup>KU Leuven, Dept. of Movement Sciences, Belgium; <sup>3</sup>University of Padua, Dept. of Medicine, Italy

Email: all.pavandavide@federugby.it

### Summary

Epidemiological studies underline high anterior cruciate ligament (ACL) injury and reinjury rates.

Although gait analysis has already identified biomechanical variables strongly related with ACL ruptures, a demanding task is likely to be needed to investigate knee biomechanics in trained athletes.

The present contribution addresses ACL injury prevention through musculoskeletal modelling (MSM), with a dedicated model developed for high knee flexion tasks, having enhanced degrees of freedom (DOFs) at the knee and ligaments.

### Introduction

ACL injuries are instantly disabling and in the majority of cases will require surgery and long rehabilitations; moreover, reinjury has a higher occurrence rate than first ACL injury [1].

MSM implements experimental measurements with estimates of important variables, as muscle and joint forces, and could be applied focusing on ACL injury prevention [2]. Among the available musculoskeletal models, one with enhanced knee DOFs and ligaments [3], and one specifically developed for the squatting task [4] have been identified, along with the one developed by Delp [5]. The aim of the present work is to develop a knee model which overcomes the limitations of the currently available ones, in simulating the knee biomechanics during deep flexion tasks for ACL injury prevention purposes.

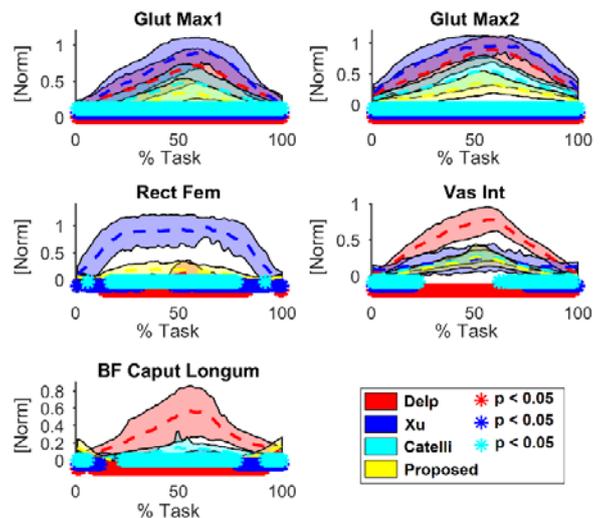

### Methods

Ten healthy athletes were recruited (mean±SD; age=25,6±1,5 years; BMI=21,7±2,4 Kg/m<sup>2</sup>). Each participant performed three repeated monopodal squats: reflective markers were placed as in [6] and data were acquired by means of 3D stereophotogrammetry (BTS Smart-E, 6 cameras, 60 Hz) and 1 force plate (Bertec FP6040, 960 Hz); an electromyography system (BTS Free1000, 8 channels, 1000 Hz) recorded the activation of: Rectus Femoris, Biceps Femoris Caput Longus, Tibialis Anterior, Gastrocnemius Lateralis. MOTO-NMS [7] and OpenSim [8] were adopted, and scaling, inverse kinematics, inverse dynamics, and static optimization (SO) computed. Experimental EMG envelope peak occurrence within the task were compared with the related SO outcome (Wilcoxon signed-rank,  $\alpha=0.05$ ) for validation purposes as in [6]. A new knee model was developed, with enhanced knee DOFs and ligaments repositioned based on published cadaveric geometries [9]. Data were further processed according to [3-5] and results of each simulation compared with the model proposed herein (rm-ANOVA, Tukey post-hoc,  $\alpha=0.05$ ).

### Results and Discussion

Results showed differences (Fig.1) mainly associated to the number of knee DOFs (i.e. [4,5] vs the one proposed and [3]).

Xu model showed task-related issues, while Delp, Catelli and the current model showed good compliance with the squat task, even though the models reported in [4,5] have limited DOFs at the knee and no ligaments.

**Figure 1:** Gluteus maximus 1, Gluteus maximus 2, Rectus femoris, Vastus intermedius, and Biceps femoris caput longum normalized activations. Models: Delp, Xu, Catelli, proposed. Significant differences are flagged referring to the proposed model comparison with the model relative to the flag color in the legend.

### Conclusions

The current study allowed comparing the performances of different knee models in critical conditions, providing further insights on the knee biomechanics during the squat task. The former could be adopted for ACL injury risk evaluation, to better inform the clinical decisions making and to aid in planning prevention and post-rehabilitation return on field programs.

### Summary

Ankle Foot Orthoses (AFO) improve foot clearance in the swing phase of walking in patients suffering from drop-foot. While standard-size off-the-shelf AFOs are normally suitable to support the foot and ankle, patients with concomitant morphological and postural alterations of the foot and lower limb need custom solutions. In this study, a dynamic custom AFO made of fiber-glass reinforced polyamide was designed according to the 3D shape of the leg and foot and manufactures via Selective Laser Sintering (SLS). An original setup replicating natural ankle plantar/dorsiflexion and Finite Element Analysis (FEA) were used to assess AFO mechanical properties and material stress levels during physiological deformations. Functional evaluation was performed via gait analysis on a small cohort of drop-foot patients. While confirmation on a larger population of drop-foot patients is required, the custom AFOs resulted in improved gait parameters and more comfortable than off-the-shelf orthoses.

### Introduction

Dynamic AFOs can be prescribed to address a deficit of the main ankle dorsiflexor muscles in drop-foot patients, mostly due to neuromuscular pathologies. 3D scanning devices and additive manufacturing technology have been shown to allow designing and production of custom AFOs with improved fit and comfort [1, 2]. This study reports design principles, analysis of the mechanical properties, and functional evaluation in a small cohort of drop-foot patients, of a novel dynamic custom AFO manufactured via SLS of fiber-glass reinforced polyamide powder. The AFO aims at supporting the foot, correcting for foot postural alterations and providing better comfort with respect to standard off-the-shelf orthoses.

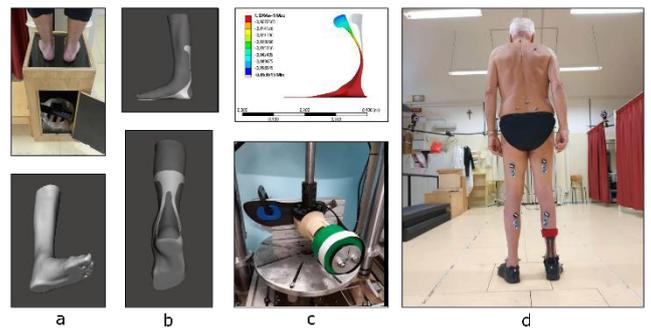

### Methods

Two patients (67 years, 83 kg, 1.80 m; 80 years, 96 kg, 1.95 m) suffering from drop-foot due to lumbar disc herniation and spine surgery volunteered in the study. The patients' foot and lower limb were scanned in bipedal upright posture using a Kinect-based 3D scanner (fig. 1a) [3]. Custom AFOs were designed in Blender (fig. 1b) (Blender Foundation, Amsterdam), and manufactured via SLS of fiber-glass reinforced polyamide powder (Windform GT®, CRP Technology, Modena). AFOs were tested for mechanical properties using an ad-hoc setup replicating the AFO deformation during the stance phase of walking (fig. 1c, bottom). FEA was used to assess stresses in the regions subjected to the larger deformations under the same boundary conditions (fig. 1c, top). Functional evaluation was performed using the IOR-gait lower limb protocol

[4] in three conditions (fig. 1d): 1) without the AFO; 2) wearing the custom AFO, and 3) wearing a standard off-the-shelf AFO in polyethylene (Molla di Codivilla, Ottobock). The perceived comfort was scored via a 0-10 VAS scale.

### Results and Discussion

The subjects walked at faster speed and with increased stride length wearing the custom AFO ( $0.91 \pm 0.04$  m/s;  $1.22 \pm 0.03$  m) with respect to both the Codivilla ( $0.85 \pm 0.03$  m/s;  $1.17 \pm 0.03$  m) and the no-AFO ( $0.67 \pm 0.01$  m/s;  $1.09 \pm 0.02$  m) conditions. The ankle maximum dorsiflexion in the swing phase was larger while wearing the custom AFO ( $-16.9 \pm 0.3$  deg) with respect to the no-AFO condition ( $-33.4 \pm 0.4$  deg). The custom AFO resulted overall more comfortable than the Codivilla (9.7 vs. 7.3). Moreover, it scored higher in the shank support (9.6 vs. 7.5), in the plantar aspect (9.8 vs. 3.5) and in the perceived elastic return (9.7 vs. 6.9).

**Figure 1:** a) Leg and foot scan via Kinect-based sensor; b) design of the custom AFO via Blender; c) FEA of the AFO subjected to 15 deg ankle dorsiflexion (top), and corresponding bench-testing (bottom); d) functional evaluation via gait-analysis of one patient.

### Conclusions

While confirmation on a larger population of drop-foot patients is required, this pilot study has shown that custom AFOs may be used to improve patients' gait and comfort with respect to standard off-the-shelf orthoses. Further customization of the mechanical properties with respect to subject-specific functional impairments and physical demand should be sought.

# EFFECTS OF TAI CHI EXERCISE ON POSTURAL STABILITY AMONG THE ELDERLY DURING STAIR DESCENT UNDER DIFFERENT LEVELS OF ILLUMINATION

Yaya Pang<sup>1</sup>, Li Li<sup>2</sup>, Qipeng Song<sup>1</sup>

<sup>1</sup>College of Sports and Health, Shandong Sport University, Jinan, China

<sup>2</sup>Department of Health Sciences and Kinesiology, Georgia Southern University, Statesboro, 30460, USA

Corresponding author: Dr. Qipeng Song, songqipeng@sdpei.edu.cn

## Summary

The elderly prone to stair descent falls under low illumination. Tai Chi, a traditional Chinese conditioning exercise, has been proved to improve postural stability by altering movement pattern, gait, and proprioception. This study investigates whether Tai Chi exercise could improve postural stability during stair descent under high and low illumination. Three groups of elderly women who practice Tai Chi, brisk walking, and no exercise were included. They descended from a simulated staircase. Decreased horizontal velocity, center of mass (COM) sway, and increased foot clearance were observed among the Tai Chi group, compared with other groups. Compared with under high illumination, Tai Chi participants decreased horizontal velocity, loading rate, braking impulse, and increased inclination angle COM sway, center of pressure displacement under low illumination. Tai Chi participants were more sensitive to the difference in illumination and took corresponding strategies to stabilize their bodies during stair descent.

## Introduction

Recent reports have identified that stair gait falls account for 26% of all self-reported falls [1] and have become the leading cause of accidental death for the elderly [3]. Stair descent imposes significant challenges to movement control in people of all ages [2], but especially to the elderly due to the functional decline in many of their physiologic systems. Tai Chi is a traditional Chinese conditioning exercise. It has been proved that Tai Chi could improve postural stability in the elderly by altering their movement pattern, gait, and proprioception [4,5]. A kind of exercise that could improve postural stability in the elderly during high-risk activities, such as stair descent under low illumination, remains unclear.

## Methods

Three groups of elderly women who practice Tai Chi (TC), brisk walking (BW), and no exercise (NE) were included. Each participant was asked to complete one testing session per day for a total of three testing sessions. In each session, the participants were asked to descend the staircase step over step under different illumination conditions. A simulated staircase with six steps was constructed for data collection in this study. Two force plates (KISTLER, 9287BA and 9281CA, Switzerland) were embedded in the third and fourth steps, to collect ground reaction force data at a sample rate of 1000 Hz. The stair descent test was recorded (100 Hz) by an eight-camera motion analysis system (Vicon, Oxford Metric, England). Descriptive analysis was conducted with the mean and

standard deviations for both kinematic and kinetic variables. Subgroup comparisons were assessed via respective 95% confidence intervals of mean difference. The confidence interval of mean difference values between groups was calculated by using the one-way ANOVA post hoc pairwise comparison with Bonferroni adjustment. The confidence interval of mean difference values between two illumination levels was calculated by using paired-sample t-test.

## Results and Discussion

Horizontal velocity was lower in TC group compared with BW group (95% CI: -125.09 to 3.46) and decreased under low illumination in TC (95% CI: 15.23-105.07) and BW groups (95% CI:54.22-99.78). TC group had a greater foot clearance than BW (95%CI: 24.96-45.41) and NE (95% CI: 3.39-38.93). There were no significant group differences for head and trunk inclination angles. Under low illumination, the TC group had a higher head inclination angle (95% CI: -8.03 to -1.32), whereas BW and NE groups had higher trunk inclination angles (95% CI: -4.38 to -0.99; -4.06 to -1.47, respectively). TC group had a smaller COM<sub>ml</sub> Sway than walking (95% CI: -19.32 to 0.31) and no exercise participants (95% CI: -23.97 to -3.59). All the three groups increased their COM<sub>ml</sub> Sway (95% CI: -15.26 to -5.87, -18.15 to -4.32, -11.08 to -2.19, respectively) under low illumination. TC group had a lower loading rate than the BW group (95% CI: -5.75 to -0.02). Under low illumination, TC group decreased their loading rate (95% CI: 0.86-4.34), braking impulse (95% CI: 0.001-0.005), and increased their COP<sub>ap</sub> (95% CI: -92.76 to -2.82) and COP<sub>ml</sub>(95% CI: -26.50 to -3.47). Under low illumination, BW group increased their COP<sub>ml</sub> (95% CI: -34.07 to -2.08).

## Conclusions

TC group adjusted their movement pattern to increase postural stability during stair descent. Furthermore, the TC group were more sensitive to the difference in illumination and took corresponding strategies to stabilize their bodies during stair descent.

<sup>2</sup>Faculty of Engineering, Kiel University, Kiel, Germany

Email: e.warmerdam@neurologie.uni-kiel.de

## Summary

Arm swing has a high clinical relevance, especially in patients with idiopathic Parkinson's disease. This study developed an accurate inertial measurement unit-based algorithm to quantify arm swing during walking of healthy adults and patients with idiopathic Parkinson's disease. The algorithm was sensitive enough to detect differences between healthy older adults and patients with idiopathic Parkinson's disease, and can be applied to both clinical and daily-living data.

## Introduction

A swinging motion of the arms characterizes gait. A reduction or asymmetry in the swinging motion is often seen in patients with idiopathic Parkinson disease (IPD) and could be a potential prodromal and progression marker of IPD, highlighting the need of an accurate assessment tool. The aim of this study was to develop and validate an algorithm that quantifies arm swing during walking that can be used in both clinical and daily-living environments.

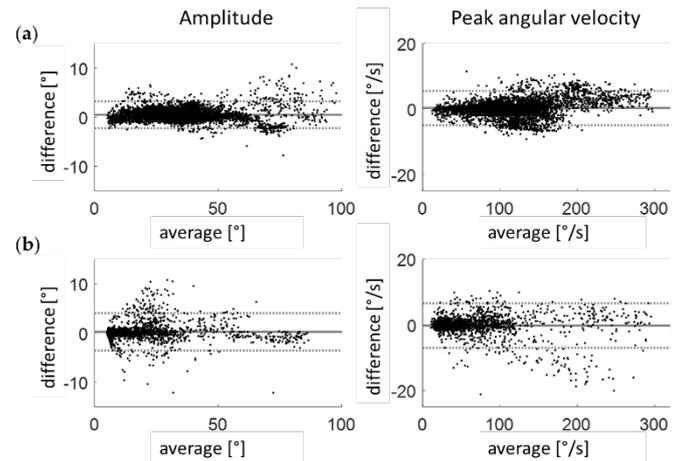

## Methods

Walking data were collected during treadmill walking from 15 healthy participants and 13 patients with IPD. An inertial measurement unit (IMU) and a marker cluster measured with an optical motion capture system were attached to the wrists of the participants. From the gyroscope data of the IMU, main amplitude, peak angular velocity, sideways amplitude, regularity, coordination and asymmetry of arm swing were calculated. A principal component analysis was performed to calculate the parameters in the main swing direction and make the algorithm robust to different wearing locations on the forearm. The peaks in the first principal component were detected to obtain the peak angular velocity. The data was then integrated and filtered with a moving average filter to obtain the angle which was used for the calculation of the amplitude. The regularity of the arm swing was calculated based on the autocorrelation of the angular velocity. The coordination between the left and right arm was based on a normalized cross-correlation. The asymmetry between both arms was extracted from the average arm swing amplitude of each arm. The angle and angular velocity were also calculated from the optical motion capture data to validate the arm swing parameters from the algorithm.

## Results and Discussion

A Bland-Altman analysis was performed for the comparison between the IMU-derived and optical-derived data (Figure 1). The analysis resulted in small errors (Table 1). The comparison of the IMU-derived parameters between the two

groups even showed that differences between healthy adults and patients with IPD can be detected with the algorithm. This all makes the algorithm a valid and accurate tool to quantify arm swing during walking. In combination with a gait detection algorithm it could also be used to analyse daily-living data.

**Figure 1:** Bland-Altman plots with the arm swing amplitude and peak angular velocity for the healthy adults (a) and patients with IPD (b). On the x-axis the average of the IMU and optical results and on the y-axis the IMU minus the optical results.

**Table 1:** Error measures of IMU-derived arm swing data, compared to optical system-derived data.

		Healthy adults	Patients with IPD
Amplitude [°]	Systematic error	0.5	0.2
	Random error	2.7	3.8
	Absolute error	1.1	1.1
Peak angular velocity [°/s]	Systematic error	0.3	-0.3
	Random error	5.3	6.8
	Absolute error	1.9	2.0

## Conclusions

An accurate arm swing algorithm was developed for both healthy adults and patients with IPD.

# One-shot learning for personalized golf swing monitoring to overcome motion variability between users

Myeongsu Kim<sup>1</sup>, Jung Kim<sup>1</sup>, Suhyung Park<sup>1</sup>

<sup>1</sup> Dept. Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea

Email: [myeongsu@kaist.ac.kr](mailto:myeongsu@kaist.ac.kr)

## Summary

During motion monitoring with wearable devices, some users suffer from low estimation accuracy according to the motion variability between users. In the previous study about golf swing segmentation using an inertial measurement unit (IMU), one out of 20 skilled golfers revealed an exceptionally large estimation error. To overcome this, we personalized the segmentation algorithm with one-shot learning using the user's single swing sample. One-shot learned convolutional neural network (CNN) reduced the estimation error more than four times compared to the simple fine-tuning method. One-shot learning overcame the motion variability between users by adapting the golf swing segmentation model using a single motion sample from the new user and personalized the motion monitoring algorithm.

## Introduction

Motion monitoring using wearable devices is widely applied and getting more attention in daily activities, sports, and clinical fields. Since the variability in the human body's movement appears due to individual characteristics, the accuracy of the estimated motion metrics to be monitored may decrease depending on the users. In the golf swing segmentation study using IMU, one out of 20 skilled golfers revealed an exceptionally large segmentation error for the address point [1]. However, building a vast motion dataset to learn and overcome a wide range of motion variability is time-consuming and expensive.

Meta-learning, or learning to learn, trains a model on various learning tasks to solve new learning tasks using only a few training samples [2]. If the individual users are considered as the learning tasks of the meta-learning, the motion variability might be overcome by adapting the model with a few motion samples of the new user. If only one training sample is used to adapt the model, it is called one-shot learning.

Therefore, in this study, we proposed a personalized golf swing monitoring using one-shot learning to overcome motion variability between users.

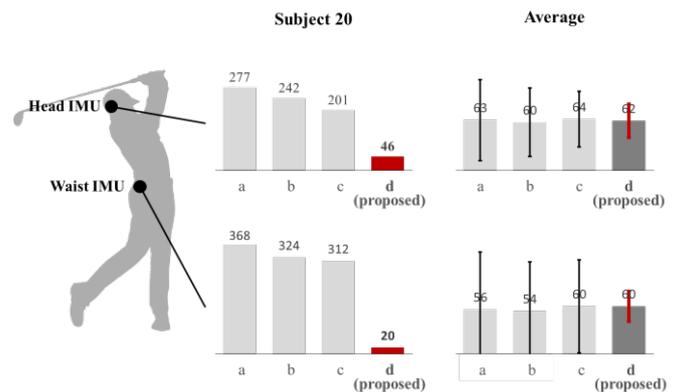

## Methods

To verify that one-shot learning can personalize the model, we applied the method to the CNN, which segments golf swing phases from 6-axis IMUs attached to body parts [1]. The comparison was carried out between the following four models: a) CNN from Kim and Park [1], b) reproduced version of model a, c) fine-tuned from model b with one training sample of a new user, d) one-shot learning, or adapted to one training sample of a new user after meta-learning, applied to model b.

A total of 389 swing samples [1] from 20 skilled golfers with drivers and 7-irons were used. Subject 20, who revealed an exceptionally large segmentation error of the address point, was set as a new user (task). The one-shot learning algorithm was built based on ANIL [3], which simplified the inner loop of MAML [2] to offers computational improvements. Training and calculations were performed in Python 3.8.5 and PyTorch 1.7.1 environments.

## Results

As a result of applying four models to subject 20, model d with one-shot learning demonstrated extremely smaller estimation errors of an average of 46 ms and 20 ms from the head and waist IMU, respectively, compared to all other models, including fine-tuned model c (Figure 1). As a result of applying four models to each of all 20 subjects, the standard deviation of the errors between subjects with model d significantly decreased compared to the reproduced model b from  $60 \pm 43$  ms to  $62 \pm 21$  ms using the head IMU, and from  $54 \pm 62$  ms to  $60 \pm 19$  ms using the waist IMU.

**Figure 1:** Comparing segmentation errors (ms) of the address point during golf swing between model a, b, c, and d (proposed).

## Conclusions

One-shot learning can personalize motion monitoring algorithms to overcome the motion variability between users by adapting them to individual users with various motion characteristics.

# Identifying the Objective of Human Behavior using Inverse Reinforcement Learning: A Case of Human Postural Control

SeongWoong Hong<sup>1</sup>, Jung Kim<sup>1</sup> and Sukyung Park<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea  
Email: sukyungp@kaist.ac.kr

## Summary

Finding the objective of the human behavior can provide useful insight into the motion, but selecting the form of the objective function highly depends on the investigator's intuition. Inverse Reinforcement Learning can be a solution to learn the objective function directly from the behavior observation. Hence, we apply IRL to learn the objective of human behavior from its observation. The reference observations are created with a similar controller to the human postural control. This IRL architecture learns the reference objective function successfully. In the future, it could be extended to learn the objective of real human behaviors.

## Introduction

When analyzing a specific behavior, an objective can provide valuable insight into that behavior. Some human behaviors could be represented by an optimized behavior of objective function by the CNS, and the behaviors could be successfully understood by that objective. However, the investigator should select the form of the objective function through their intuition to represent the objective of the behavior. Therefore, we suggest the architecture that could learn the objective from the observation of the behavior that does not depend on the investigators' intuition.

Inverse Reinforcement Learning (IRL) is used to find the objective of the behavior that was assumed as near-optimal of the objective [1]. Therefore, we try to find the objective assuming that human behavior is near-optimal according to the objective. In this study, we apply this architecture to known behavior before applying it to human behavior, and we successfully learned the objective through this architecture.

## Methods

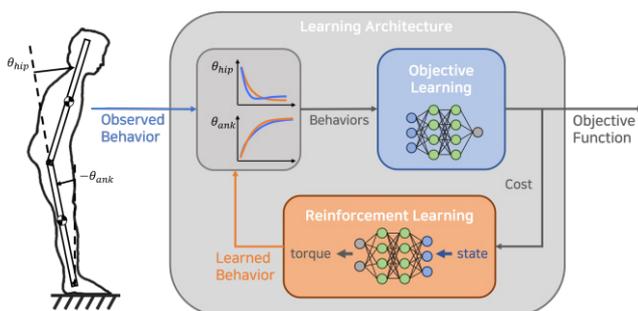

Figure 1: Overall architecture for learning the objective function

The target behaviors are produced to follow the Linear-Quadratic Regulator (LQR) objective which well describes the human postural control [2]. When the behavior follows the objective near-optimally, the observation can be assumed as a sample from the probability distribution according to the objective function value. The probability distribution is

modeled as (Eq. 1). The objective function and control policy are each updated iteratively to maximize the likelihood of the probability distribution over the observed behavior and to minimize the expected objective and the entropy of the policy [1]. Proximal Policy Optimization [3] is used to optimizing this control policy update rule.

$$p(\tau) = \frac{1}{Z} \exp(-c_{\theta}(\tau)) \quad (\text{Eq. 1})$$

The target behavior follows the noisy PD controller that optimizes randomly selected LQR objective function and have a gain noise that follow the gaussian  $0.25 \times N(0, I)$ . The simulator for learning control policy is modeled as 2-segment uniform inverted pendulum both have 5kg mass and 1m length.

## Results and Discussion

We compared the control policy following the learned objective and the reference control policy for the randomly selected initial point (Fig. 2).

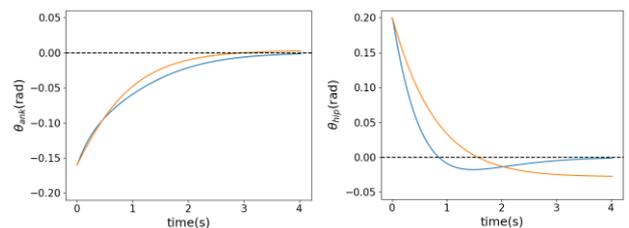

Figure 2: Each joint angles that follow the reference policy(blue) and learned policy(orange)

The learned control policy showed similar behavior to the reference motion for various initial states other than the selected one. Through this, we concluded that the objective was learned well.

## Conclusions

The objective could be learned directly from the observation without the intuition about the form of the objective. This architecture reproduces the objective without information about the objective so it may learn more complex behavior's objective. In the future, it could be extended to learn the objective of human behaviors.

Email: weronikajoanna.piatkowska@studenti.unipd.it

## Summary

Fragile X Syndrome (FXS) is a genetic condition, mainly characterized by intellectual disability, behavioral problems and musculoskeletal alterations. Somatic mosaicism for pre and full mutation, can be a strong phenotype modulator of the FXS clinical manifestations [1]. Therefore the aim of the present contribution was to develop a gait analysis driven classification of FXS children with classical full mutation of the FMR1 gene (FX-FM) and the ones who carried a full mutation with mosaicism (FX-M). Different supervised classification techniques were applied to a set of kinematic and sEMG data and the dataset who could better discriminate between the two populations of subjects was investigated. By including only sEMG parameters a better classification with 90,9 % of performance was provided.

## Introduction

FXS is the leading form of inherited intellectual disability and autism spectrum disorder, caused by a tri-nucleotide CGG repeat expansion in the promoter region of the FMR1 gene [1]. Somatic mosaicism for pre and full mutation can be a strong phenotype modulator of the FXS clinical manifestations [1]. In FXS subjects musculoskeletal manifestations [1] justify a referral for gait analysis.

Supervised classification is used to determine the relation between a set of input parameters and a target variable[2]. In this contest it was driven by gait analysis parameters and adopted in order to distinguish between FX-FM and FX-M.

## Methods

After appropriate informed consent by the parents, 12 FX-FM children (mean  $\pm$ SD age 10,69 $\pm$ 3,67 years and BMI 18,82 $\pm$ 4,09 Kg/m<sup>2</sup>) and 5 FX-M children (mean  $\pm$ SD age 9,00 $\pm$ 3,35 years and 18,70 $\pm$ 2,34 BMI Kg/m<sup>2</sup>), were evaluated at the BiomovLab and at the Women and Children Health Department (University of Padua). Kinematics and sEMG data were simultaneously acquired through 4 synchronized cameras (GoPro Hero3, 30fps) and an sEMG system (8 channels FreeEmg, BTS, 1000Hz) that collected the activity of Tibialis Anterior (TA), Gastrocnemius Lateralis (GL), Rectus Femoris (RF) and Biceps Femoris (BF). Each subject performed several gait trials and at least three trials per subject were processed. The following sEMG parameters were extracted: duration of muscle contraction, onset and offset activation timing [3], peak of the envelope and its occurrence [4] and number of co-contractions and their occurrence. The following kinematic parameters were estimated: minimum and maximum hip, knee and ankle joints angles, their range of motion (ROM) [5]. A supervised classification was performed

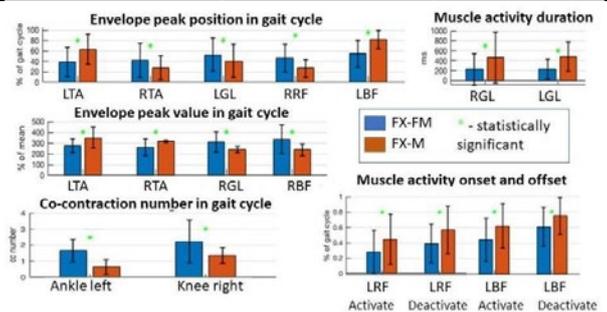

by means of 7 different classifiers: Decision Tree, Random Forest, CN2 Rule Induction, SVM, k-NN, Neural Network and Naïve Bayes and 2 different sets of vectors were used: S1. only sEMG parameters; S2. only kinematic parameters.

## Results and Discussion

The best classification on a training set (66% of subjects) was obtained by applying the Neural Network algorithm for both S1 and S2; and this was further tested on the test set (33% of subjects) (Tab.1). Statistically significant differences ( $p < 0.05$ ) between groups of subjects were detected on sEMG parameters but not on the kinematics (Fig. 1).

**Table 1:** Performance of the most performant classification algorithms on training and test data.

SET OF VECTORS	S1	S2
ALGORITHM	Neural Network	Neural network
TRAINING SET ACC (%)	98,5	83,1
TEST SET ACC (%)	90,9	84,8

**Figure 1:** EMG parameters in subjects classified as FX-FM and FX-M by Neural Network classifier, \*-statistically significant difference ( $p < 0.05$ )

## Conclusions

Both kinematics and sEMG parameters showed their ability to discriminate between FX-FM and FX-M thus showing their potential to be used in support decision making applications.

# FFH Detection Using SVM with SMOTE, Normalization, and Univariate Feature Selection

Bummo Koo<sup>1</sup>, Jongman Kim<sup>1</sup>, Yejin Nam<sup>1</sup>, and Youngho Kim<sup>1,\*</sup>

<sup>1</sup>Department of Biomedical Engineering and Institute of Medical Engineering, Yonsei University, Republic of Korea  
Email: \*younghokim@yonsei.ac.kr

## Summary

FFH (Fall-from-height) detection using various machine learning algorithms was performed in this study. Twenty healthy male volunteers performed 15 non-FFH, 5 low-hazard-FFH and 1 high-hazard-FFH. An IMU was placed on the 7<sup>th</sup> thoracic vertebrae (T7). FFHs were successfully detected with an high accuracy (98.3%) by SVM (Support Vector Machine) with SMOTE, normalization, and univariate feature selection.

## Introduction

ILO [1] reported that the fatality rate observed for FFH is the highest among industrial accidents. As for the medical emergency, time is a critical factor for patients who are exposed to trauma [2]. This study aims to detect FFH using SVM with SMOTE, normalization, and univariate feature selection.

## Methods

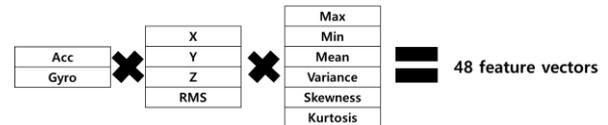

20 healthy volunteers performed 15 non-FFH, 5 low-hazard-FFH and 1 high-hazard-FFH (Table 1). An IMU sensor was positioned on the T7. Totally, 48 feature vectors were extracted from 3-axis acceleration and 3-axis angular velocity. Three pre-processing techniques were applied: SMOTE (Synthetic Minority Oversampling Technique), normalization, and univariate feature selection.

**Table 1:** Experimental Protocol

Non-FFH	sitting quickly and getting up, sitting on the floor and getting up, climbing up and down stairs, climbing up and down a ladder, working with a pickaxe, lifting(front), lifting(back), lifting(side), 0.7m jump, walking on a beam, walking on a beam with luggage in one hand, shoveling, stretching, climbing up and down a scaffold, moving up and down in an elevator
Low-hazard FFH	forward trip, lateral trip, backward slip, forward trip, fainting
High-hazard FFH	0.7m forward FFH

**Table 2:** Performance of classifiers for FFH detection

Pre-processing Technique	Accuracy (%)						
	Two-class			Three-class			
	FFH	Non-FFH	Total	Low-hazard FFH	High-hazard FFH	Non-FFH	Total
None	85.6	96.4	93.3	92.0	0	96.9	91.1
SMOTE	90.6	93.8	92.9	56.7	63.3	89.3	80.3
SMOTE +Normalization	98.9	100.0	99.7	92.9	90.0	100.0	97.9
SMOTE +Normalization + Feature selection	98.9	99.8	99.5	94.7	96.7	99.6	98.3

**Figure 1:** Feature vectors

The SVM classifier was applied with RBF kernel. Data from 10 subjects were used to train the classifier and those from the remaining 10 subjects were used to test the classifier.

Classification was conducted in two ways: two-class and three-class. Two-class represents non-FFH vs. FFH, and three-class represents non-FFH vs. low-hazard FFH vs. high-hazard FFH.

## Results and Discussions

Since SMOTE is an oversampling approach that creates synthetic minority class samples [3], it did not improve the overall performance, but was able to create a balanced algorithm. Normalization improved the performance by reducing deviations between feature vectors. In addition, the feature vector selection contributed to improve the performance by solving the curse of dimensionality.

## Conclusions

FFHs were successfully detected with an high accuracy (98.3%) by applying SVM with SMOTE, normalization and univariate feature selection. The present technique would be helpful to save the FFH victims by increasing the golden time.

### Summary

In this study, finger posture recognition algorithm was developed using armband-type-sEMG sensor and ANN classifier. In the re-wearing, the classification accuracy (CA) depended on the feature vector and the number of training data (TRN). Feature vectors with the high CA showed a strong linear relationship(LR) in inter-session. The present study can be useful to select the feature vector and the number of the training data to design the sEMG-based posture recognition.

### Introduction

sEMG signal is useful to the pattern recognition (PR) algorithm for classification of the user's motion or intention. Most previous studies tried to avoid the misclassification, and the sEMG sensors on the specific muscle were usually used to minimize the effect of electrode shift in sEMG-based PR system [1]. However, these previous studies were difficult to use by non-experts and did not perform well when the sensors were worn again in daily life [2]. This study presents the sEMG-based finger posture recognition algorithm using the various feature vectors in the re-wearing of the sensor.

### Methods

Ten healthy adults were recruited to perform twelve finger postures in MVC of 20% (rest, spread, cylindrical/spherical grasp, palmar/lateral/tip pinch, V-sign, O.K., scissor, finger-pointing, thumb-up). A pre-developed armband sensor [3] was aligned on flexor carpi radialis of the right lower arm. Each posture was repeated twice with ten times donning and doffing of the sensor. Twenty-one time-domain feature vectors were calculated using the filtered (10-250Hz) sEMG signal. The predefined threshold values [4-5] and additional threshold values as in eq (1) were applied to the feature vectors. Pearson's correlation coefficients (PCCs,  $r$ ) were used to analyze the LR of inter-session ( $0 < \text{weak} \leq 0.3 < \text{moderate} \leq 0.7 < \text{strong} \leq 1.0$ ). The 10-fold cross-validation was performed using an ANN classifier with a single feature vector by the different training data. The MATLAB and IBM SPSS Statistics 25 were used for the classification and the statistical analysis (Kruskal-Wallis test).

$$\text{Threshold Value} = T \times \text{RMS}_{\text{sEMG in REST}} \quad (T=0:0.5:10) \quad (1)$$

### Results and Discussion

CA increased with the increased the number of training data for all feature vectors, but there was no significant difference in the range of TRN 1 to TRN4 and TRN5 to TRN9. In TRN9, the high CAs in ZC, WAMP, MYOP and SSC were  $77.8 \pm 5.0$  % with a threshold of 15.0mV ([5]  $r=0.840$ ),  $79.3 \pm 4.9$  % with a threshold of 9.9mV ( $T=3.0$ ,  $r=0.855$ ),  $79.7 \pm 4.5$  % with a threshold of 8.3mV ( $T=2.5$ ,  $r=0.857$ ) and  $77.2 \pm 5.5$  % with a threshold of 15mV ([5],  $r=0.843$ ), respectively. However, no

significant differences in CA were observed for ZC, WAMP, MYOP and SSC with the range of  $2.5 \leq T \leq 9.5$ ,  $1.5 \leq T \leq 8.5$ ,  $1.0 \leq T \leq 6.0$  and  $2.5 \leq T \leq 9.5$ , respectively. VAR showed the highest CA ( $81.6 \pm 13.1$  % with  $r=0.709$ ).

As for the re-wearing of the sensor, the additional training data was useful to improve the CA, and the feature vectors with a strong LR showed high CA ( $\geq 60.0\%$ ). CA of higher than 70.0% was obtained for the feature vectors with  $r \geq 0.8$ .

**Table 1:** CA and PCCs of each feature vectors

CC	24.7±4.7	32.3±5.5	36.5±5.9	0.291

### Conclusions

The robustness on the re-wearing the sensor is important in sEMG-based PR system for non-expert and daily life. In this study, CA was improved by the additional training data, and inter-session PCCs correlated well with the CA depending on the feature vectors. The present study suggested that various finger postures could be recognized using an armband sensor, and the problem of the re-wearing the sensor could be solved using the feature vectors with a high inter-session PCCs.

## Introduction

Classifying gait patterns into several categories for gait analysis is helpful for clinical decision making; managing muscle spasticity, surgical lengthening of the shortened muscles, and applying orthosis to improve gait patterns. However, the gait pattern classification is still conducted with subjective judgement and the personal experience of healthcare providers.

In this study, we proposed a deep learning model to classify gait patterns in children with cerebral palsy (CP) through a combination of some of the extracted kinematic data based on 3D motion capture system.

The proposed deep learning model was trained using specific data made from custom datasets and evaluated for model performance. Then, the results were compared with clinical classification by experienced physician and trainee physician [1].

## Methods

### 1. Custom Dataset

- The four gait patterns (True equinus, Jump knee, Apparent equinus, Crouch) were classified according to the widely used definition by Rodda et al. [2].

- 267 children with bilateral CP for model train & validation, 91 for model test.

- From 3D motion capture kinematic data, the custom datasets were reconstructed with joint kinematics (hip, knee and ankle) (6) and marker coordinates data (sacrum, anterior superior iliac spine, thigh, knee, tibia, ankle, and toe) (26) from the sagittal plane.

### 2. Deep Convolutional Neural Network (DCNN)

- The model was constructed to train time-series data using Conv1D. These convolutional layers were layered to form DCNN.

### 3. Comparison with experienced and trainee physician

- We compared the results of learned model to those of physicians' classification using the same patients' data to validate the model.

## Results and Discussion

On test datasets, we obtained the accuracy(71.6), precision(69.0), recall(68.9), f1\_score(68.1) and ROC-AUC(Fig.1) as classification performance metrics.

Table 1 showed that overall classification accuracy of the model was lower than experienced physician, but higher than trainee physician.

Especially in Jump knee, our model showed lower accuracy compared to physicians' classification and hard to discriminate it from True equinus.

However, our model showed higher accuracy in Apparent equinus and Crouch even compared to the classification accuracy of experienced physician. (Fig. 2)

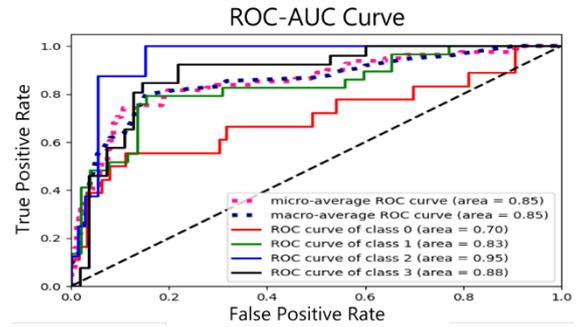

Figure 1. ROC-AUC for test dataset

(\*class0-Jump knee, class1-Apparent equinus, class2-Crouch, class3-True equinus)

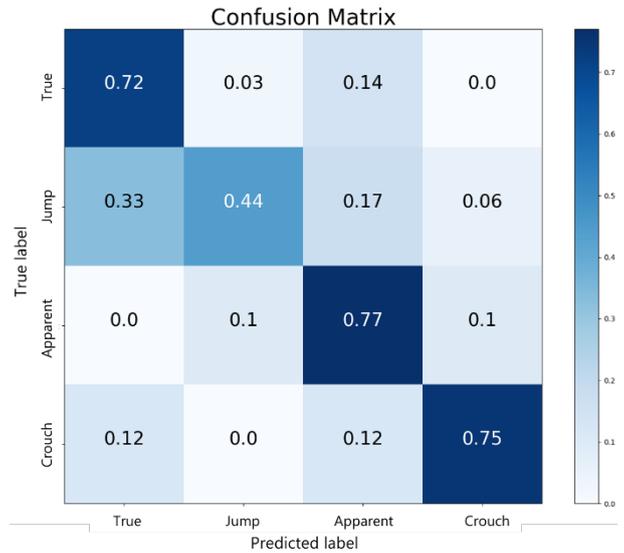

Figure 2. Confusion Matrix for test dataset

## Conclusions

The higher classification accuracy of our model compared to the trainee physician was an encouraging result. Furthermore, deep learning analysis is expected to help physicians make more objective and fast clinical decisions.

However, further study is needed to optimize the model for better performance and apply a motion analysis model using 2D walking videos.

## Summary

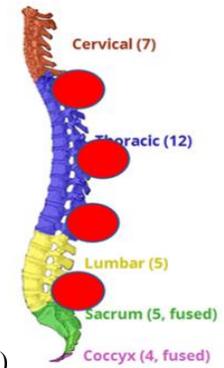

An athletic fit shirt imbedded with 4 IMU's sensors and machine learning algorithm was developed for sitting posture recognition tasks by seven static sitting postures classification (N=8). Time domain features served as input to a deep long short-term memory-based recurrent neural network (LSTM-RNN) architecture. The performance test explores the relevance between sensor information and postures. The overall results in performance indicated that IMU-based data and LSTM-RNN structural scheme was appropriate for sitting posture recognition.

## Introduction

The main factor related to adult spinal deformity (ASD) is inappropriate postures e.g. poor sitting posture and following physiological stress on the vertebral which may cause spinal fractures. In clinical practices, the most common examinations for spinal deformity are traditional radiography and MRI with less invasiveness and higher precision, however, because of time and cost consumption, these tools cannot give rapid enough upper body postures information to patients. Upper body postures recognition (UPR) related to spinal pressure is investigated to understand people's behavior. Compared to diagnostic tools such as X-rays, wearable inertial measurement sensors (IMU), composed of a gyroscope, an accelerometer and a magnetometer, have received more and more attention in human activities recognition tasks. The purpose of this study is to evaluate the appropriateness of an IMU-based scheme and the LSTM-RNN for measurement of spine curvature provided an efficient option for posture recognition.

## Methods

An athletic fit shirt imbedded with 4 IMU's sensors and machining learning algorithm was developed for UPR tasks in seven static sitting postures: upright/slump/flat back sitting, right/left bending, and right/left twisting. Four IMUs with 9 degrees of freedom were uniformly distributed in the range of thoracolumbar spine to acquire kinematics information in the spine (N=8) with controlled trial procedures. Time and frequency domain features, as input data in sequence-to-sequence classification tasks, a deep long short-term memory (LSTM) neural network architecture was used in the performance test to explore the relevance between sensor information and postures.

(a) prototype of system (b) relative positions to spine  
**Figure 1:** Sensors distribution during human trials

## Results and Discussion

The averaged accuracy of 7 classes is  $99.0 \pm 0.3\%$  and F1-score ups to  $0.966 \pm 0.012$ . The best performance is on humpback recognition and the worst is on right twisting. To evaluate the performance in the training model, we input a test sequence into this model and the accuracy is 81.2%, which indicated a slight overfitting. Also, we found the less sensors we used, the worse performance the model had, and the upper sequence of sensors combination can give better performance due to different distance to the rotational center of the upper body.

## Conclusions

The overall results in performance evaluation indicated this IMU-based scheme was appropriate for measurement of spine curvature and that LSTM-RNN provided an efficient option for this application.

## A Biomechanical Testing Platform for the Stability and Mobility Assessment of Extracapsular Stabilization of Cranial Cruciate Ligament-Deficient Dogs

Wei-Ru Hsu<sup>1</sup>, Cheng-Chung Lin<sup>2</sup>, Ching-Ho Wu<sup>1\*</sup>

<sup>1</sup>Institute of Veterinary Clinical Science, School of Veterinary Medicine, National Taiwan University, Taiwan

<sup>2</sup>Department of Electrical Engineering, Fu Jen Catholic University, Taiwan

Email: chinghowu@ntu.edu.tw

### Summary

This study aimed to demonstrate a testing platform designed for the kinematics assessment of extracapsular stabilization (ECS) in cranial cruciate ligament deficient (CCLD) dogs. The testing platform was consisted of a custom-made jig and a motion capture system. The testing platform was used to evaluate *in vitro* the surgical outcome of ECS with bone anchors at two different pairs of isometric attachment sites. The jig was devised to drive the full range of flexion and extension, craniocaudal translation and internal rotation of the stifle joint in three-dimensional (3-D) space. The results showed that ECS tended to diminish the tibial cranial motion but increased excessive tibial external rotation in comparison to those of intact stifle. The testing platform was demonstrated to allow identify the changes of the post-surgical stability of the canine stifle joint.

### Introduction

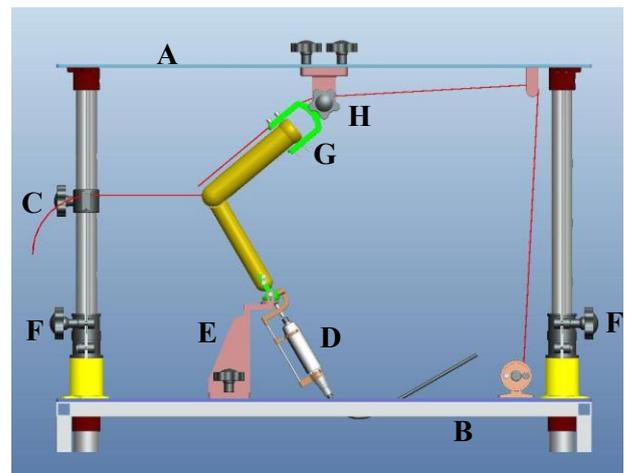

Cranial cruciate ligament disease is one of the most common causes of lameness in dogs. The biomechanical outcome after surgical correction for CCLD has been widely investigated. However, there were only a few studies that evaluated the reconstructed stifle in terms of 3-D kinematics. The study aimed to present a custom-made, high-mobility testing platform, which allowed quantify six-degrees-of-freedom kinematics of the stifle joint during various testing protocols and enabled to assess the performance of extracapsular stabilization.

### Methods

The testing jig was designed to drive the full range of flexion and extension, craniocaudal translation and internal rotation of the stifle joint in 3-D space (Figure 1). The top plate of the jig was adjustable by the four vertical retractable columns. The proximal femur was affixed to a metal fixture via two 2.5-mm Steinmann pin, which was attached to the top plate with a bolt. A sliding base connecting with a torsionmeter on the bottom plate hold the distal end of the tibia, which provided stabilization during tests and allowed torque measurement during internal/external rotation of the stifle joint. A motion capture system (VICON, Oxford Metrics Group, Oxford, UK) was employed to record the motions of the stifle joint.

Three cadaveric pelvic limbs were harvested from three donors (Age: 5-14 y/o; BW: 7.0-16.8 kg). Each specimen was tested under different CCL condition: intact, CCLD, and repaired with ECS using bone anchors. Two 3.5-mm stainless steel anchors (Securos inc., Massachusetts, USA) were placed and connected with 80 lbs nylon leader line (NLL, Securos inc., Massachusetts, USA). Under the tension that cranial

drawer test became negative in stifle angle of 135°, the NLL was fixed with 80 lbs crimp clamp (Securos inc., Massachusetts, USA) The ECS group was divided into two subgroups, each with different chosen pair of isometric points (F2-T1 and F2-T3). The craniocaudal drawer tests and tibial internal rotation tests were conducted for each CCL conditions.

**Figure 1:** The schematic representation of the custom-made testing platform consisted of (A) a top plate, (B) a bottom plate, (C) a suture providing the cranial force, (D) a torsionmeter, (E) a sliding base, (F) fixation screws, (G) a metal fixture and (H) a bolt.

### Results and Discussion

Tibial cranial translation of CCLD group was notably greater than that of intact group. The magnitude of internal rotation was greater in CCLD group in comparison to those of intact group, and both the ECS groups led to less tibial internal rotation comparing to both intact and CCLD group, which was in agreement with previous studies [1]. The new testing platform allowed 3D measurement of translation and rotation stability of the stifle joint at various positions of the hindlimb under precisely controlled loads.

### Conclusions

A new biomechanical testing platform specifically devised for the kinematics assessment of canine limbs was constructed. The testing platform was demonstrated to enable identifying the changes of the post-surgical stability of the canine stifle joint.

# Acute Effects of Transcranial Direct Current Stimulation on Dynamic Postural Stability in Healthy Young Adults

**Baofeng Wang**, Songlin Xiao, Liqin Deng, Changxiao Yu, Weijie Fu\*  
 School of Kinesiology, Shanghai University of Sport, Shanghai, China  
 Email: fuweijie@sus.edu.cn

## Summary

This study aims to investigate the acute effects of transcranial direct current stimulation (tDCS) on postural control in healthy young adults. Eight healthy male adults were recruited. All participants were asked to complete a dynamic postural stability task before and immediately after a 20-minute session of either anodal tDCS (a-tDCS) or sham tDCS (s-tDCS). Results showed that compared to the pre-intervention and s-tDCS group, the displacement of the center of pressure (COP) and the center of gravity (COG) was significantly decreased during a Y-balance task in the a-tDCS group. This suggests that a-tDCS can effectively improve the dynamic stability of healthy young adults.

## Introduction

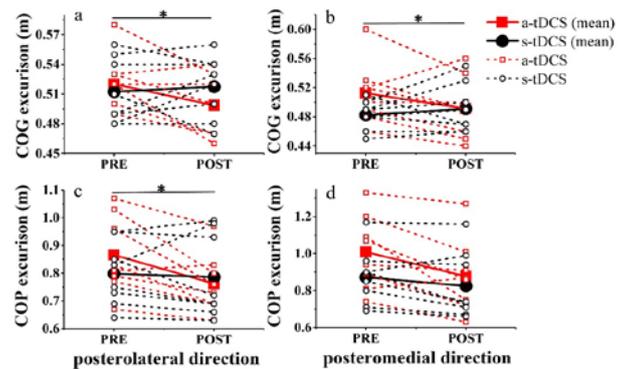

Postural control plays a major role in daily activities [1]. The maintenance of balance is controlled by the integration of sensory information and complex interaction between musculoskeletal and neurological systems [2]. Recently, the non-invasive brain stimulation technique emerged and has been widely used to improve postural control in the elderly. As one of the non-invasive brain stimulation technique, tDCS is a method stimulating specific brain regions by applying a constant weak current to the scalp. Therefore, this study aims to investigate the effects of tDCS on dynamic postural control in healthy young adults.

## Methods

In this double-blinded sham-controlled study, eight healthy male adults (age:  $25.9 \pm 1.5$  yrs, height:  $1.75 \pm 0.06$  m, weight:  $72 \pm 17.8$  kg) without exercise habits were asked to complete assessments of dynamic postural stability before and immediately after a 20-minute session of either a-tDCS or s-tDCS at two visits separated by one week. For the dynamic postural stability test, participants performed a Y-balance task (anterior, posteromedial, posterolateral directions) with a non-dominant leg on the force plate. The period and distance from the start position to the point of maximum reach in each direction was defined as analysis period and reach distance, respectively. Two-way repeated-measures analysis of variance was used to examine the effects of tDCS on the COG and COP excursion.

## Results and Discussion

There were no significant main effects and interactions for the reached distance in both a-tDCS and s-tDCS groups (Table 1). The significant intervention by time interaction effects for the COG excursion at the posterolateral and posteromedial directions, COP excursion at the posterolateral direction were observed ( $p < 0.05$ ). The results of the post-hoc analysis showed that compared to pre-intervention and s-tDCS, a-tDCS significantly decreased the COG excursion at the posterolateral and posteromedial directions, COP excursion at the posterolateral direction (Figure 1).

**Figure 1:** The changes of the center of gravity and center of pressure excursion before and immediately after a-tDCS and s-tDCS. COG: center of gravity, COP: center of pressure, \*Significantly changes in the a-tDCS group,  $p < 0.05$

## Conclusions

A-tDCS could significantly decreased the displacement of the COG and COP compared to the pre-intervention and s-tDCS. This suggests that a-tDCS can effectively improve the dynamic stability of healthy young people.

## Evaluation of Position and Variability of the Center of Pressure During Walking with Limited Knee Flexion

Seobin Choi, Jieon Lee, Gwanseob Shin

Department of Biomedical Engineering, Ulsan National Institute of Science and Technology, Ulsan, Republic of Korea  
Email: gshin@unist.ac.kr

### Summary

Stiff-Knee Gait, which is a common abnormal gait pattern, might cause loss of balance and falls. However, the isolated effect of limited knee flexion on the center of pressure (COP) movement has not been well studied. This study examined how walking with limited knee flexion would influence the position and variability of the COP.

### Introduction

Stiff-Knee Gait (SKG) is a typical abnormal gait pattern following a stroke, spinal cord injury, and cerebral palsy, and it is known to reduce knee flexion range during the swing phase of the gait cycle [1]. Individuals with limited knee flexion may trip over obstacles and falls. Previous research has shown that the asymmetry and variability of COP movement are considered an indirect gait stability assessment [2]. However, the isolated effect of limited knee flexion on the movement of the COP has not been well studied. Therefore, this study aimed to examine how walking with limited knee flexion would influence the COP position and variability.

### Methods

Sixteen healthy young male participants were recruited. The means (and standard deviations) of their age, height, body weight, and foot length were 23.1 (3.0) years, 173.4 (2.1) cm, 69.9 (8.1) kg, and 25.1 (0.7) cm, respectively. They walked on a 10-m walkway equipped with a 1.5m pressure platform (Zebris FDM 1.5; zebris Medical, Isny, Germany). They walked under four different conditions (Normal, L60, L40, and L20 conditions): normal and limited knee flexion of their left knee up to 60, 40, 20 degrees, respectively, at a self-selected comfortable speed. For the limited knee flexion walking, participants wore a hinged knee brace that permitted knee joint rotation from full extension to 120 degrees flexion. Their position and variability of the intersection point of the COP between both feet were captured by the pressure platform and compared between the four walking conditions. One-way repeated measure ANOVA and Tukey's post-hoc tests were conducted with a significance criterion of  $p < 0.05$ .

### Results and Discussion

ANOVA found significant effects of the walking conditions on the anterior-posterior, lateral symmetry of the COP position and variability (Table 1). Tukey's post-hoc test showed that the position and variability of the COP were significantly different between the L20 and the normal walking conditions. The participants shifted their COP posteriorly and laterally on the left side while walking with limited knee flexion up to 20 degrees, compared to normal walking. The increase in the anterior-posterior and lateral symmetry variability was also observed during the L20 walking compared to normal walking. The limited knee flexion would change the position of COP and increase gait asymmetry and variability. The abnormal shifting of the COP could be a compensatory behavior to reduced foot-ground clearance associated due to the limited knee flexion. This finding may help assess gait stability and safety, and design guidelines for preventing falls for individuals with SKG.

### Conclusions

Study findings show that limited knee flexion during walking might affect the dynamic balance, and it may be a risk factor for fall accidents who have stiff knee joints.

### Acknowledgments

This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea [HI19C1234].

### Summary

This work aimed to visualise the loading distribution of specific anatomical landmarks of the knee throughout various kneeling tasks. Force sensitive resistors (FSRs) were used to determine which structures were contacting the ground. Heatmaps of kneeling load distribution, and normalised vertical ground reaction forces ( $F_z$ ) between left and right knees of 14 healthy participants were generated across two sessions. This study demonstrates an effective technique for visualising kneeling load distribution about the knee. This work is intended to inform future projects investigating the origins of anterior knee pain after fracture related surgery.

### Introduction

Kneeling is an important activity of daily living. Trauma, degenerative conditions such as osteoarthritis, or the after-effects of local surgery may all lead to difficulty or the inability to kneel [1]. The anatomical structures contacting the ground changes with varying kneeling postures [2]. Previous work [3] has focused on the magnitude of applied loads but techniques for visualising which structures are contacting the ground requires further investigation. The aim of this study was to develop a technique for visualising loading distribution about the knee throughout kneeling.

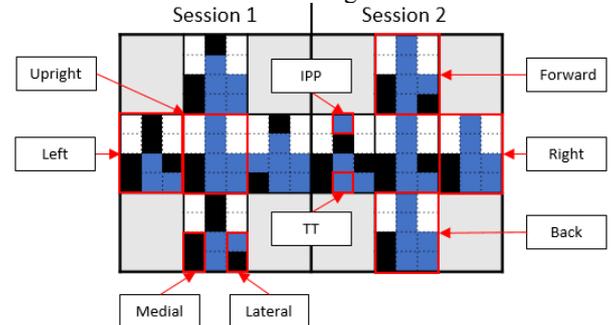

### Methods

Eight 12.7 mm circle diameter FSRs (Delsys, Boston, Massachusetts, USA, 2000 Hz) were placed about the right knee of 14 healthy participants (M/F: 7/7, age:  $26.4 \pm 2.5$  years, height:  $171.8 \pm 4.9$  cm, mass:  $68.5 \pm 12.8$  kg). Four FSRs were placed in a line from the inferior pole of the patella (IPP) to the tibial tuberosity (TT); two FSRs were placed medially and laterally to this line, respectively.  $F_z$  data were captured using two in-ground force platforms (AMTI Optima, Watertown, Massachusetts, USA, 2000 Hz). Data were recorded using Vicon Nexus 2.9 (Vicon Motion Systems Ltd, Oxford, UK). Participants performed upright kneeling (60 secs) and reaching tasks: forward, back, left, and right (5 secs). Participants underwent a second session after a minimum three-day break. Matlab 2019b (MathWorks, Natick, Massachusetts, USA) and R 4.0.3 (R Core Team, Vienna, Austria) were used for data analysis. All participants provided informed consent.

### Results and Discussion

The heatmaps (Figure 1) are a 4 x 3 array representing the average FSR activation of the right knee on the ground as if viewed from above. Columns 1, 2, and 3 are the medial 2 x FSRs, the 4 x FSRs located from the IPP to the TT, and the

2 x lateral FSRs. The TT and distal aspect of the patella tendon were active for all kneeling conditions.

**Figure 1:** Average FSR activation of the right knee during kneeling tasks. Black = no activation, blue = activation, white = no FSR placed.

The intra-class correlation coefficient (ICC(2,1)) of the  $F_z$  showed good-to-excellent [4] intersession repeatability between left and right sides for all kneeling tasks except for upright kneeling on the left side (Table 1), which may be in-part more variable due to the increased recording time.

**Table 1:** Mean normalised  $F_z$  data (bodyweight (standard deviation)) and ICCs for left and right knees during kneeling tasks.

Task	Side	Session 1	Session 2	ICC
		Mean (SD)		
Upright	Left	0.46 (0.03)	0.47 (0.04)	0.35*
	Right	0.47 (0.04)	0.46 (0.06)	0.74 <sup>†</sup>
Forward	Left	0.28 (0.09)	0.30 (0.09)	0.81 <sup>‡</sup>
	Right	0.33 (0.10)	0.32 (0.08)	0.87 <sup>‡</sup>
Back	Left	0.28 (0.09)	0.28 (0.09)	0.85 <sup>‡</sup>
	Right	0.28 (0.09)	0.28 (0.08)	0.88 <sup>‡</sup>
Left	Left	0.51 (0.13)	0.51 (0.12)	0.67 <sup>†</sup>
	Right	0.24 (0.06)	0.24 (0.05)	0.89 <sup>‡</sup>
Right	Left	0.21 (0.05)	0.22 (0.06)	0.80 <sup>‡</sup>
	Right	0.54 (0.15)	0.51 (0.13)	0.82 <sup>‡</sup>

\* poor, \*\* fair, <sup>†</sup> good, <sup>‡</sup> excellent [4]

### Conclusions

The TT and distal patella tendon were most commonly loaded during kneeling. Most kneeling tasks were performed with good-to-excellent  $F_z$  intersession repeatability between left and right sides. FSR activation coupled with  $F_z$  data provides valuable insights into the magnitude and locations of applied load during kneeling. This study demonstrates an effective technique for visualising kneeling load distribution about the knee.

## Effects of dual-task training on gait in stroke patients: a meta-analysis

Zhang Xueyi<sup>1</sup>, Wan Xianglin<sup>1</sup>

<sup>1</sup>Beijing Sport University, Beijing, China

Email: yicoia@qq.com

### Summary

A systematic review and meta-analysis were performed to investigate effects of dual-task training on gait in stroke patients. The effect of dual-task training on the improvement of gait in stroke patients is better than that of conventional rehabilitation training, but the advantage of dual-task training in the improvement of gait speed in stroke patients may be affected by the time of intervention.

### Introduction

Stroke is a common disease and the first cause of death in China. The average annual increase of the first incidence is 8.3%[1], and the recurrence rate 1 year after the first stroke is as high as 12.4%[2]. It is crucial to help patients recover functional disorders through various rehabilitation methods. The recovery of independent walking ability is the basis of improving the quality of life of stroke patients. Studies have found that dual-task training intervention can more effectively improve walking ability, and improve the independence of daily activities and quality of life of patients[3]. The purpose of this study is to systematically evaluate the effects of dual-task training on gait and balance of stroke patients, in order to provide reference for rehabilitation training programs of stroke patients.

### Methods

The systematic review protocol described in the Preferred Reporting Items for Systemic Reviews and Meta-Analysis statement (PRISMA) were adopted to guide the review process. Keyword search was performed in Pubmed, Web of science, Cochrane Library, Embase, CNKI and Wanfang Database. All meta-analysis has been performed in Revman 5.4 software. A random-effect model was estimated given a P-value less than 0.05 for the Cochran's W test or I<sup>2</sup> statistics at or above 50%; otherwise, a fixed effect model was estimated.

### Results and Discussion

A total of 15 RCTs involving 509 patients were included. The results of meta-analysis showed that the dual-task group was better than the control group in improving the gait speed, step length, stride length, cadence, and the difference was

statistically significant (Table 1). The results of subgroup analysis showed that when the intervention time was less than 4 weeks, dual-task was more effective in improving the gait speed of stroke patients (Figure 1). There was no statistical difference between the dual-task group and the control group when the intervention time was more than 4 weeks. Compared with previous studies, this meta-analysis covers a wider range of dual-task training types and provides a more comprehensive and reliable systematic evaluation result.

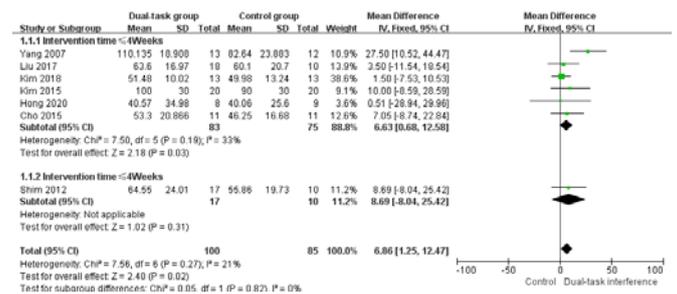

Figure 1: subgroup analysis of gait speed

The results of subgroup analysis indicated that dual-task training had certain advantages on gait speed of stroke patients in the short term, but might gradually lose the advantages in the long term. This conclusion suggests that in the middle and late stage of rehabilitation training for stroke patients, it may be necessary to change the training program for further intervention of patients.

### Conclusions

(1) The effect of dual-task training on the improvement of gait in stroke patients is better than that of conventional rehabilitation training; (2) The advantage of dual-task training in the improvement of gait speed in stroke patients may be affected by the time of intervention. Due to the limitation of the quantity and quality of included studies, more high-quality studies are required to verify above conclusions.

# Effects of Transcranial Direct Current Stimulation on Dynamic Postural Control: A Meta-Analysis

Changxiao Yu<sup>1</sup>, Songlin Xiao<sup>1</sup>, Baofeng Wang<sup>1</sup>, Bin Shen<sup>1</sup>, Weijie Fu<sup>1\*</sup>

<sup>1</sup> School of Kinesiology, Shanghai University of Sport, Shanghai, China

\*corresponding author: E-mail: [fuweijie@sus.edu.cn](mailto:fuweijie@sus.edu.cn)

## SUMMARY

The purpose of this study was to investigate the effect of a-tDCS on dynamic postural control compared to sham stimulation, and confirm whether a-tDCS can be used as an effective ergogenic technology to improve postural control. Based on the PRISMA guidelines, this meta-analysis was performed until November 2020 in the Google Scholar, PubMed, and Web of Science. English full-text studies with sham-controlled, randomized, single/double-blinded experimental design whereby healthy adults were included. The results showed a-tDCS can significantly enhance the dynamic postural control in healthy adults.

## INTRODUCTION

Dynamic postural control as the essential motor function plays an important role in our daily life, which often coincides with non-postural cognitive tasks [1]. Over recent years, increasing cortical excitability could enhance mental and physical performance has been widely accepted. As a promising technique, anodal transcranial direct current stimulation (a-tDCS) strengthens synaptic connections [2], promotes postural control [3], and improves motor sensation [4]. However, the results of a-tDCS are inconsistent or cannot be replicated. The purpose of current study is to investigate the effect of a-tDCS on dynamic postural control for healthy adults during different experimental tasks.

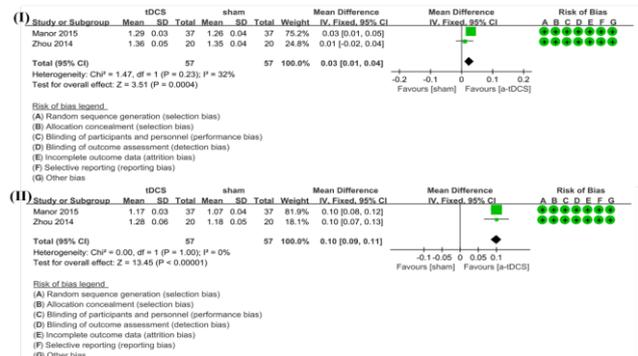

## METHODS

We searched the following databases: Google Scholar, PubMed, and Web of Science before November 2020. The key search terms were the following: “tDCS” or “transcranial direct current stimulation” and “postural control” or “motor control” or “physical performance”. Studies that met the following criteria were included: (1) English full-text articles; (2) the design of the study was randomized, double/single-blinded, sham-controlled; (3) the application of a-tDCS for healthy adults; (4) the outcome measures include before and immediately after the trials; (5) perform dynamic postural control tasks.

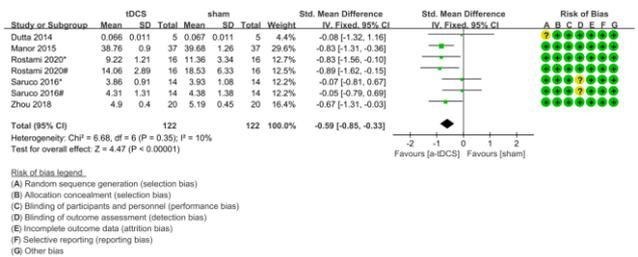

The data used for meta-analysis are as follows: the speed of walking under single and dual tasks and the reaction time.

## RESULTS AND DISCUSSION

Seventeen studies (424 participants) were included in the systematic review, and six of which for meta-analysis. The meta-analysis indicated that significant enhancement was found comparing a-tDCS vs. sham stimulation on dynamic postural control (Figure 1). There was no age-related process under dual-task conditions using a-tDCS over targeted brain areas in dynamic task performance. Additionally, a-tDCS has a significant reduction in reaction time for both the young and older populations (Figure 2).

**Figure 1:** Forest plot showing mean different from the comparison of walking speed between a-tDCS and sham stimulation in single (I) and dual task (II) conditions during dynamic postural control.

**Figure 2:** Forest plot showing standardized mean different from the comparison of reaction time between a-tDCS and sham stimulation in dynamic postural control tasks. Rostami 2020\* - the time of TUG test; Rostami 2020# - the time of the Modified Figure of Eight Walk; Saruco 2016\* - the time of a CONDITION × TEST interaction; Saruco 2016# - the time of a CONDITION × TEST × DIFFICULTY interaction.

## CONCLUSION

Compared with sham stimulation, a-tDCS can significantly enhance the capabilities of dynamic postural control. Future studies should use larger sample sizes and imaging technology for in-depth study of brain mechanisms.

### Summary

We examined the differences of the activity pattern of the trunk muscles during horseback riding therapy between healthy children and two low-birth weight children with cerebral palsy (CP) using electromyography (EMG). In the children with CP, the characteristics of the muscle activity pattern in the lumbar region showed low activity during horseback riding in comparison with that of healthy children. The proportion of EMG activity at the cervical region for the total muscle activities of trunk muscles was larger than that at the lumbar region in the children with CP. The children with CP had better control of trunk posture during horseback riding therapy mainly during the activities of the cervical muscles. It was suggested that the proportion of EMG activity of the cervical muscles and the lumbar muscles might also be a useful index for evaluating the horseback riding intervention for the children with CP.

### Introduction

Horseback riding therapy is one of the rehabilitation methods for spinal injury or brain damage [1]. Over the past few years a considerable number of studies have been made on the effects of horseback riding therapy [e.g.: 2]. These results obtained in the present review show the potential benefit of horseback riding therapy in improving gross motor function in children with CP. What seems to be lacking, however, is an effective method of quantitative evaluation for horseback riding therapy from the viewpoint of biomechanics, and more experimental research is needed. The purpose of this study was to estimate the characteristics of muscle activity pattern in trunk muscles during horseback riding therapy. The proportion of surface EMG activity at the cervical region for the total muscle activities of trunk muscles was examined by root-mean-square (RMS) of the EMG. The values of proportion of RMS (%RMS) were compared between the children with CP and healthy children.

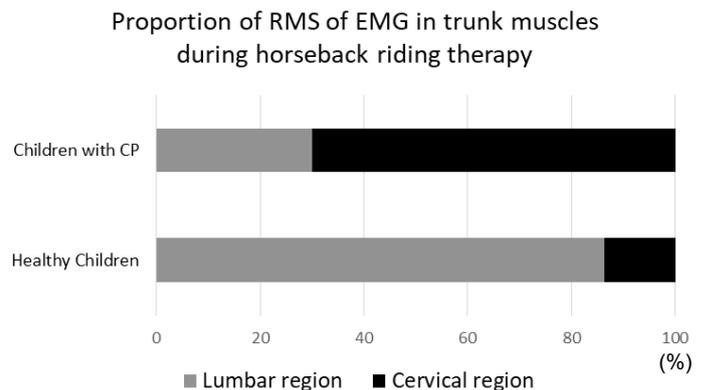

### Methods

The subjects comprised two low-birthweight children with CP (a 10-year old and a 3-month old girl, a 10-year old and a 3-month old boy, respectively) and two healthy children (a 9-year old and a 3-month old girl, an 8-year old and a 10-month old boy, respectively) as a control. Two subjects with CP had been receiving horseback riding therapy for over 7 years. The horseback riding therapy was approximately 30 minutes in duration and was performed once weekly. The surface EMG values were recorded bilaterally from the four trunk muscles during the horseback riding therapy at the riding course. The muscle activity was quantified by the value of root-mean-square (RMS) for the surface EMG during the horseback riding. The mean values of RMS were compared between the children with CP and the normal children in each muscle. A proportion of RMS for the muscle activity amount at the trunk

was evaluated as a %RMS. The values of %RMS were compared between the cervical region and the lumbar region. For comparisons of %RMS, a chi-square test for independence was performed to investigate the independent difference with significance levels of 0.01.

### Results and Discussion

The %RMSs values were compared between the children with CP and the healthy children and are shown in Figure 1. The proportion of EMG activity at the cervical region for the total muscle activities of trunk muscles was larger than that at the lumbar region in the children with CP. The chi-square test for independence showed statistical differences of 1%. The values of mean power frequency (MPF) of surface EMGs for the lumbar region were higher in the children with CP compared with that of the healthy children. The previous study showed the benefits of horseback riding therapy for improving gross motor function in the children with CP [2]. Our results suggested that there is a relationship between the characteristics of trunk muscle activity and the strategy of controlling the trunk posture during the horseback riding therapy in the children with CP.

**Figure 1:** The value of mean %RMS from the lumbar muscles (Rectus abdominis and Erector spinae) and the cervical muscles (Splenius capitis and Trapezius) was compared between the children with CP and healthy children.

### Conclusions

The proportion of the value of RMS for the cervical muscle and the lumbar muscle might be a useful index for estimation of the effectiveness of horseback riding intervention for the children with CP.

## Effects of Different Pressure Lower-Body Compression Garments on Proprioception

Siyao Wang<sup>1</sup>, Hanjun Li<sup>2</sup>

<sup>1,2</sup>Sports Science College, Beijing Sports University, Beijing, China

Email: [1178449559@qq.com](mailto:1178449559@qq.com)

### Summary

To study the effects of different pressure lower-body compression garments (CGs) on proprioception. Male students (n=18) from Beijing Sports University were selected as participants in tests. Participants were required to perform in three trial conditions: wearing conventional shorts, low-pressure CGs and high-pressure CGs. These conditions were randomized for each subject. Participants were required to perform an active joint repositioning task with conducting a secondary cognitive task. The result was assessed by measuring repositioning error from baseline measures. The repositioning error while wearing high-pressure CGs was significantly reduced ( $P=0.04$ ). The effect of high-pressure CGs on proprioception was obvious. The high-pressure CGs significantly improved the ability of repositioning in the joint repositioning task with conducting a secondary cognitive task, which showed that CGs could improve the ability of proprioception. And it seems that the improvement of proprioception has relation with the pressure increase.

### Introduction

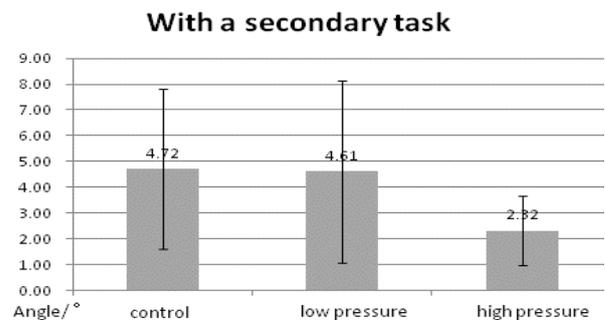

Balance is mainly depended on the visual system, the vestibular system and proprioception [1]. In a randomized controlled trial for institutionalized older adults, Luis Espejo-Antúnez [2] found that a proprioceptive exercise program demonstrated significant improvements compared with the control group in areas such as functional mobility, musculoskeletal endurance, balance, gait, and risk of falls in institutionalized older adults. This shows the importance of proprioception to balance, and it is by affecting proprioception that compression garments (CGs) affects balance.

### Methods

Participants: Eighteen healthy and active males (20.61±2.29 yrs, 175.28±3.36 cm, 70.22±6.63 kg) from Beijing Sports University volunteered to participate in this study. An eight camera motion analysis system was used to sample the participants' repositioning angle. Subjects' 3D trajectories were captured by using a motion capture, measurement and analysis software using the plug-in gait full body model. Twenty-one spherical shaped retro-reflective markers were used to define rigid, linked segments of the participant (pelvis, thighs, shanks and feet) during each trial. The 3D trajectories of the reflective markers (14 mm diameter) were computed with a dynamic accuracy of 0.5 mm. Participants were required to use their dominant legs to carry out an active (knee-joint) repositioning task while conducting a concurrent secondary task. They performed in three trial conditions: wearing conventional shorts, low-pressure CGs (pressure on quadriceps femoris=8.0kPa) and high-pressure

CGs (pressure on quadriceps femoris=17.5kPa). These conditions were randomized for each subject. The secondary task (random word generation) was designed to make conscious attention away from the repositioning task. The target angle for the repositioning task was a random angle from 30 to 45, respectively, to reduce learning effects. Statistical analyses were performed by using Statistical Package for Social Science (V. 25.0, SPSS Inc.). The experimental data was expressed as mean ± standard deviation (mean ± std). The post-hoc test used the LSD test.

### Results and Discussion

**Figure 1:** the error of reposition

The repositioning task is a general experiment to measure the proprioception. In this experiment, we use a knee-joint repositioning task. The cognitive task is added to interfere with the conscious attention, to maximize the effects of different pants on proprioception. Figure 3 shows the knee-joint repositioning task without conducting a concurrent secondary task. It can be seen that the difference between the reposition while wearing conventional shorts has the smallest error, and low-pressure CGs get the largest one.

### Conclusions

High-pressure CGs is more conducive to reducing the error in reposition with a secondary task. Proprioception is very important when conscious control was gone. It shows that CGs could improve the ability of proprioception, and it seems that the improvement of proprioception has relation with the pressure increase.

## Comparison of foot kinematics of toe walking in the able-bodied to spastic equinus gait of cerebral palsy

**Beomki Yoo**<sup>1</sup>, Wonhee Lee<sup>1</sup>, Dongho Park<sup>1</sup>, Dain Shim<sup>1</sup>, Joong-on Choi<sup>1</sup>, **Dong-wook Rha**<sup>1</sup>

<sup>1</sup>Department and Research Institute of Rehabilitation Medicine, Yonsei University College of Medicine, Seoul, Republic of Korea

Email: medicus@yonsei.ac.kr

### Summary

Various neurological and musculoskeletal disorders can induce pathologic toe walking, also called equinus gait, and lead to changes in foot kinematics during walking[1]. Knowledge of foot kinematics during toe walking by non-disabled individuals is necessary to understand changes in foot kinematics during pathologic toe walking. Foot kinematics of spastic equinus gait of cerebral palsy were different from those of toe walking in young non-disabled persons.

### Introduction

Toe walking is a gait without the heel-strike during the stance phase. Various neurological and musculoskeletal disorders can induce pathologic toe walking, also called equinus gait, and lead to changes in foot kinematics during walking[1]. Knowledge of foot kinematics during toe walking by able-bodied individuals is necessary to understand changes in foot kinematics during pathologic toe walking. In this study, we compared foot and ankle kinematics between toe walking in young non-disabled persons and spastic equinus gait of cerebral palsy.

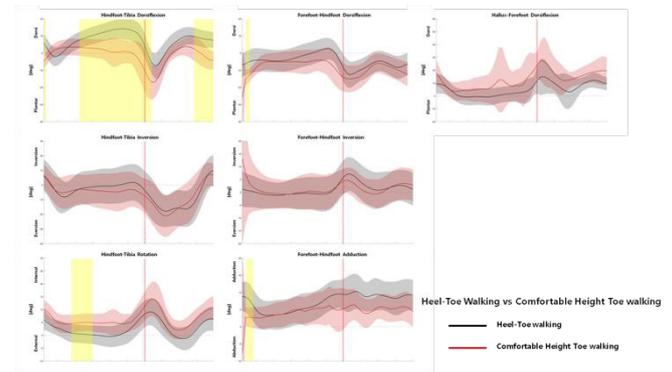

### Methods

The study group was consisted of fifteen young non-disabled adults (7 males and 8 females, age  $23.1 \pm 2.5$  years old) and fifteen children(3-18 years of age) with spastic cerebral palsy who had true equinus gait pattern(maximum ankle dorsiflexion during stance phase was less than 5 degrees). The group of non-disabled persons walked in two conditions: Heel-toe walking(HW) and comfortable height toe walking(CTW) that kept lifting their heels to a height that was most comfortable for walking. All of participants walked at self-selected comfort speed through 10-meter pathway. Each trial was recorded using a 6-camera motion analysis system (MX-T10, Vicon, UK) and kinematic data were calculated. A modified Helen Hayes marker set for lower limbs and Oxford Foot Model for foot and ankle were used for analysis. Foot kinematics between each group were analyzed by paired t-test and student t-test using SPM.

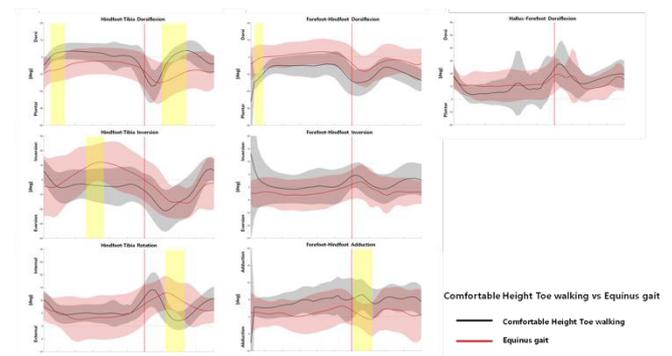

### Results and Discussion

Between HT and CTW in non-disabled group, there were no differences in foot kinematics on coronal plane. The hindfoot internal rotation and the forefoot abduction were higher for CTW than HW during stance phase ( $p < 0.05$ )(Fig. 1). Between CTW and spastic equinus gait, the hindfoot inversion was higher for spastic equinus gait during mid stance phase( $p < 0.05$ ). The hindfoot internal rotation and the

forefoot abduction was higher for spastic equinus gait than CTW during swing phase( $p < 0.05$ )(Fig. 2).

**Figure 1.** Between HW and CTW, mean kinematic angle of the hindfoot relative to the tibia, the forefoot relative to the hindfoot, and the hallux relative to the forefoot during the gait cycles of participants. Statistically significant differences are represented by yellow band. All of the kinematic angle curves were normalized over the gait cycle.

**Figure 2.** Between CTW and spastic equinus gait, mean kinematic angle of the hindfoot relative to the tibia, the forefoot relative to the hindfoot, and the hallux relative to the forefoot during the gait cycles of participants. Statistically significant differences are represented by yellow band. All of the kinematic angle curves were normalized over the gait cycle.

### Conclusions

Foot kinematics of spastic equinus gait of cerebral palsy were different from those of toe walking in young non-disabled persons.

# Systematic Review of In Vivo Foot and Ankle Kinematics during Gait Measured Using a Dual Fluoroscopic Imaging System

Dongqiang Ye<sup>1</sup>, Xiaole Sun<sup>1</sup>, Cui Zhang<sup>1,2</sup>, Shen Zhang<sup>1</sup>, Xini Zhang<sup>1</sup>, Shaobai Wang<sup>1</sup>, Weijie Fu<sup>1</sup>

<sup>1</sup> School of Kinesiology, Shanghai University of Sport, Shanghai, China

<sup>2</sup> Shandong Institute of Sport Science, Jinan, China

Email: fuweijie@sus.edu.cn

## Summary

The dual fluoroscopic imaging system (DFIS) is a potential valuable measuring tool that can detect small differences in the six degree-of-freedom (6DOF) in foot and ankle joints, especially when wearing shoes for both healthy and pathological populations. Thus, DFIS application is greatly important to understand the role of foot and ankle in human movement, identify abnormal joint movements and cure foot and ankle diseases.

## Introduction

The foot and ankle joints play an important role in dynamic activities of the human body and are always the focus of biomechanics and medicine to prevent injury and speed up recovery [1]. While the technical deficiencies in traditional medical imaging methods limit the study of in vivo foot and ankle biomechanics. DFIS provides accurate and non-invasive measurements of dynamic and static activities in joints of the body (Figure 1). This paper evaluates existing literature that used DFIS to measure the in vivo kinematics of the foot and ankle during various activities in healthy and pathologic populations to provide effective theoretical support and constructive research direction for the future study of human foot and ankle.

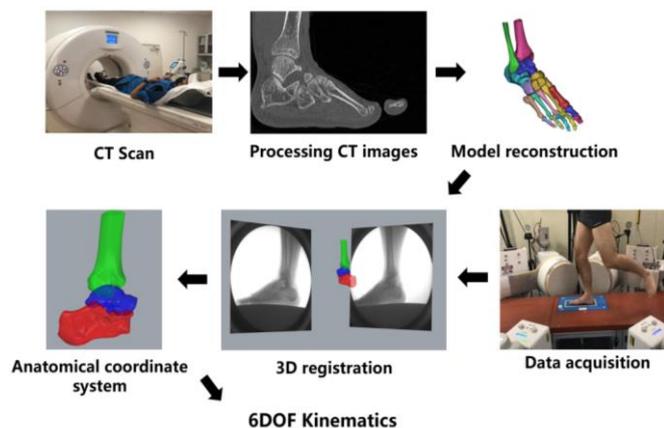

Figure 1: Process of DFIS in determining in-vivo foot and ankle kinematics

## Methods

This systematic review was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines [2]. PubMed, WoS, and EBSCO databases were searched from inception to April 2020 for related biomechanical studies that used DFIS. 20 experimental studies were identified after excluding the duplicated and irrelevant articles (Figure 2).

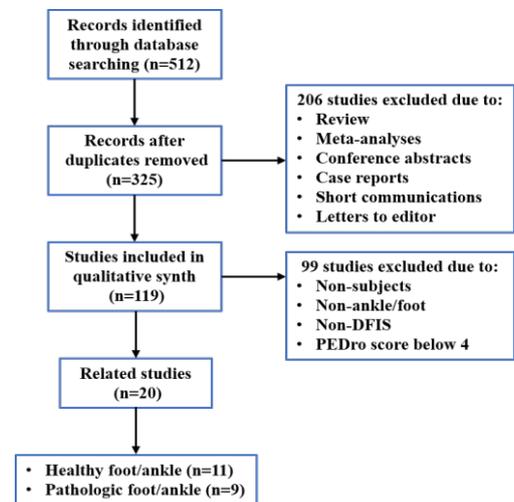

Figure 2: Literature search and study selection.

## Results and Discussion

Included studies were categorised into healthy populations and injured conditions. Main findings: 1) the tibiotalar and subtalar joints are capable of 6DOF motion during activities for healthy people in barefoot conditions, 2) the minimalist shoes could not mimic barefoot running; meanwhile, the motion control shoes decreased the navicular drop compared with barefoot and minimal shoes, 3) patients with lateral ankle ligament sprains (LAS) and chronic ankle instability showed larger anterior/posterior translation and inversion of the tibiotalar joint than healthy control during walking and stair descent, and 4) the ankle brace thought to protect the foot neither limits anterior translation and plantarflexion of the subtalar joints nor improves abnormal foot movements.

## Conclusions

DFIS has incomparable advantages compared with traditional biomechanical measurement methods. It detects small but substantial differences in foot and ankle 6DOF kinematics for healthy and pathological populations, especially those LAS patients. Therefore, future research should broaden the application of DFIS in foot and ankle biomechanics and even kinesiology.

### Summary

The comfort in the binding parts of a wearable robot is essential for the human-robot interaction which can cause skin lesions and pressure ulcer. VAS (visual analogue scale) was used to quantify the comfort. The assessment was performed on four different levels of pressure using a pneumatic cuff on the thigh, the shank, and the knee. The comfort was analyzed using the temperature, PI index and SpO<sub>2</sub>. The more pain was found in the thigh than in the shank or the knee. The present study would be helpful to determine an optimal binding parts for a standing wearable robot.

### Introduction

With the development of robot technology, the wearable robot has been widely used [1]. Human-robot interfaces refers to the physical interaction between the user and the wearable robot. If an excessive load persists, it can lead to soft tissue damage such as pressure ulcers [2]. It is necessary to define a comfortable binding part in a standing wearable robot. The interface pressure depends on the cuff design and the human anatomy. With the pressure for a relatively long time, the temperature and the oxygen saturation in the blood also change.

### Methods

Twenty healthy subjects (10 males and 10 females, age: 23.7±1.9years, height: 170.1±8.3cm, weight: 68.8±11.4kg) participated in the experiment. Measurements were made at 5 different locations (anterior/posterior of the thigh(TA/TP), anterior of the knee(K), and anterior/posterior of the shank(SA/SP)) using a pressure sensor (14x14cm, Pliance, Novel, Germany), a pneumatic cuff (DTS-2000s, DS Maref, Korea), a temperature sensor (RDXL6SD, Omega, Canada), a PPG sensor (Ubpulse 360, Laxtha, Korea) and a SpO<sub>2</sub> sensor (PM100N, Covidien, Ireland). The cuff pressure was set in 10, 20, 30 and 40 kPa. VAS ('0': no pain, '10': worst possible pain) was obtained based on VAS = 1 for 10kPa of the thigh after applying pressure for 2 min. The temperature was measured under the cuff. PPG and SpO<sub>2</sub> were attached to the distal ends of fingers and toes, respectively. Areas of interests were defined as three different masks (medial, center and lateral) to analyze the pressure distribution. Statistical analysis was performed using IBM SPSS Statistics 25 (IBM, New York, NY, USA) (p < 0.05).

### Results and Discussion

The interface pressure and VAS increased with the increasing cuff pressure. Larger pressure was observed in the medial parts of TA and K. In SA and SP, the medial and lateral parts

showed higher pressure than the center part. Large pressure in the center part was shown in only TP. No significant differences in the mean pressure were found among the thigh, the knee and the shank. No significant gender difference in the mean pressure was also observed.

**Table 1:** VAS for cuff pressures in different locations

Pressure [kPa]	TA	TP	K	SA	SP
10	1.02 ± 0.45	0.68 ± 0.36	0.15 ± 0.20	0.24 ± 0.29	0.29 ± 0.35
20	2.30 ± 0.93	1.90 ± 0.70	1.12 ± 0.47	1.08 ± 0.45	1.07 ± 0.68
30	4.01 ± 1.20	3.64 ± 1.16	2.22 ± 1.01	2.04 ± 0.86	1.95 ± 1.33
40	5.48 ± 1.60	5.52 ± 1.69	3.21 ± 1.42	3.24 ± 1.45	3.14 ± 1.62

Table 1 shows VAS values for different cuff pressures at each location. The change in VAS as well as VAS itself were the largest in the thigh. Results showed no significant differences in temperature, SpO<sub>2</sub> and PI index for different cuff pressures. The increase in cuff pressure did not increase the temperature in that location even though the temperature increased due to the long period wearing. Localized pressures affected neither oxygen supply to the entire body nor PI index. SpO<sub>2</sub> would not be reliable to determine comfort because of the motion artifact.

### Conclusions

VAS, interface pressures, temperature, PI index and SpO<sub>2</sub> were measured to determine the comfort in different cuff pressures for the lower extremity. Even though no significant differences in the interface pressure was found, the more pain was found in the thigh when the same pressure was applied. Temperature, PI index and SpO<sub>2</sub> would not be good indicators for the comfort assessment.

## The Differences between Bonded and Frictional Contact Settings in Foot-Sneaker Finite Element Analysis

Email: 1114181977@qq.com

### Summary

In finite element analysis, different contact settings will affect the accuracy of simulation results. In order to obtain a reliable foot-sneaker coupling model, this experiment compared the simulation results of binding contact and friction contact models to discuss the problem of contact surface setting in finite element simulation of foot and ankle, so as to provide an optimal contact setting for future research in this field.

### Introduction

Finite element analysis had been widely used in researches of mechanical changes of foot skeletons, ligaments, plantar aponeurosis and other soft structures. However previous studies have not provided a uniform standard for the setting of bonded contact and frictional contact between foot-shoe connection [1].

By comparing the measured results with the simulated results to analyze which contact model is more accurate. And to determine a more realistic connection model through the simulated results of bonded contact and frictional contact.

### Methods

CT scan was performed to obtain the foot-shoe imaging data of one subject(67kg) wearing experimental shoes and CT data saved as DICOM files. The Mimics19.0 and Ansys19.1 software were used to reverse model the foot-sneaker finite element model. By setting the connection of foot and shoe as bonded contact and frictional contact(frictional coefficient 0.5) to get two coupled finite element models. The contact between shoe and support plate was set as frictional contact with frictional coefficient 0.6 and those two coupled models should be used to simulate human static standing when force reaction was half weight(328N) [2]. Through Pedar-x pressure insole to measure plantar pressures of subject under static standing. In order to obtain more accurate comparison result, the plantar was divided into 10 regions [3], A-J, both pressure insole result and simulation. And the peak plantar pressure of these 10 regions was selected for comparison analysis and it would be compared with simulation data.

### Results and Discussion

The bonded contact model has a poor simulation effect on the peak pressure of the forefoot, with a maximum error of 1576.7% but friction contact model has a peak pressure error of only 55.9% in the same region. It means that the friction contact is

closer to the actual working condition than the bonded contact..

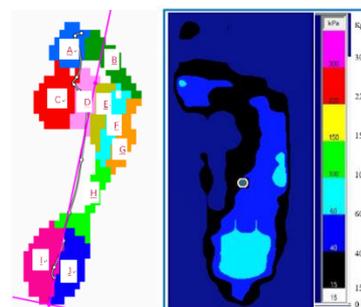

Figure 1: Plantar regions(left) and pressure insole result(right).

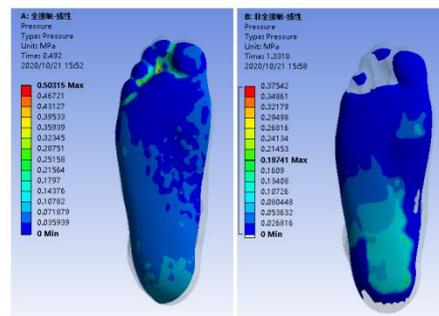

Figure 2: Bonded contact result (left) and frictional contact result(right).

Any model must be doing validation before mechanical simulations [4]. Although heel pressures of these two contact models were very close to measured results, the finite element model of foot-shoe without verification of other plantar regions shouldn't be used in simulation study.

### Conclusions

The friction contact model can accurately reflect the mechanical changes of the foot inner structures and plantar pressures. It is suggested that the frictional contact setting of foot-sneaker connection should be carried out in the future finite analysis.

## Summary

The purpose of the present investigation was to examine the mechanomyogram (MMG) with dynamic behavior. Six adult males (mean  $\pm$  SD age = 23  $\pm$  1) were performed concentric muscle action of the forearm flexion from 40deg to 140deg. To measure MMG, a microphone and an accelerometer were placed on the biceps branch muscle. The MMG signal was calculated microphone's MMG amplitude (MMGmic) and accelerometer's MMG amplitude (MMGacc) every 10deg of elbow flexion. We found that MMGmic was increased as the elbow flexion increased. However, there was not an increase in MMGacc. The result was considered that there were effects of mechanical artifacts such as body movement with the accelerometer. Therefore, it was considered that the microphone was suitable for measuring the MMG with dynamic behavior.

## Introduction

The MMG is mechanical vibration by the lateral expansion of active muscle fibers [1]. MMG is important as a way to obtain biometric information. To measure MMG, an accelerometer was widely used. However, this transducer has a problem of susceptibility to mechanical artifacts. Research of this problem made progress and it was found that a microphone of the transducer was preferred for measuring MMG during static behavior because effects of mechanical artifacts with a microphone were less than an accelerometer in case of static behavior [2]. Although MMG with a microphone during static behavior was studied, MMG with a microphone during dynamic behavior was not studied. Therefore, the microphone will need to study the effectiveness of the microphone during dynamic behavior. In this study, we examine the MMG during dynamic behavior using a microphone and an accelerometer.

## Methods

The subjects were six adult males (mean  $\pm$  SD age = 23  $\pm$  1). Microphone and accelerometer were placed on the biceps branch muscle with double-sided tape and a bipolar electrode was placed similarly to measure electromyogram (EMG). Elbow flexion was recorded while measuring MMG and EMG.

In the first, the maximum voluntary contraction (MVC) was measured. Then the subjects were asked to the flexed elbow from 40deg to 140deg and performed three trials at the velocity and under the weight. The velocities of the order were 10deg/s and 20deg/s. The weights corresponded to approximately 20% MVC and 40% MVC. The subjects took a rest for five minutes each the velocities and the weights

MMG and EMG amplitudes were estimated as the mean of the root mean square (RMS) of three trials. The values of RMS were calculated every 10deg of elbow flexion between 60deg and 120deg.

## Results and Discussion

Fig.1 presents the relationship between RMS and elbow flexion at 40% MVC. There was an increase in EMG from 60deg to 120deg. There was an increase in MMGmic as well. However, there was not an increase in MMGacc. If we showed Fig.1, we find the difference in the velocities. There was a comparative increase in EMG and MMG. Similar propensities were shown at 20% MVC.

EMG RMS reflects the level of recruitment and firing rates of the motor units. The propensity of MMGmic was similar to the propensity of EMG. This result is considered that MMGmic reflected the level of recruitment and firing rates of the motor units without effects of mechanical artifacts. The difference between MMGmic and MMGacc was considered that there were effects of mechanical artifacts with the accelerometer as well as during static behavior.

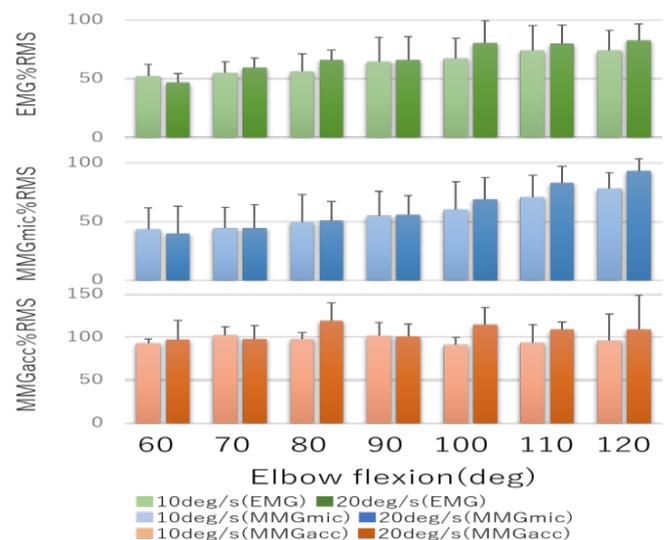

Figure 1: The relationship between elbow flexion and %RMS in EMG and MMG

## Conclusions

This study investigated MMG with a microphone and an accelerometer during dynamic behavior and compared them. The result indicated MMGmic was increased and MMGacc was not increased as elbow flexion increased. These findings suggest that the microphone was suitable for measuring the MMG during dynamic behavior as well as during static behavior.

# The Functional Role of Collagen Content in the Human Cartilage Cell Microenvironment

Awuniji Linus<sup>1</sup>, Ari Ronkainen<sup>2</sup>, Rami Korhonen<sup>1</sup>, Petri Tanska<sup>1</sup>

<sup>1</sup>University of Eastern Finland, <sup>2</sup>Kuopio University Hospital

## Summary

Recently, we observed that collagen content in the cartilage pericellular matrix (PCM, a narrow region around cartilage cells) is reduced in human osteoarthritis. However, it is unknown how this content reduction affects cell volume, and thus, potentially cell synthesis. Here, we conducted a parametric multiscale modeling analysis using experimentally characterized human cartilage material properties to simulate how the changes in the PCM collagen content alter cell volumes following mechanical loading. The parametric analysis was conducted for the superficial and middle zone cartilage. We observed that the PCM collagen content modulates cell volume in a tissue depth specific manner. Reduced PCM collagen content reduced cell volume increase in the superficial zone (up to ~20%), but barely affected cells in the middle zone (changes less than 1%).

## Introduction
