Cartilage cells, chondrocytes, synthesize collagen, and proteoglycan (PG) molecules of the extracellular matrix (ECM). Their turnover is affected by the mechanical forces experienced by the cells and these mechanical signals are modulated and transferred to cells by the PCM [1]. Recent studies have suggested that PG content alterations that occur, especially during early phases of osteoarthritis, may alter the volumetric deformation of chondrocytes [2]. This may lead to altered cell synthesis. Recently, we observed that collagen content is reduced in the PCM of the middle zone cartilage during early osteoarthritis in human tissue [3]. However, it is unknown how these collagen content alterations contribute to the cell deformation. Thus, this study aimed to conduct a parametric investigation on how changes in the pericellular collagen content modulate cell volume using a computational multiscale modeling approach.

## Methods

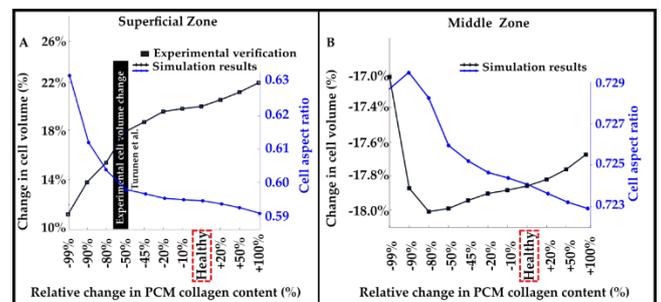

An axisymmetric ( $h = 2.83$  mm,  $r = 4$  mm) model of bulk cartilage was constructed in Abaqus/CAE (Providence, RI USA). A fibril-reinforced poroelastic swelling (FRPES) model with measured human cartilage properties, i.e. mechanical material parameters, depth-wise collagen architecture, collagen content and PG content, was used [4]. Two distinct zones were defined according to cartilage thickness, superficial zone: 0-10% and middle zone: 10-25%. Additional cell-level submodels representing the chondrocyte microenvironment (cell, PCM, and local ECM) were constructed at the center of each zone. The structure and composition of the PCM were based on the experiments and literature [1, 3]. After swelling equilibrium was established, a stress-relaxation test (10% compression at 10  $\mu$ m/s followed by a 20 min relaxation) in indentation geometry (indenter diameter = 1 mm) was imposed on the bulk cartilage model,

while the cell-level submodel was driven by the displacements and pore pressures of the bulk model. A parametric analysis was conducted by varying the PCM collagen content to assess its effect on cell volume change and aspect ratio after relaxation. This analysis also included an experimentally detected decrease in the human PCM collagen content; from healthy to -20% [3] in osteoarthritis. The average composition of healthy tissue served as a reference.

## Results and Discussion

Changes in cell volume were zone specific. In the superficial cartilage, the mechanical loading resulted in an increased cell volume when compared to the initial swelling equilibrium state (Figure. 1A). Reduction in the PCM collagen content reduced this cell volume increase. In the middle zone, mechanical loading resulted in decreased cell volume when compared to the initial swelling equilibrium state (Figure. 1B). Reduction in the PCM collagen content barely affected the cell volume change (cell volume change was less than 1%).

Earlier both increased and decreased cell volumes have been observed experimentally and computationally in the superficial zone of cartilage [2]. Increased cell volume has been earlier linked mostly to cartilage softening in OA, allowing greater cell expansion in mechanically loaded cartilage. Here, analogously, the cell volume increase in the superficial zone is likely related to the relatively soft human cartilage, compared to other species.

**Figure 1:** Simulated cell volume changes in the superficial and middle zone human cartilage.

## Conclusions

Following mechanical loading of cartilage *in situ*, the PCM collagen content alters cell volume in a depth-specific manner, with superficial zone cells being more sensitive to the PCM collagen content changes than the middle zone cells.

# ROLE OF ACTIN FILAMENT IN DYNAMIC CHANGES OF INTRANUCLEAR STRAIN INDUCED BY CYCLIC STRETCHING

T. ASAKAWA<sup>1</sup>, S. Tsukamoto<sup>1</sup>, N. Takesue<sup>1</sup>, N. Sakamoto<sup>1</sup>

Email: asakawa-takumi@ed.tmu.ac.jp

## Summary

Mechanical stimuli such as cell-substrate cyclic stretching are transmitted to the nucleus via actin filaments and thought to changes in cell function and morphology with changes in gene expression, but the mechanisms behind these relationships are still unclear. Here, we investigated changes in intranuclear strain induced by continuous cyclic stretching. The strain in the center of the nucleus induced by substrate stretching was higher than that in the periphery before the application of cyclic stretching. After exposure to continuous cyclic stretching for 15 min, strain at both the central and peripheral regions of the nucleus increased. Inhibition of actin filament polymerization abolished the changes in local strain caused by cyclic stretching. These results indicate that the local strain in the nucleus changes in response to cyclic stretching, and actin filaments play an important role in its change.

## Introduction

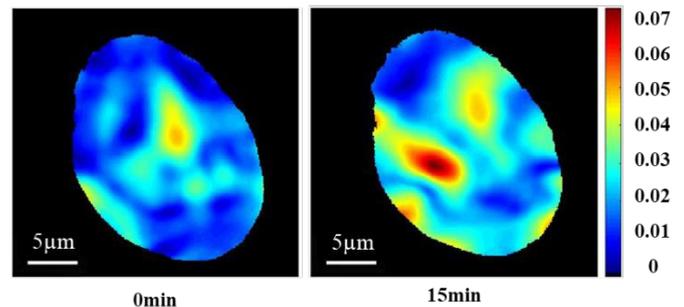

Cells change their morphology and function in response to mechanical stimuli from the surrounding environment [1]. Mechanical stimuli transmitted from the cell-substrate through actin filaments cause nuclear deformation, which has been recently recognized as an important factor regulating chromatin structure and transcription factor binding to DNA [2]. Since the structure of actin filaments as well as mechanical properties of the nucleus changes in response to mechanical stimuli [3, 4], dynamic changes of nuclear deformation caused by mechanical stimuli need to be elucidated to understand the role of nuclear deformation in cell responses. We have developed a technique to evaluate cell-substrate stretching-induced nuclear strain with consideration of its heterogeneity [5]. In the present study, we investigated the changes of local intranuclear strain in a cell under a cyclic stretching condition.

## Methods

To evaluate intranuclear strain induced by the substrate stretching, fluorescence images of the nucleus in a cell-seeded in a stretch chamber (Strex, Japan) were taken before and after applying a 10% step-stretching of the chamber using a custom-made uniaxial stretching device equipped on the stage of an inverted microscope (Olympus, Japan), and Von Mises equivalent strain then calculated with Ncorr according to the method previously reported [5]. Cells before and after exposure to continuous cyclic stretching for 15 min were evaluated. To assess the role of actin cytoskeletons, cells were treated with 1  $\mu$ M cytochalasin D, an inhibitor of actin filament polymerization, for 15 min prior to the continuous cyclic stretching.

## Results and Discussion

The nuclear strain in the central region caused by the substrate stretching was higher than that in the periphery before the application of continuous cyclic stretching (Fig. 1), which is consistent with our previous work [5]. After exposure to continuous stretching for 15 min, nuclear strains at both the central and the peripheral regions increased. Treatment with cytochalasin D abolished the changes in the local strain caused by continuous cyclic stretching (data not shown), suggesting that force transmission through actin filaments is crucial for changes in intranuclear strain induced by exposure to continuous cyclic stretching. There are two possible mechanisms that cause the changes of intranuclear strains by continuous cyclic stretching; changes of actin filament structure which affects force transmission to the nucleus [4], and changes in the deformability of the nucleus. We will perform further studies to elucidate these mechanisms that causes the changes of local strain.

**Figure 1:** Von Mises equivalent strain distribution under a 10% step-stretching condition (before (0 min), and after exposure to continuous cyclic stretching for 15 min).

## Conclusions

The present study shows that local nuclear strain increased after being subjected to cyclic stretching, and the actin filaments are thought to be responsible for the change of the nuclear strain.

## Dynamic responses of cells govern the boundary instability at the closing wound

Hyuntae Jeong<sup>1</sup>, Jinwook Yeo<sup>1</sup>, Seunghwa Ryu<sup>\*1</sup>, and Jennifer H. Shin<sup>\*1</sup>

<sup>1</sup>Dept. Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea

### Summary

Motions and forces in cells play critical roles in many pathophysiological events. Especially, wound healing requires dynamic responses of cells to achieve the boundary closure, which includes migration of active leader cells and tensional forces to tug the follower cells. Interplays between these two factors result in a complex interfacial landscape. Here, we investigated the correlations in dynamic responses of cells that give rise to interfacial instabilities. We found that the density-based cellular pressure governed the development of the instability in the boundary landscape, and the frequency of these instabilities was shown to correlate directly to the closure speeds of the wound.

### Introduction

Cells' dynamic behaviors, marked by motions and forces, arise as consequences of complicated biochemical interactions amongst proteins and macromolecules within the cells. The dynamic behavior of individual cells also determines the collective functions of cell clusters through the physical responses amongst neighboring cells in various physiological events [1]. Especially, the wound closure is predominantly achieved by the collective cell migration of the epithelial cell layer resulting in boundary proceedings. Many studies have reported the boundary movement-induced interfacial instabilities that stemmed from the heterogeneously distributed collective motions near the boundary [2]. The interfacial instability presents varying curvatures whose values correlate with the cellular forces near the curve. Therefore, understanding this instability phenomenon would be fundamental to modeling the wound closures.

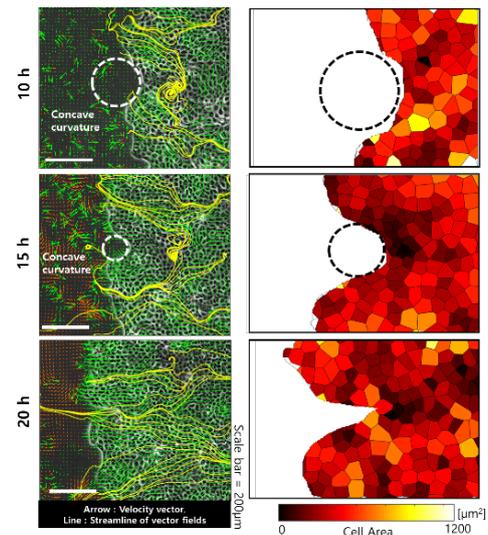

### Methods

As an epithelial tissue model for wound healing, we used the normal kidney epithelial cell line, Madin-Darby Canine Kidney (MDCK). We patterned a silicon wafer with engravures of various geometries to use it as a mold to fabricate a polydimethylsiloxane (PDMS)-based stencil. We then put the stencil on the culture dish with cell suspension and waited until the cells were grown to ~90% confluency. Then, the PDMS stencil was carefully removed to make undamaged wound shapes. Migrations and forces of cells were visualized by DPIV(Digital Particle Image Velocimetry) and TFM(Traction Force Microscopy), respectively, to quantify the mechanical behaviors of the cells.

### Results and Discussion

During the wound closures, interfacial instability was formed due to the differential accumulation of cellular motilities near the boundary. The constantly protruding cells at the wound boundary formed the finger-like extrusions, and retarded cells between two adjacent fingers exhibited concave

edges. The spreading area of the following cells simultaneously changed according to the proceeding speeds of the leading front. The overly compressed cells behind the concave edge gave the expansion pressure to the adjacent cells, then the novel streamlines were formed. By these sequential processes of physical features, the vacant area at the concave edge was closed. Consequently, we found that the interfacial instability was formed by the heterogeneously distributed migrating cells and was modified by cellular pressures amongst adjacent cells.

**Figure 1:** Interfacial instability correlated to the physical behaviors of cells near the boundary.

### Conclusions

Here, we analyzed the formation of interfacial instabilities during the wound closure for advancing the knowledge about this complex phenomenon in terms of dynamic responses between cells. The visualized physical traits, especially the cellular migrations and shapes, demonstrated the interesting mechanisms for regulating the interfacial instability not in a stochastic manner. We expected these results would be a fundamental source for developing the mechanical model for wound closures.

## Hypoxic postconditioning on astrocyte activation in a 3D cortical stroke model

Mong Lung Steve Poon<sup>1</sup>, Eunmin Ko<sup>1</sup>, Eunyong Park<sup>1</sup>, Jennifer H. Shin<sup>1,\*</sup>

<sup>1</sup>The Shin Lab, Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, South Korea  
Email: j\_shin@kaist.ac.kr

### Summary

Hypoxic postconditioning (HPC) has been shown to protect brain from secondary reperfusion injury after stroke. However, the optimal protocol for HPC has not been investigated. The current study aims to examine the effect of HPC on the functional recovery of the brain cells after stroke using a 3D spheroidal cortical stroke model. Based on astrocyte activation indicated by GFAP expression, we found that single hypoxia treatment most significantly enhanced the GFAP expression of astrocytes within the cortical stroke model.

### Introduction

Hypoxic postconditioning (HPC) has emerged as a promising strategy to block secondary reperfusion injuries after stroke [1]. A variety of treatment protocols for HPC had been examined, including single hypoxia treatment for 1h or 2h or repeated intermittent hypoxia treatments for 1h or 2h with 24h intervals. Nonetheless, a few studies have reported the protective effect of HPC among different protocols. Therefore, we aim to investigate the optimal protocol for HPC using a 3D cortical stroke model based on astrocyte activation as indicated by GFAP expression.

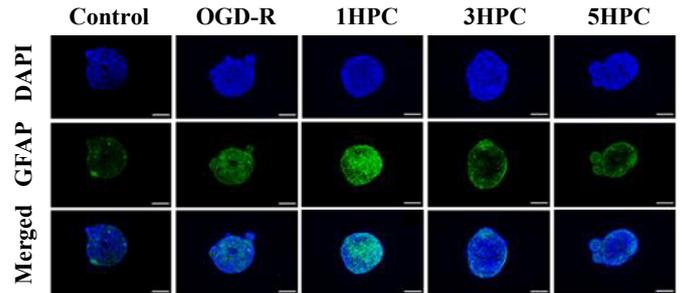

### Methods

Primary rat cortical cells were isolated from postnatal day 1-2 Sprague Dawley rat pups. Dissociated cortical cells were mixed with the culture medium (Neurobasal-A, B27 (1X), GlutaMAX (100X), and Penicillin–Streptomycin (1X)). The cell suspension was seeded onto the 96-well round-bottom Ultra-low attachment (ULA) plate and incubated at 37°C with 5% CO<sub>2</sub>. Half of the culture medium was replaced with fresh medium every three days. Stroke induction was achieved by oxygen-glucose deprivation-reoxygenation (OGD-R). In brief, samples on day 7 were suspended in the culture medium without GlutaMAX and exposed to hypoxia (1% O<sub>2</sub>) for 4h, followed by 24h of reoxygenation. For hypoxic postconditioning (HPC), single hypoxia treatment for 2h (1HPC) and three (3HPC) or five (5HPC) intermittent hypoxia treatments for 2h spaced at 24h intervals were applied to the samples after reoxygenation with 1% O<sub>2</sub> and normal culture medium. All samples were collected 144h after reoxygenation.

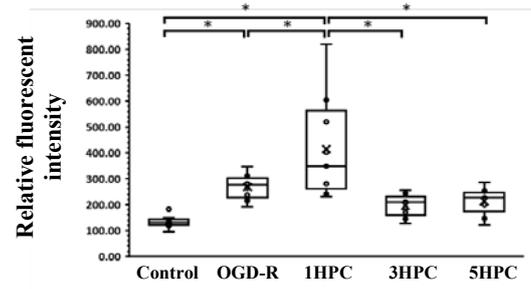

### Results and Discussion

After a stroke, astrocytes become reactive, exhibiting increasing GFAP expression. These reactive astrocytes are essential to tissue remodeling and restoration of cellular integrity [2]. Therefore, to examine the effect of HPC in promoting functional recovery, GFAP within the cortical

spheroids was immunostained. Stroke induction by OGD-R significantly enhanced GFAP expression compared to the control. 1HPC further upregulated the GFAP expression. However, 3HPC significantly suppressed the GFAP expression compared to 1HPC. 3HPC and 5HPC shown no significant difference in GFAP expression. This result suggested that 1HPC best enhanced the astrocyte activation within the cortical stroke model.

**Figure 1:** Immunofluorescent images of GFAP (green) and DAPI (blue) in cryosectioned cortical spheroids. Scale bars represent 200 μm.

**Figure 2:** Box plots of relative fluorescent intensity of GFAP expression within the cortical spheroids. Data are expressed as means ± S.D. (\* $p < 0.05$ ).

### Conclusions

Single hypoxia has the greatest potential to promote astrocyte activation and hence promote functional recovery of the brain after stroke. Our study emphasizes the need to consider the differential effect of HPC on stroke under varying protocols.

Email: j\_shin@kaist.ac.kr, jinhchoi@uos.ac.kr

### Summary

This study investigated the physical traits and mechano-stress response of human bronchial epithelial cells, BEAS-2B, to two different biocides, PHMG and CMIT/MIT, known as toxic components in humidifier disinfectants. When exposed to these biocides, the cells exhibited distinct average responses in their biophysical traits, and the heterogeneity in the responses was significantly higher in CMIT/MIT treated cells. Traction and intercellular stresses of the cellular monolayer were also measured over 24 hours based on live imaging data where two biocides showed remarkably distinct temporal responses. Based on the temporal stress evolution over 24 hours, protein and gene expressions were analyzed at specific time points for further confirmation of the changes in the physiological state of the cells. This study will contribute to the proper management of hazardous biocides related to humidifier disinfectants.

### Introduction

Changes in the physical parameters of the cells can be important indicators of stress response because they are closely associated with changes in cellular functions. Physical traits allow continuous monitoring over a long culture time based on live-imaging data from which the morphological features and the stresses at the cell-matrix and cell-cell adhesions can be conveniently assessed.

From 2006 to 2011, fatal lung injury was observed, which later confirmed the chemical disinfectants (PHMG and CMIT/MIT) used in household humidifiers as the causal agents. In this study, we conducted the various real-time imaging-based cell-mechanical analysis using these two biocides on human lung cells.

### Methods

BEAS-2B cells were obtained from American Type Culture Collection and cultured under a normal culture condition. Polyacrylamide (PA) gel (3kPa) and collagen type I were used to construct *in vitro* measurement platform. Traction and intercellular stress were measured based on the displacements of the fluorescent beads embedded in the PA gel. For the monolayer stress analysis, we cultured BEAS-2B cells on circular patterned collagen. This circular island was created by PDMS stencil to allow selective attachment of the cells only inside the circular pattern.

### Results and Discussion

We characterized the cell and nuclear size, nuclear aspect ratio and cell traction based on single-cell measurements. While the

average responses of all 4 parameters were not significantly different, the degree of dispersion measured by standard deviation was remarkably higher in CMIT/MIT treated conditions.

Traction and intercellular stress of cells in the monolayer were also measured. The stress of PHMG and CMIT/MIT treated condition exhibited unique temporal responses compared to that of control during 24hours (Figure 1). We also investigate the expression of actin structures by immunofluorescence imaging and specific biomarkers (TGF- $\beta$  and pSMAD-2) by western blot at two specific time points based on temporal stress evolution.

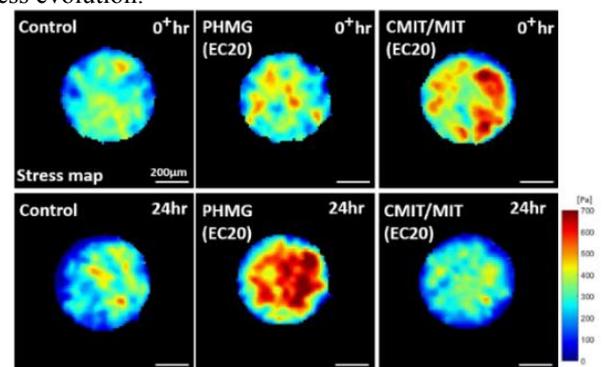

Figure 1: Temporal evolution of stress map.

### Conclusions

This study highlights the strength of live imaging-based biophysical analysis that can provide a temporal portrait of the cellular response over a long time. The comparative analysis between CMIT/MIT and PHMG enabled better understanding of less studied substance, CMIT/MIT, in relation to a more studied substance, PHMG. Furthermore, this study is meaningful in that it can contribute to the proper management of hazardous biocides related to humidifier disinfectants.

## Arm Profile Score represents ability of activity using upper limb in individual with stroke.

Dain Shim<sup>1</sup>, Deog Young Kim<sup>1</sup>, Joong-on Choi<sup>1</sup>, Dongho Park<sup>1</sup>, Beomki Yoo<sup>1</sup>,  
Dong-wook Rha<sup>1</sup>

<sup>1</sup> Department and Research Institute of Rehabilitation Medicine, Yonsei University College of Medicine  
Email: medicus@yonsei.ac.kr

### Summary

Arm Profile Score (APS) is a simple index that evaluates severity of upper limb movement pathology based on kinematic data. The correlation between APS and the clinical upper limb function test in hemiplegic persons with stroke was measured. APS correlated moderately with the BBT and JHFT, which measure the ability of the activity using the upper limb.

### Introduction

The 3D upper limb motion analysis is increasingly used to measure the impairment of the upper limb in persons with stroke, but it is difficult to interpret the enormous kinematic data. [1]

Arm Profile Score (APS) and Arm Variable Scores (AVS) are quantitative measurements that compare the characteristics of upper limb kinematics in individuals with motor impairments to those of non-disabled persons in a direct and simple way. [2]

The purpose of this study is to investigate whether the APS and AVS derived from 3D motion analysis reflect the upper limb function in hemiplegic persons with stroke.

### Methods

A total of 74 individuals with stroke (44 males, 30 females; mean age 60±15.3 years) who could perform the Reach and Grasp Cycle [3] were recruited. Upper extremity subscale of the Fugl-Meyer assessment (FMA-UE), Box and Block Test (BBT), Jebsen-Taylor Hand Function Test (JHFT) were conducted. Computerized motion analysis was conducted during the Reach & Grasp Cycle include 4 tasks; reaching out to the cup and grabbing the cup, lifting the cup to the mouth, putting the cup back in its original position, and putting the hand back in place.

APS was calculated from root mean square error of the kinematic data of the subject with upper limb motor impairment compared to the mean kinematic value of non-disabled persons as a reference data. APS can be decomposed into 10 AVS representing each joint of upper extremity; thorax (3), shoulder (3), elbow (1), wrist (3) joints. [2] To evaluate correlations of APS and AVS with clinical upper limb function tests, the Spearman rank coefficient was used.

### Results and Discussion

APS during Reach & Grasp Cycle showed moderate negative correlation with BBT score ( $r^s = -0.581$ ;  $p < 0.01$ ). (Table. 1)

Especially, AVS of wrist rotation showed moderate negative correlation with BBT score ( $r^s = -0.513$ ;  $p < 0.01$ ).

APS during Reach & Grasp Cycle showed moderate positive correlation with most items of JHFT ( $r^s = 0.460-0.526$ ;  $p < 0.01$ ). Especially, AVS of shoulder abduction/adduction showed moderate positive correlation with writing and lifting large object items of JHFT ( $r^s = 0.433-0.520$ ;  $p < 0.01$ ).

APS correlated moderately with BBT and JHFT, which measure the activity ability using the upper limb. But APS showed no significant correlation with FMA-UE, which measures physical function rather than ability of activity using upper limb.

**Table 1:** Spearman rank correlation between upper limb function measurements and the APS in hemiplegic persons with stroke.

	APS
<b>Box and Block Test (n=67)</b>	-0.581**
<b>Jebsen Taylor hand function test (n=39)</b>	
Writing	0.365*
Turning cards	0.363*
Lifting small objects	0.336*
Simulated feeding	0.460**
Stacking checkers	0.486**
Lifting Large, Light object	0.492**
Lifting Large, Heavy object	0.526**

\*  $P < 0.05$  by Spearman's rank correlation test

\*\*  $P < 0.01$  by Spearman's rank correlation test

### Conclusions

BBT and JHFT, measuring limitation of upper limb activities, showed moderate correlation with APS. However, FMA-UE, measuring impairments of upper limb functions and structures, showed no significant correlation with APS. APS may be able to reflect activity limitation better than functional impairments of upper limb.

### Summary

Degenerative Disc Disease (DDD) is a major musculoskeletal disorder often surgically operated using fusion implants and associated with high failure rates. Statistical shape models (SSM) can predict patient-specific geometry to better predict clinical outcomes. By performing principle component analysis on vertebrae, sacrum and pelvis the main modes of shape variation within the population was captured. The predictive capability of SSM was compared between with and without integrating bone measurements. The results showed that with the measurements, SSM can better predict the bone shapes by 0.38mm (average across all of the bones) in case of RMS. For Dice score it improved by 3.5%, 2.3%, 3.5%, 2.4%, 3% and 1.35% respectively.

### Introduction

DDD is a major musculoskeletal disorder often surgically operated using fusion implants. However, the surgery is associated with high failure rates (up to 40%), with only 25% of failures may be revised [1]. SSM can predict patient-specific geometry and compare intersubjective variability to better predict clinical outcomes. Therefore, the aim of this study was to compare the prediction accuracy of lumbar vertebrae, pelvis and sacrum bone shapes with different input measurements to the SSM.

### Methods

De-identified CT scans (Siemens, Munich, Germany) from 79 healthy adult participants were collected (43 F, 45 ±6 y.o.). A total of 70 L1, L2 and L3, 67 L4, 68 L5, 64 sacrum and pelvic surfaces were segmented using Mimics (Materialise, Belgium) and remeshed using 3Matics. Template meshes were built for each vertebral level, sacrum, and pelvis. Bones coordinate system were built for each template according to the ISB standard [2]. Manually reconstructed bone surfaces were fitted and aligned to each template meshes for nodal correspondence. A PCA was performed on each vertebral level, sacrum and pelvis using an in-house python library, GLAS2 [3]. Based on the PCA outcome we extracted the

weights from 69 principal component and imported it in a Partial Least Square Regression (PLSR) along with the patient's age and sex. Additional bone measurements were included to the PLSR such as vertebral height length and width (for L1 to L5), sacrum's S1 upper plateau length and width and pelvic ASIS and PSIS distances. A leave one out analysis (LOO) was performed to understand the predictive power of each model; with and without bone measurements. Prediction accuracy was quantified by computing the Root Mean Square (RMS) error of the Euclidian distance and the Dice score quantified between the SSM-predicted shapes and CT-reconstructed shapes.

### Results and Discussion

For L1-L5, the first three PCs accounted for 1) the vertebral body height, 2) posterior arch shape variation, and 3) superior, inferior articular process variations respectively. For the pelvis and sacrum, the first and second PCs described 1) bone height and 2) width variation and the third PC described iliac width (pelvis) and superior articular process (sacrum) shape variation. For the SSM models, the comparison between RMS and dice score for the 7 bones are shown in Table 1. In this work, we have developed a SSM of the lumbar vertebrae, sacrum, and pelvis on 72 healthy participants. We also aimed to compare the predictive capability of SSM considering with and without landmarks. Our results demonstrated that when we consider the anatomical landmarks in our SSM, the results improve significantly.

### Conclusions

Bone shape prediction of the lumbar vertebra, sacrum and pelvis were more promising considering integrating bone measurement as input to the SSM.

## Evidence Literature Summary: Patellofemoral pain in adolescents and objective test routines for the movement analysis laboratory

Josephine Meissner<sup>1</sup>, Katharina Hermes<sup>1</sup>, Annika Stampfler<sup>2</sup>, Beat Göpfert<sup>3</sup>

<sup>1</sup>Health Division, Bern University of Applied Sciences, Bern, Switzerland

<sup>2</sup>BZG, Bildungszentrum Gesundheit Basel-Stadt, Münchenstein, Switzerland

<sup>3</sup>Department Biomedical Engineering, University of Basel & University Children's Hospital Basel; Switzerland

Email: beat.goepfert@unibas.ch

### Summary

Patellofemoral pain in adolescents is a common pathology but there are no standardized test routines for movement analysis laboratories. An evidence literature summary could not find any specific information for adolescents. An extended literature search found some functional tests for adults. The described tests suggest, that squatting and climbing stairs should be used as progress parameters.

### Introduction

Patellofemoral pain (PFS) in adolescents and adults is one of the most common pathologies of the musculoskeletal system [1]. Up to 30% of adolescents are affected by this pain, especially girls and physically active people [2]. The cause of PFS is largely unclear [3]. Because of this, there are no clear guidelines for treatment. Physiotherapy is usually the first intervention in PFS. [4].

### Methods

A literature search on PFS, test routines and adolescents was carried out. Due to a lack of studies, adults were included in a second search until May 17 2020.

- Used Databases: PubMed, Embase, Web of Science, Cochrane Library, Google Scholar.
- Articles published by May 17, 2020
- Evaluating the risk of bias (GATE-Frame, DELBI)
- Rating the Grade of Recommendation (A-E) based on the OCEBM Level of Evidence (Oxford Centre for Evidence Based Medicine)

### Results

No literature could be found in relation to the question of objective PFS test routines and adolescents. Nonetheless, a study was included in the analysis because it provided meaningful insights. Eleven articles were included in the adult literature search (Tab 1).

**Table 1:** Summary table of the included articles. VGRF = Vertical Ground Reaction Force; EMG = electromyography; ↑ = climb up; ↓ = go down; DELBI = German Guideline Evaluation Instrument

As part of this work, a study was found that examines and compares the reliability of various functional tests [5].

### Discussion

- Functional tests like squatting and climbing and descending stairs are best suited.
- As reliable are described: Lateral and forward step-down as well as the single leg hop test.
- For EMG measurements, it is recommended to measure in the frequency domain instead of the time domain.
- Due to possible different causes of PFS in adolescents and adults, the suggested tests can only be used with caution.
- Inconsistent test execution makes it difficult to compare the functional tests.

### Grades of recommendation for the various tests according to OCEBM [18].

- Squatting and climbing stairs
- EMG measurements using the frequency domain
- Frontal Plain Projection Angle during SLS; Lateral and Forward Step-down; Vertical Ground Reaction Force during the forward step-down

### Conclusions

The articles reviewed did not provide consistent evidence of the accuracy of the tests. The results suggest that functional tasks such as squatting and climbing stairs should be used as progress parameters. In the future, standardized tests with homogeneous samples will have to be carried out.

## Kinematics Comparison of Two Posterior Stabilized Knee Implants During Daily Activities

Chang Shu<sup>1</sup>, Fangjian Chen<sup>1</sup>, Michael Bates<sup>2</sup>, Ronald W. Singer<sup>2</sup> and Nigel Zheng<sup>1</sup>  
<sup>1</sup>The University of North Carolina at Charlotte, NC, <sup>2</sup>OrthoCarolina, NC, USA  
 Email: nzheng@uncc.edu

### Summary

Posterior stabilized (PS) TKA implant is the optimal choice for patient who needs knee replacement surgery but has relatively weak posterior cruciate ligament (PCL). It is important to assist surgeons to identify appropriate PS implants due to their different philosophy of design. This study compared two popular PS implants (Journey II, Persona) kinematically for level walking and stair ascending and found the significant differences between the implants.

### Introduction

Total knee arthroplasty (TKA) is the most common surgical procedure aiming at reducing pain and improving physical function for patients with end-stage knee osteoarthritis. Posterior-stabilized (PS) knee implants were designed for patients with an incompetent or attenuated PCL [1]. The amount of bone resection may be related to the risk of popliteus tendon injury [2]. The aim of this study was to compare two PS knee implants (Journey II from Smith & Nephew, Persona from Zimmer) with healthy controls. 3-D knee joint kinematics of TKA patients and control group were compared during five daily activities such as level walking (LW) and stair ascending (SA). We hypothesized that there was no significant difference of two selected implants in 3D knee joint motion during daily activities.

### Methods

20 patients with Journey II (J), 20 patients with Persona (P) implant and 11 healthy subjects (CG) were recruited. Both implant groups were tested pre-op and 6-month post-op using a motion capture system (FX 40, VICON). Due to the pandemic, only 10 patients with J and 8 patients with P completed the 6-month post-op tests. The knee joint kinematics were computed using a custom developed MATLAB program (MathWorks Inc.) One-way ANOVA was performed with 0.05 alpha level.

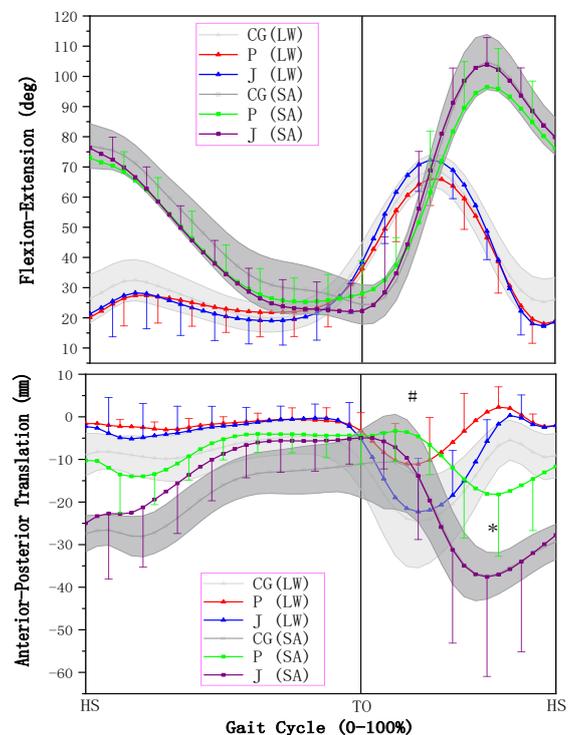

### Results and Discussion

There were no significant differences in demography and pre-op knee joint kinematics between two groups. Group P had a knee flexion deficit during these activities (Fig.1). Group J had a closer range of motion (ROM) as CG than group P. AP

**Table 1:** Knee joint flexion/extension (deg), anterior/posterior translation (mm) and their range of motion (ROM) at 6-month post-op. \*: significant difference between two implants.

	Level Walking			Stair Ascent		
	P	J	CG	P	J	CG
Flex.	66±9	72±9	74±6	100±9	106±9	108±10
Ext.	17±8	15±7	17±5	23±7	20±7	24±6
ROM	50±8*	57±5	57±7	79±6	86±6	83±8
Ant.	4±3	3±3	-2±3	1±5	-4±7	-3±3
Post.	-13±8*	-24±11	-26±11	-21±13*	-42±19	-41±15
ROM	17±6*	27±9	24±8	22±12*	39±15	31±13

translation in group J was closer to normal knee than patients in group P. Group P exhibited a significant deficit in posterior translation (Figure.1). The statistical significances were found between the two groups (Table.1). Although the joint rotation at the early stance phase was similar, the maximum knee flexion and ROM were different. Similar results for AP translation, the posterior translation and ROM were different between the two implants. Thus, the hypothesis was rejected. The difference may be linked to the different designs in cam-post shape of two implants. Further research is needed to explore the causes of these differences in knee joint movement and develop an optimal PS implant design.

**Figure 1:** Knee flexion(+)/extension(-) and anterior(+)/posterior(-) translation. # and \* represent the significant difference between group P and group J in terms of level walking (LW) and stair ascent (SA), respectively.

### Conclusions

Findings from this study indicated implant design had influence on the functional improvement. Furthermore, it will provide useful information to PS knee implant design.

### Acknowledgments

### Summary

This study presents a novel exploration of the biomechanics of the lower limb joints in adults with JHS during a high intensity physical task - the vertical jump test (Figure 1). This study showed that people with JHS are able to actively stiffen their joints during a high intensity task. Considering that multiple joint hypermobility is the primary feature in JHS. These changes can be considered dominant and should be maximized during rehabilitation to improve the activity of people with JHS.

### Introduction

Biomechanical impairments are not apparent during walking in people with Joint Hypermobility Syndrome (JHS). This research explored biomechanical alterations during a higher intensity task, vertical jumping.

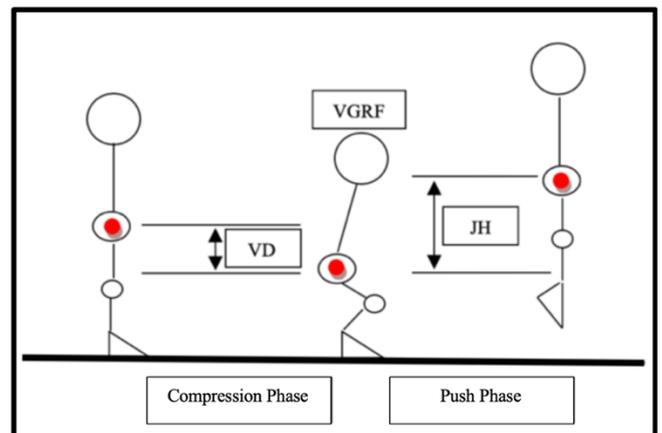

### Methods

This cross-sectional study compared a JHS group (n=29) to a healthy control group (n=30). Joint kinematics and kinetics were recorded using a Qualisys motion capture system synchronized with a Kistler platform. Independent sample t-tests and standardized mean differences (SMD) were used for statistical analysis.

### Results and Discussion

No significant statistical or clinical differences were found between groups in joint kinematics and jump height ( $p \geq 0.01$ ). Sagittal hip and knee peak power generation were statistically lower in the JHS group during the compression phase ( $p \leq 0.01$ ), but not clinically relevant ( $SMD < 0.5$ ). Clinically relevant reductions were found in the JHS group knee and ankle peak moments during the compression phase, and hip and knee peak power generation during the push phase

( $SMD \geq 0.5$ ), although these were not statistically significant ( $p \geq 0.01$ ).

**Figure 1:** A drawing illustrating the jump test phases: compression and push phase. The compression phase is the phase between still standing to the lowest reached distance before the jump. The push phase is the phase between the first frame after the lowest reached distance to the maximum height reached. A pelvis marker; the red dot, was used to measure vertical displacement and jump height. VD = vertical displacement, VGRF = vertical ground reaction force, JH = jump height.

### Conclusions

The JHS group achieved a similar jump height but with some biomechanical alterations. Further understanding of the joint biomechanical behavior could help to optimize management strategies for JHS, potentially focusing on neuromuscular control and strength/power training.

# Are biomechanics during gait associated with the structural onset and progression of lower limb osteoarthritis? A systematic review and meta-analysis.

Email: ndso3565@uni.sydney.edu.au

## Summary

The objective of this systematic review and meta-analysis is to evaluate if gait biomechanics are associated with increased risk of structurally diagnosed onset or progression of lower limb osteoarthritis (OA). Twenty out of the twenty-one included studies found an association between at least one biomechanical measure and structural onset/progression defined by image-based changes/ conduct of replacement surgeries. PROSPERO: CRD42019133920

## Introduction

Osteoarthritis is one of the leading contributors to disability [1] in the world and is associated with a considerable economic burden to the individual, healthcare system, and the community [2]. In the attempt to reduce this burden, an understanding of the modifiable risk factors of disease onset and/or progression is needed. One of the key emerging risk factors for understanding OA onset and progression is theorised to be the loading of weight-bearing joints during gait [3].

## Methods

A systematic review of Medline and Embase was conducted from inception to November 21<sup>st</sup>, 2020. Records were screened, data extracted, and methodological quality assessed by two independent reviewers. Included studies reported gait biomechanics at baseline, and either structural imaging or joint replacement outcomes in lower limb at follow-up. The primary outcome was the Odds Ratio (OR) (95% confidence interval (CI)) of the association between biomechanical measures and structural OA outcomes with data pooled, where possible, for meta-analysis.

## Results and Discussion

Twenty-one studies reporting 28 different biomechanical measures and 10 OA imaging outcomes were included. Eighteen studies investigated knee OA progression; two of these also investigated knee OA onset. Three studies investigated hip OA progression. No longitudinal studies were found in relation to biomechanics and the risk of ankle OA or progression. Study quality score ranged from 14-20 out of 21

points. All but one study (95%) reported a significant association between at least one biomechanical outcome and OA onset or progression. There was an association between frontal plane kinematics and kinetics with medial tibiofemoral OA progression, and sagittal plane kinetics with patellofemoral and hip OA progression. Meta-analyses demonstrated increased odds of medial tibiofemoral OA progression with greater baseline early stance peak knee adduction moment (KAM) (Figure 1) (OR: 2.00 [95%CI: 1.04-3.84]), and varus thrust prevalence (Figure 2) (OR: 2.00 [95%CI: 1.32-2.98]).

Early stance peak KAM and medial tibiofemoral OA progression

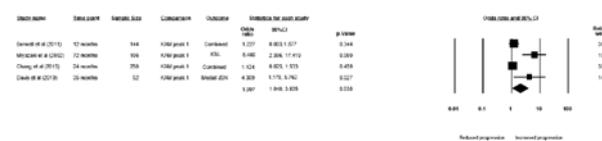

Figure 1: The association between early stance peak KAM and medial tibiofemoral OA progression.

Varus thrust and medial tibiofemoral OA progression

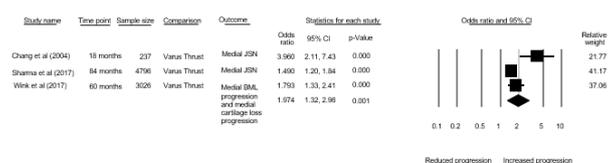

Figure 2: The association between varus thrust and medial tibiofemoral OA progression.

## Conclusions

There is evidence that certain gait biomechanics are associated with an increased odds of OA onset and progression in the knee, and progression in the hip.

## Influence of ankle joint angle on Achilles tendon stiffness

Evan D. Crotty<sup>1</sup>, Laura-Anne M. Furlong<sup>2</sup>, Andrew J. Harrison<sup>1</sup>

Biomechanics Research Unit, Department of Physical Education and Sport Sciences, University of Limerick, Limerick, Ireland<sup>1</sup>

### Summary

Tendon stiffness ( $K_T$ ) is a widely examined musculoskeletal measure due to its reported links with muscle-tendon unit performance and as a potential injury risk factor. This study examined the influence of ankle joint angle ( $\theta_{ANK}$ ) on  $K_T$  and the inter-day reliability of  $K_T$  across  $\theta_{ANK}$ .  $K_T$  was measured during maximal voluntary plantarflexion contractions at three  $\theta_{ANK}$ . A significant difference was not observed between  $K_T$  measured at the three  $\theta_{ANK}$  however,  $K_T$  at the dorsiflexion  $\theta_{ANK}$  demonstrated the best inter-day reliability. Measuring  $K_T$  at the dorsiflexion  $\theta_{ANK}$  may improve the reliability of the measure when examining  $K_T$  across multiple time periods.

### Introduction

$K_T$  is commonly examined using B-mode ultrasound and dynamometry during isometric contractions [1] but can be methodologically challenging. Variability in  $K_T$  can be attributed to a number of reasons including measurement equipment, inherent individual variation, and methodological issues e.g. tendon moment arm measurement and ankle joint rotation [1]. Researchers commonly examine  $K_T$  at a neutral  $\theta_{ANK}$  of  $0^\circ$  with the knee at  $180^\circ$ . Limited research has examined the influence of different  $\theta_{ANK}$  on  $K_T$ , and the reliability of  $K_T$  acquired during dynamometry and ultrasound-based protocols. The study aims to investigate changes in  $K_T$  across  $\theta_{ANK}$ . The objectives are: 1) to determine the inter-day reliability of  $K_T$  across  $\theta_{ANK}$ , 2) to examine  $K_T$  changes across  $\theta_{ANK}$ , and 3) to identify the main factors influencing  $K_T$  reliability.

### Methods

Fourteen physically active individuals (7 ♂, 7 ♀) performed isometric maximal voluntary plantarflexion contractions at three  $\theta_{ANK}$  ( $-10^\circ$  plantarflexion (PF),  $0^\circ$  (NE),  $10^\circ$  dorsiflexion (DF)) on a calibrated dynamometer (Con-trex, Dubendorf, Switzerland) on two occasions separated by 7 days. The distal aponeuroses of the gastrocnemius medialis were visualized using a 128-element linear ultrasound probe (Telemed, Vilnius, Lithuania) during the contractions. Tendon force was estimated by dividing ankle moment by the tendon moment arm. Tendon elongation was digitized and corrected for elongation due to joint rotation. Resting tendon

length was calculated at rest with the knee at  $180^\circ$  and ankle joint plantarflexed at  $-20^\circ$ .  $K_T$  was calculated as the slope of the force elongation (relative  $K_T$ ), and force strain (absolute  $K_T$ ) relationship between 10% and 90% of maximal tendon force. A one-way repeated measures ANOVA and Bonferroni post-hoc test examined  $K_T$  differences across  $\theta_{ANK}$ . Inter-day reliability was examined using intra-class correlation coefficient (ICC), mean difference (Mdiff), coefficient of variation (CV), and effect size (ES).

### Results and Discussion

**Reliability:**  $K_T$  at the DF  $\theta_{ANK}$  demonstrated the best inter-day reliability for relative and absolute  $K_T$  (Table 1). Further investigation of the components that contribute to the calculation of  $K_T$  showed that time to maximum tendon force demonstrated improved inter-day reliability (ICC = 0.651) at the DF  $\theta_{ANK}$  compared to other  $\theta_{ANK}$  (PF ICC = 0.268, NE ICC = 0.255). Time to maximum tendon force is a factor in calculating tendon strain rate, and tendon strain rate is known to influence calculated  $K_T$  [2]. Thus, improved inter-day reliability of this component of tendon strain rate may contribute to the improved reliability of  $K_T$  at the DF  $\theta_{ANK}$ .

**Ankle angle:**  $K_T$  tended to increase as  $\theta_{ANK}$  moved from PF toward DF (Table 1). No significant difference was observed between the three  $\theta_{ANK}$  for  $K_T$  measures.

### Conclusions

$K_T$  measured at the DF  $\theta_{ANK}$  demonstrated improved inter-day reliability, potentially due to a participant's ability to produce a more uniform tendon strain rate at this  $\theta_{ANK}$ . Examining  $K_T$  at this  $\theta_{ANK}$  could improve the reliability of  $K_T$  for studies examining the influence of mechanical loading on tendon adaptation over multiple time periods.

## Summary

Developing Brain-Computer Interfaces (BCI) with reproducible and stable Information Transfer Rate (ITR) is challenging as many cognitive and neural factors [1] influence an individual's ability to perform a specific cognitive task. One such factor is dysregulation of brain iron metabolism [2] which profoundly affects neurophysiological mechanisms, neural connectivity and brain structures. This study attempts to understand whether dysregulation of ferritin iron in motor and frontal lobes of individuals plays a significant role in fluctuation in ITR of the BCI system for early prediction of motor intention in hand gripping task. The study further presents novel microstate-based Motion Related Cortical Potential (MRCP) neural information as input information for deep learning models.

## Introduction

The neural circuitry of motor intention is complex and varies inter-individually based on functional, structural and metabolic differences. This poses a challenge in developing a motor intention decoding BCI system with stable ITR. Recently, dysregulation of ferritin-iron deposited in brain regions was found to affect dementia and motor disorders. This study thus aims to understand the influence of iron deposited in the neural circuitry of motor intention on the ITR of the BCI system that classifies motor intention. The study also presents novel microstate-based MRCP neural information for training Long Short Time Memory–Stacked Autoencoder (LSTM-SAE) algorithms [3].

## Methods

80 healthy, non-anemic, right-handed volunteers participated in simultaneous EEG-fMRI and Susceptibility Weighted Imaging (SWI) through 3T MRI and 32 Channel MR Compatible EEG systems. Each volunteer performed 90 randomized motor tasks of hand grip and release. The acquired data was subjected to the methodology illustrated in (Figure 1) consisting of two analyses: the development of a Deep neural BCI system based on microstate MRCP neural information, and the quantification of iron in the neural circuitry of motor intention. MRCP microstate analysis was carried out by collecting MRCP (0.2Hz to 2.5 Hz) [4] from pre-processed EEG prior to every motor action and the data was subjected to k-mean based microstate EEG analysis. The resultant microstates were back fitted to every

individual's EEG data and subsequently used to train the deep learning system LSTM-SAE. The performance of the trained BCI system was assessed by estimating its classification accuracy and ITR. Additionally, the neural circuitry of motor intention was estimated by subjecting MRCP information to EEG informed fMRI analysis. Then the SWI images were preprocessed and subjected to Quantitative Susceptibility Mapping (QSM) [5] for ferritin-iron quantification in the neural circuitry of motor intention. Finally, the estimated iron quantity was correlated with the ITR of the BCI system of the individual.

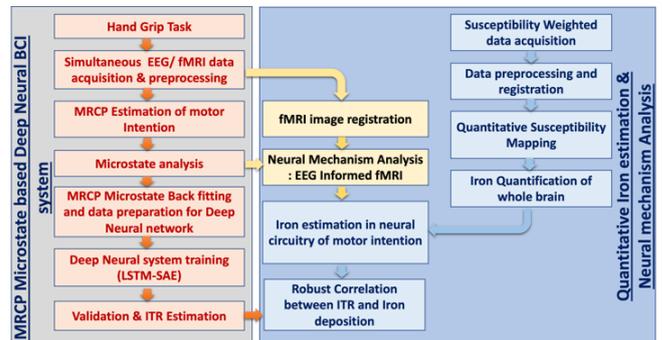

Figure 1: Overview of methodology employed

## Results and Discussion

The performance of trained MRCP based LSTM-SAE BCI system is correlated with the iron quantification in the neural circuitry of motor intention as shown in (Table 1). It was found that Cerebellum, Lingual, Medial Frontal, Pre and Postcentral gyri have significant engagement during motor intention and corresponding iron quantification is observed to be correlating negatively with the ITR of the BCI system.

## Conclusions

Iron dysregulation in the cerebellum, motor, frontal and cortical regions in healthy people is strongly associated with the neural engagement of motor intention and thus affects the ITR of the BCI system.

**Summary:** Recent interest in musculoskeletal connective tissues—e.g. tendon, aponeurosis, and fascia—has motivated *in vivo* medical imaging of these tissues, particularly using MRI. Due to the rapid T2\* decay properties of collagenous tissues, advanced ultrashort echo time (UTE) MRI sequences are useful to produce images with high signal[1-2]. UTE MRI is now practical for connective tissue imaging, but limitations still exist, especially in signal and contrast. Image post processing can be implemented to improve feature extraction, particularly for thin tissues that may otherwise be obscured in images. Here we outline image processing methods suitable for enhancing MRI of the thin musculoskeletal connective tissues of aponeurosis and fascia.

**Keywords:** Connective Tissue, MRI, fascia, aponeurosis, imaging, image processing, feature extraction.

**Introduction:** MRI of fascia and aponeurosis is important for biomechanics and modeling applications of the musculoskeletal system, for anatomical assessment and probing clinical pathologies such as myofasciitis or compartment syndrome. The challenge of imaging these tissues with MRI has motivated the exploration of image processing methods that may enhance imaging and modeling of fascia and aponeurosis. We present four image processing techniques for fascia and aponeurosis imaging, and we identify and segment aponeurosis and fascia in processed images.

**Methods:** MRI was conducted on three participants on two different 3T MRI scanners which had different sequences available to trial. All images were collected using dual-echo ultrashort echo time (UTE) non-Cartesian MRI. Images collected on a 3T Siemens Skyra were acquired with a 2D stack of spirals sequence[3]. Images collected on a 3T GE Signa Premier were acquired with a 3D radial cones sequence[4]. In-plane spatial resolution was between 0.3x0.3 mm<sup>2</sup> and 0.5x0.5 mm<sup>2</sup> and the slice thickness was between 3mm and 5mm.

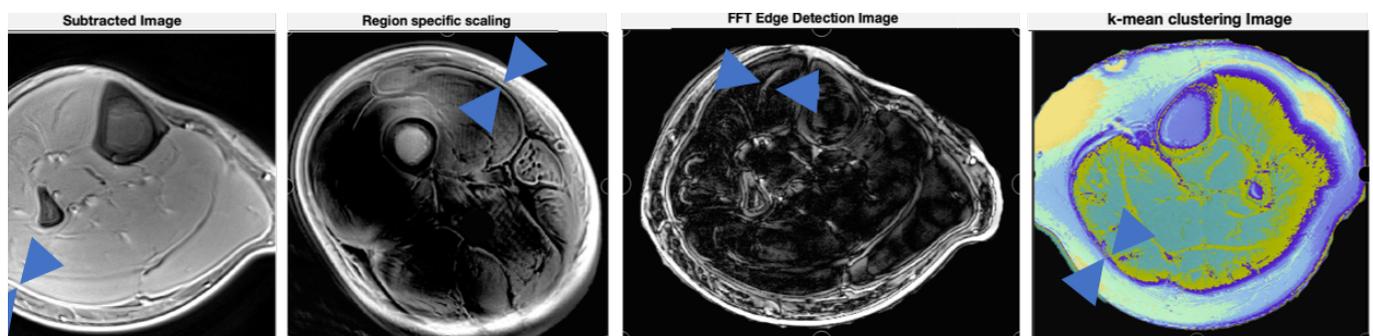

**Tissue localization Methods:** *Dual-echo image subtraction:* We use subtraction between the UTE image and the short TE image from our dual echo protocol to enhance connective tissue contrast. *Region specific scaling:* Region specific scaling was applied to reduce the signal intensity of unwanted tissues in one of the dual-echo images such that those signals cancel with less residual noise. This is useful for fat or muscle signal suppression to improve connective tissue contrast. *FFT edge detection:* Edge detection was implemented using a high-pass filter in the Fourier domain. This approach highlights the transition between muscle and internal connective tissue, resulting in high contrast in aponeurosis. *K-means Clustering:* Applied over dual-echo UTE images, this identifies regions by intensity and connectedness. In generic k-means clustering, each data point belongs to the cluster with the nearest mean. In our case, this approach identifies unique regions within the image that may not be easily identifiable via naked eye inspection.

**Results and Discussion:** Images of fascia and aponeurosis from our image processing methods are shown in Fig 1, regions of interest displaying fascia and/or aponeurosis are highlighted with arrows. Fascia was identified to run along the peripheral surface of muscle structures with widths between 1mm and 1.5mm. Aponeurosis width in the tibialis anterior was 1.8±0.2mm.

**Conclusion:** This work suggested several feature extraction image processing methods that could be used to enhance the MR signal quality of connective tissue in UTE MRI. Results demonstrate that fascia and aponeurosis are identifiable and measurable and suggest that these techniques improve imaging and modeling of thin connective tissues from MRI.

### Summary

This study aims to investigate the correlations of cardiac mechanical parameters in tissue speckle tracking measurement and the coronary artery stenosis diagnosed by cardiac catheterization in patients with clinically diagnosed coronary artery disease (CAD). The actual stenosis rate in catheterization proved the evidence of this technique to assess coronary artery condition and implied the application of non-invasive method of tissue speckle tracking to evaluate the CAD.

### Introduction

It is widely known that cardiovascular disease is a leading cause of mortality worldwide. CAD, a major adverse cardiac event is coronary stenosis, which is the underlying cause of ischemia, myocardial infarction, and sudden cardiac death. Although coronary angiography is the gold standard method to identify a blockage in cardiac vessels, catheterization is relatively invasive compared to other methods. Echocardiography is the most accessible and cost-effective technique routinely used for these patients. This non-invasive imaging model can detect the presence, extent and severity of the disease. Emerging ultrasound procedures such as tissue Doppler imaging, and the speckle tracking method are generally required as the first-line clinical utility [1]. Particularly, speckle tracking echocardiography can characterize cardiac mechanics [2].

### Methods

The clinical practice in the cardiology department at Taipei City Hospital Yangming Branch has been studied since August 2020. All suspected CAD patients (n=53) were recruited as selection criteria by clinical diagnosis. Among the patients, 140 vessels were evaluated by coronary angiography and echocardiography. All patients underwent comprehensive transthoracic imaging as clinically indicated to rule out significant valvular heart disease. All biological parameters derived from tissue Doppler imaging were collected for further analysis. The echocardiographic views, in standard apical 4 chambers, 3 chambers, and 2 chambers from tissue speckle tracking were selected to quantify the left ventricle myocardial strain using EchoPAC software; GE, Norway. The vessel strains of three main arteries; right coronary artery (RCA), circumflex artery (LCX), and left anterior descending artery (LAD) were quantified (Figure 1) in longitudinal strain of each wall (Figure 2). The studied vessels were categorized and diagnosed by cardiac catheterization. The luminal stenosis of three main arteries were quantified

angiographically. A stenosis rate of over 70% was regarded as severe stenosis. The results of vessel-supplied tissue tracking and catheterization were compared with each other. The risk factors hypertension, diabetes mellitus, and serum lipid profile were also determined. The statistic analysis was done using SPSS software.

### Results and Discussion

In total, 140 vessels in 53 patients were evaluated. The longitudinal strain of each vessel supplied area in severe stenosis vessels (n=39) ( $13.3 \pm 6.4$ ) was smaller than that of the insignificant stenosis vessel (n=101) ( $15.5 \pm 5.2$ ),  $p = 0.04$ . The results revealed that LAD, LCX and RCA vessel strain could be used to predict the stenosis condition in each coronary artery.

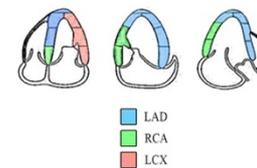

Figure 1: Myocardium is supplied by LAD, RCA and LCX.

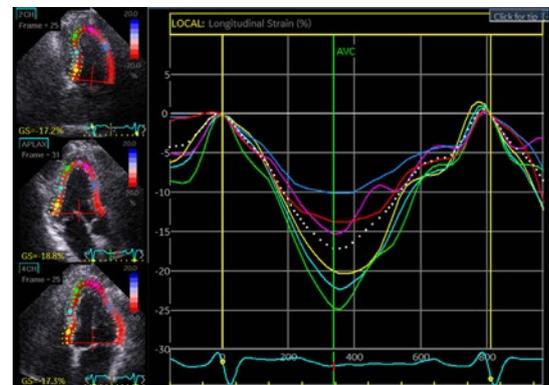

Figure 2: Myocardium was evaluated by tissue speckle tracking.

### Conclusions

The tissue speckle tracking can be evaluated in each myocardial segment to determine each vessel strain. The vessel strain is correlated to the actual stenosis condition in CAD patients.

### Summary

The present study aimed to investigate the differences in mechanical properties of hurdle bars. Bending test was performed on two hurdle bars made from different materials: ABS plastics and natural wood. From the bending test, load–deformation property was computed. The results of bending test were fitted with a regression line. There was a significant difference between the slopes of two regression lines. The wood bar was found to be more resistant to likely loads than the ABS bar. This finding suggests that materials used for the hurdle bar should consider when estimating the effect of hurdle hitting on race outcomes.

### Introduction

In hurdle events, hitting hurdle has been known to have a negative impact on race performance, and its magnitude is dependent on the hitting part of the body [1] and may also be explained by the mechanical properties of hurdle bars. However, the mechanical properties of hurdle bars have never been investigated to date. Therefore, this study aimed to investigate the differences in mechanical properties of hurdle bars.

### Methods

Two hurdle bars: made from ABS plastic and natural wood, were used for bending test. The test was performed five times to measure the deformation of the centre of bar against incremental loads (up to 10 kg from the World Athletics regulation [2]). A marker was attached to the centre of bar to detect its resultant deformation. A high-speed camera (FASTCAM Mini AX, Photron, Japan) was used to record the loaded deformations of the bars at 500Hz. Resultant deformation perpendicular to the bar was calculated using a motion analysis system (Frame-DIAS V, DKH, Japan). From this data, load–deformation property was computed as the relationship between the incremental loads (kg) and the resultant deformations (mm). In addition, the shore A hardness of each bar was measured at five points of each bar surface using shore A durometer (HTTK-37A, Tekcoplus Ltd., HKG). The results of bending test were fitted with a regression line. Analysis of covariance (ANCOVA) was used to compare the regression line slopes between the two conditions. A student's t-test was used to compare the shore A hardness between the two conditions. Significance level was set at  $\alpha < 0.01$ .

### Results and Discussion

Figure 1 shows the load–deformation property of ABS and wood bars. The slope of the regression line of the wood bar was steeper than that of the ABS bar, and there was a significant difference between the slopes ( $p < 0.01$ ). This finding indicated that the wood bar is more resistant to the given likely loads than the ABS bar. This could be affected by shore A hardness. In terms of shore A hardness, the wood bar was significantly harder than the ABS bar (Wood bar:  $93.5 \pm 0.8$  HA, ABS bar:  $87.1 \pm 0.7$  HA,  $p < 0.01$ ). A previous study speculated that hitting hurdles might not affect overall performance in the 110-m hurdle race [3], thereby conflicting with another study [1]. These inconsistent findings may have been partially affected by the differences in mechanical properties of hurdle bars. Thus, this finding suggests that a detailed investigation on the material of the bar is necessary to estimate the exact impact of hitting hurdles on resultant race outcomes.

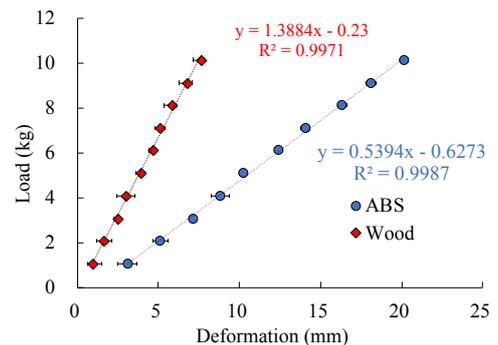

Figure 1: The load-deformation property between ABS and Wood

### Conclusions

The present study demonstrated a clear difference in the mechanical property of hurdle bars made from ABS plastic and natural wood. This difference may affect the impact force of hitting hurdle and should be taken into account when examining its exact effect on race outcomes.

## Reliability of measuring ACL injury risk associated knee morphology in adolescent females

### Summary

A comprehensive examination of early adolescent and adolescent knee morphologies associated with ACL injury provides critical knowledge of potential underlying risk, aiding efforts in injury prevention, ligament reconstruction and rehabilitation for this population. In this work, we characterize 11 morphological features of the tibia and femur that have a reported association with anterior cruciate ligament (ACL) injury risk using two raters and repeated measures. Measurements were conducted on retrospectively acquired MRI database of 36 healthy girls aged 13 to 18 years.

### Introduction

The number of pediatric and adolescent ACL reconstructions has dramatically increased over the past decade [1]. Due to chondral and meniscus injury in an unstable knee, reconstructive ACL surgery is often the preferred treatment for skeletally immature patients. Adolescent individuals with ACL injury experience reduced knee related quality of life, increased risk for early-onset knee osteoarthritis, and high re-injury rates. Greater understanding of risk factors for ACL injury is key to injury prevention. Studies on the occurrence of ACL risk knee morphologies in pediatric populations, especially early adolescent and skeletally immature populations are limited. In this study we report on the reliability of MRI-based anatomical parameters associated with ACL injury risk around the knee joint in a healthy female adolescent population.

### Methods

MRI datasets of adolescent girls between 13 to 18 years were retrospectively acquired (n = 36) from the Children's Mercy Hospital, Kansas City's radiology department. The data usage protocol was approved by the institutional review board. Each dataset was anonymized and examined by a radiologist for anatomical integrity and abnormality. Based on the literature,

11 morphological parameters were selected and manually measured (3D Slicer, ver. 4) in each acquired dataset. An instructive guideline was created based on the literature available for each of the parameters. Two independent and medically trained observers measured these parameters. Each observer performed the measurements twice. Inter-observer reliability was defined by intraclass correlation coefficient (ICC), using a two-way mixed effects ANOVA [3]. Intra-observer reproducibility was also defined by ICCs, using a two-way ANOVA and considering the choice of the observer as fixed effects [3]. All the ICCs were obtained using Matlab (Mathworks Inc., Natick, MA, USA).

### Results and Discussion

ICC for Intra-observer repeatability ranged from 0.43 to 0.96 and ICC for inter-observer reliability ranged from 0.01 to 0.86 (Table 1). Bicondylar width, femoral notch angle and femoral trochlear depth measures were found to be highly reliable and repeatable within and between the observers). Low reliability found in lateral femoral condylar ratio and Beck angle could be attributed to ambiguous instructions and guidance from the literature, which are open to observer interpretation.

### Conclusions

Achieving reliability in measuring the ACL risk factors is crucial for determining injury risk population and monitoring those. This study emphasizes the importance of clear and unambiguous guidelines in determining these measures.

### Acknowledgments

This study was partially funded by the University of Missouri South Africa Education Program (UMSAEP).

## The effect of low back pain on plantar pressure during gait

Clara Leyh<sup>1,2</sup>, Véronique Feipel<sup>1,2</sup>

<sup>1</sup>Laboratory of Functional Anatomy, Université Libre de Bruxelles (ULB), Belgium

<sup>2</sup>Laboratory of Anatomy, Biomechanics and Organogenesis, Université Libre de Bruxelles (ULB), Belgium

Email: [clara.leyh@ulb.be](mailto:clara.leyh@ulb.be)

### Summary

To evaluate the effect of low back pain (LBP) on the plantar pressure distribution, 125 subjects suffering of LBP and 94 healthy controls walked at three different self-selected speeds on the GAITRite instrumented walkway. While patients with LBP walked slower at fast speed, the results showed an integrated pressure (P\*t), a peak pressure and an active area impacted by LBP. Subjects with LBP increased P\*t at preferred and fast speeds at the lateral forefoot. Furthermore, subjects with LBP displayed an increase of P\*t and peak pressure in the heel region at slow speed, as well as decreased P\*t and peak pressure in the medial forefoot. Even if gait velocity was not identical between groups at fast speed, the results emphasize different foot loading and gait patterns in patients suffering from LBP.

### Introduction

The foot provides essential support during standing and gait. But in case of low back pain (LBP), especially with associated sciatica caused by nerve compression, a decrease of proprioceptive inputs and outputs on the foot sole and abnormal motion patterns could lead to changes in plantar pressure [1-2]. Because gait speed does not affect plantar pressure uniformly [3] and that patients with LBP are known to walk slower with shorter steps [4], a specific attention should be paid to the study of plantar pressure in subjects with LBP compared to healthy ones.

The aim of this study was therefore to evaluate the effect of low back pain on the evolution of plantar pressure parameters during gait at the lateral and medial heel, mid- and forefoot.

### Methods

125 low back pain subjects (LBP) and 94 healthy controls (HC) walked barefoot three times at three different self-selected speeds (slow, preferred, fast) over the GAITRite electronic walkway, (length: 6,1 m, CIR Systems). The order of gait speeds was randomized. Average values over all three trials were computed.

Each footprint is divided in 12 trapezoids (six medial and six lateral) by the GAITRite Gold software (version 3.9) and for each section, four plantar pressure variables are computed: **P\*t** (integrated pressure over time in one zone, expressed as a percentage of the overall integrated pressure over time), **peak time** (first time point at which one or more sensors in a zone were at their maximum level, expressed in seconds), **area** (sum of the active sensor areas within a zone; expressed in centimeters square) and **peak pressure** (maximum pressure per zone, expressed as a percentage of the overall maximum pressure per foot) [5]. To simplify the results, the data of the 12 trapezoids were assembled in 6 sections defined as medial and lateral fore-, mid- and hind-foot.

Normality of data distribution was explored. Repeated measures ANOVA were completed to analyze differences in pressure parameters between groups. Tukey HSD test were

computed to explore interactions between groups, pressure zones, and velocity. Level of significance was set at  $p < 0.05$ .

### Results

No statistical differences were observed between CG and LBP groups for age and gender. Gait velocity was similar in both groups at slow and preferred speeds, but CG walked significantly faster (+9%) at fast speed compared to LBP ( $p < 0.001$ ).

No group effect was found for peak time. LBP displayed a small but significant increase in active area compared to CG ( $p = 0.03$ ). At fast speed, CG presented a 1% significantly lower P\*t ( $p = 0.005$ ) and area ( $p = 0.0003$ ) than LBP. A velocity-zone-group interaction was observed for P\*t ( $p < 0.0001$ ) (Figure 1) and peak pressure ( $p = 0.0004$ ). At preferred and fast gait speeds, LBP presented higher P\*t values than CG at the lateral forefoot. At slow speed, P\*t was greater in LBP in the lateral and medial rearfoot while it was lower than in CG at the medial forefoot. At slow speed, LBP presented lower peak pressure at the medial forefoot and higher peak pressure than CG at the heel.

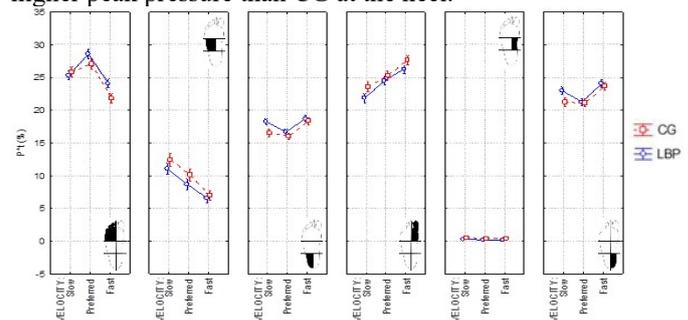

Figure 1: P\*t average and standard errors for each foot zone at slow, preferred and fast speed in LBP and CG.

### Conclusions

The results do not correspond to those of the literature where [1] no differences were found between chronic LBP and control groups and where [2] the emphasis was on the asymmetry in plantar pressure between the affected leg and the (healthy) lower limbs of control subjects.

Besides, a gait speed normalization should be effective to observe if, at fast speed, subjects with LBP presented indeed lesser peak pressure at the medial forefoot [3]. This is of interest because it impacts the push off phase of gait and suggests different roll-over pattern for subjects with LBP compared to controls. In addition, it may reflect a protection mechanism to avoid pain or reduced proprioception.

## Effects of different custom-made insoles on pressure-time integrals in cavus feet during running

Mujia Ma<sup>1</sup>, Hui Liu<sup>2</sup>, Qingquan Song<sup>1</sup>

<sup>1</sup>Beijing Sport University, Beijing, China

<sup>2</sup>China Institute of Sport and Health Science, Beijing Sport University, Beijing, China

Email: 573677921@qq.com

### Summary

Custom-made insoles could dispersion the plantar pressure and relieve pain by high pressure for the cavus feet. The purpose of this study was to investigate the effect of different custom-made insoles on pressure-time integrals (PTI) in cavus feet during running. The results showed that two types of insoles reduced the PTI for medial/lateral forefoot and medial hell, and arch support insole also reduced the PTI for big toe. However, arch support structure of insole increased the PTI for medial and lateral arch.

### Introduction

Compared to neutral feet, cavus feet is characterized of high PTI which are related to foot pain [1]. Custom-made insoles redistributed the plantar pressure concentrated by the cavus feet, and relieved the impact as well as pain by high pressure [2]. It was reported that cavus feet with forefoot valgus should raise forefoot lateral wedge in the insole [3].

The purpose of this study was to investigate the effect of different custom-made insoles on PTI in cavus feet during running. It was hypothesized that arch support insole reduced PTI for cavus feet.

### Methods

Eight cavus feet and eight normal feet were screened using arch height index (AHI). The AHI for normal feet is  $0.33 \pm 0.01$ , and the cavus feet is  $0.40 \pm 0.03$  and average forefoot valgus angle is  $11.0^\circ$ . There were no significant differences in heights, weights and feet lengths between the two groups.

There were two different types of custom-made insoles for cavus feet, including the arch support insole (ASI), arch support with  $6^\circ$  lateral wedge increased of forefoot insole (AS+ FWI). All the custom insoles were designed using Easy CAD software. The EVA block were engraved using a CNC milling machine, and the insole were polished using a grinding machine.

Each footprint was divided into 11 recorded areas using the Pedar-X system as the subject running at 3.0m/s. PTI (kPa.s) were extracted for each area. PTI was calculated as the product of the pressure and the time over which it was applied.

T-test was used to investigate the PTI differences between the normal feet and each condition of cavus feet. One-way repeated measure ANOVA was used to investigate PTI differences between the two insoles of cavus feet. The alpha level for all statistical tests was set at 0.050.

### Results and Discussion

The result showed that the PTI in the cavus feet none-insole (NI) was greater for the WF, MH, LH compare to neutral feet. The AS and AS+FWI were greater than that of neutral feet for MA. The ASI and AS+FWI demonstrated smaller PTI in the WF, MF, CF, MH compared to the NI. And the BT of PTI in the ASI was smaller than the NI. However, the MA and LA of PTI in ASI and AS+FWI was greater than the NI (Figure 1).

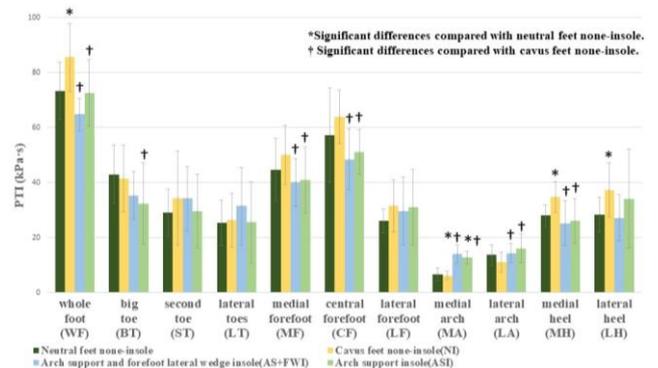

Figure 1: The PTI of neutral feet and different condition of cavus feet during running

Previous studies showed that cavus feet have a greater PTI and proportion of pain in the heel, forefoot, and toes than the neutral feet [1]. In this study, cavus feet have more PTI for the heel. Wearing ASI and AS+FWI could reduce the PTI for MH. Although there are no differences in PTI between cavus feet and neutral feet in forefoot, the PTI for MF and CF is decreased after wearing insoles. Furthermore, the ASI also reduced the PTI for BT, which can effectively alleviate the pain in MH, MF and CF with cavus feet, even in BT. However, wearing insoles increase the PTI for MA and LA, and thus increased the pressure and contact time, which would stretch the stiff arches and cause soft tissues injury in cavus feet.

### Conclusions

Arch support insole and arch support with forefoot lateral wedge insole reduced the pressure-time integrals, in which arch support insole is more effective in reducing pressure-time integrals for big toe. The arch support structure of insole may increase the arches injury, which should be considered.

## Predictive simulation of walking with weak ankle plantar-flexor using an AI gait controller

Young-Jun Koo<sup>1</sup>, Mingi Jung<sup>1</sup>, Seungbum Koo<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea  
Email: skoo@kaist.ac.kr

### Summary

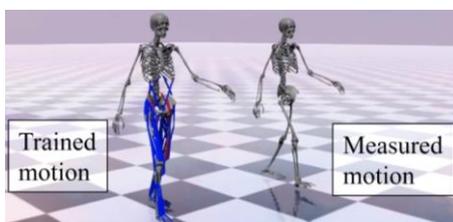

Predictive gait simulations can help understand mechanical pathways of joint injuries. A musculoskeletal model and muscle controller are required to run predictive gait simulations. The objective of this study was to perform predictive gait simulations of a human musculoskeletal model with weak plantar flexor muscles using a reinforcement learning-based muscle controller. Gait data of a healthy subject was obtained. A musculoskeletal model with 92 muscles and 8 actuatable joints was constructed in the RaiSim dynamics simulation environment. A muscle controller was trained for the dynamics model to mimic the kinematics of a subject's gait via deep reinforcement learning. Maximum strengths of ankle plantar flexors of the musculoskeletal model were reduced to make an injured model. Normal and injured models were simulated using the trained muscle controller. Ankle plantar flexion and hip extension angles were reduced in the injured model, which conforms to previous clinical studies.

### Introduction

Predictive simulations of human walking help to understand the pathomechanics of musculoskeletal disorders. However, the predictive simulation requires a muscle controller. Recently, controllers of a musculoskeletal model for various activities were predicted using deep reinforcement learning (RL) [1]. The objective of this study was to obtain a muscle controller for walking using deep RL and to perform predictive simulations of ankle plantar flexor weakness using the trained controller.

### Methods

The study was approved by the institutional review board at Korea Advanced Institute of Science and Technology. A normal gait at self-selected walking speed was obtained for a healthy male subject. A three-dimensional full-body musculoskeletal model of 31 degree-of-freedom (DoF) was constructed in the RaiSim (Fig. 1). Ninety-two muscles were modeled according to the Hill-type muscle model. Musculoskeletal geometries and their parameters were obtained from a published model [2].

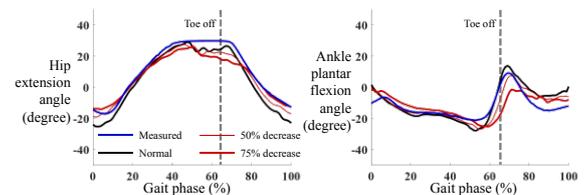

**Figure 1:** Reinforcement learning of a musculoskeletal model for normal walking

The musculoskeletal model was trained using a deep RL method, proximal policy optimization. A controller for the 92 muscle excitations and eight joint torques was trained to

mimic the measured gait motion of a subject. Maximum strengths of ankle plantar flexors (gastrocnemius and soleus) were reduced to 75%, 50%, and 25% of its original strength to make ankle plantar flexor weakness models. The normal and injured models were simulated using the muscle controller obtained from normal walking training.

### Results and Discussion

The decrease in the maximum strengths of plantar flexors affected kinematics of the ankle and hip (Fig. 2). Ankle plantar flexion angles at push-off were 7.3°, 10.3°, 2.7°, -1.5° for 0%, 25%, 50%, and 75% decreases in the maximum strengths of plantar flexors, respectively. Hip extension angles at push-off were 25.8°, 25.5°, 21.3°, 15.2° for 0%, 25%, 50%, and 75% decreases in the maximum strengths of plantar flexors, respectively. The range of motions of the hip joint decreased as the maximum strengths of plantar flexors decreased. Previous studies reported that the hip flexion might compensate plantar flexor weakness [3], and the hip extension angle and range of motion of the hip were decreased in old adults with weak plantar flexor muscles [4]. Our predictive simulations conformed to previous clinical studies [3, 4].

**Figure 2:** Kinematics of hip and ankle joints in the sagittal plane

### Conclusions

A muscle controller of a high DoF musculoskeletal model was successfully created for gait simulation. The effect of weak ankle plantar flexor muscles on gait kinematics could be simulated using the muscle controller. This study would help understand the effect of muscle pathology and post-treatment on gait kinematics.

## ISB recommendations for skin-marker-based multi-segment foot kinematics

Alberto Leardini<sup>1</sup>, Julie Stebbins<sup>2</sup>, Howard Hillstrom<sup>3</sup>, Paolo Caravaggi<sup>1</sup>, Kevin Deschamps<sup>4</sup>, Anton Arndt<sup>5,6</sup>

<sup>6</sup>Karolinska Institute, Stockholm, Sweden

Email: leardini@ior.it

### Summary

The present work [1] includes recommendations for multi-segment foot modelling, including the grouping of the foot bones, definition of landmarks and other anatomical references, experimental issues in motion data collection, analysing and reporting relevant results and finally designing clinical and biomechanical studies in large populations by selecting the most suitable protocol for the specific application. These recommendations may also be applied when writing manuscripts and abstracts.

### Introduction

The foot is anatomically and functionally complex, and thus an accurate description of intrinsic kinematics requires multiple segments. This has led to the development of many multi-segment foot models [2,3]. These models differ in the number of segments, bony landmarks, marker set, anatomical axes and frames, joint convention, neutral positions etc. The terminology used is inconsistent and frequently confusing. Therefore the aim of this paper is to provide standardized recommendations covering both the use of established models, as well as designing new ones.

### Methods

The International Society of Biomechanics has previously published proposals for standards regarding kinematic and kinetic measurements in biomechanical research; in the present work multi-segment foot modeling (MFM) is addressed. ISB is not prescribing here a particular set of standard definitions to be used in all applications, but rather aims to recommend a set of standards for collecting, calculating and reporting relevant joint kinematics data.

### Results and Discussion

Recommendations when using an established MFM are here reported. Those for designing a novel MFM and the topics requiring further investigation are reported in the paper [1].

- Define a standard operating protocol for skin marker placement consistent with the MFM used.
- Assess your own intra-rater and inter-rater repeatability.
- Define a standard and repeatable procedure for raw data processing (gap filling, smoothing, filtering, etc.).
- Establish whether bony segment motion relative to a global reference system or joint motion between body segments is reported; distinguish also between 3D joint rotations and two-dimensional projection angles.

- Use the terminology recommended previously [4].
- Collect a static trial in bipedal up-right posture, i.e. hindfoot stance position, to serve as a metric for the calculation of deformity based deviations.
- Collect a second static trial, when the foot is in 'subtalar neutral position', to serve as a weight-bearing anatomical reference alignment; both of these positions to be used as off-sets for setting an origin for the MFM kinematic graphs.
- Determine the foot type of your cohort(s).
- Compare your final kinematic results, with corresponding results from the literature.
- Discuss comprehensively the issues mentioned above and specify how these may have affected your results.

**Figure 1:** Diagram representing possible technical and anatomical references in MFM. The longitudinal (i.e., mid-diaphyseal) axis of the bone (in red) can be represented as the line (black) joining two relevant anatomical landmarks (black circles); these landmarks are tracked by the external skin markers (grey spheres and axis).

### Conclusions

It is becoming increasingly common to use MFM in biomechanical and clinical applications. Evidence suggests they provide adequate sensitivity for reporting joint motion and for distinguishing pathological from typically developing feet. But it is important that the selected MFM is well understood in order to generate accurate results and interpret the findings appropriately. Studies using these models should also use and report established references.

## Investigation of the function of walking shoes equipped with spring on the heel during gait

H. Funakoshi<sup>1</sup>, Y. Usami<sup>1</sup>, K. Kubota<sup>1</sup>, T. Kokubun<sup>1\*</sup>

<sup>1</sup> Saitama Prefectural University, Saitama, 343-8540, Japan,

\*Email: kokubun-takanori@spu.ac.jp

### Summary

This study aimed to investigate the effect of heel springs on gait, comparing walking shoes equipped with or without the spring model in gait on a treadmill. We evaluated kinetics, kinematics, and electromyography (EMG) data in five healthy elderly and six young adults. All subjects show a significant difference between shoes with and without springs in knee and ankle angle, ground reaction force (GRF), stride length, EMG data of gluteus medius. Additionally, EMG of Rectus femoris and Biceps femoris long head tend to decrease in spring shoes, but there is no significant difference. We suggest that spring shoes have the possibility of providing propulsive force association with changing kinetic control in gait.

### Introduction

Shoes play an important role in predicting systemic disability during exercise. Recently, a variety of shoes for walking are sold. However, each effect of their feature has not yet to be investigated. The detailed impact on the gait of shoes with a unique mechanism that springs on the heel have not been clarified. The feature of these shoes is a high heel with spring and enough base of support. Several studies have reported that walking with high heel shoes changes dynamics [1]. Therefore, we compared high heel shoes with or without the spring to investigate the pure effect of spring.

### Methods

Five healthy elderly (mean age  $\pm$ SD; 70.3 $\pm$ 2.6, 3 males, 2 females) and six young (21.0  $\pm$ 0.0, 6 males) walked on a treadmill at 0.6m/s, 0.8m/s, 1.0m/s with two conditions: 1) shoes equipped with 6.0cm height spring on the heel (spring shoes), 2) the same model of spring shoes but spring doesn't work (non-spring shoes). We analyzed gait data from a three-dimensional motion analysis system, a treadmill with a ground reaction force (GRF) sensor and a surface electromyogram. The lower limb angle, the center of mass (COM), stride, and EMG of gluteus medius (GMED), Rectus femoris (RF), and Biceps femoris long head (BF), medial gastrocnemius (MGAS) were used. Paired t-test using MATLAB2020 was used to compare the biomechanical variables between the different shoes. The level of significance was chosen as  $p < 0.05$ .

### Results and Discussion

Of course, the spring affects in stance phase. In spring shoes, regardless of age, an anterior component of GRF in pre swing (PSw) (Arrow 1) was significantly increasing. A backward component in Mid Stance (MSt) (Arrow 2) and the vertical component of GRF in MSt (Arrow 3) and PSw (Arrow 4) showed a significant increase only in young and all subjects (Figure 1).

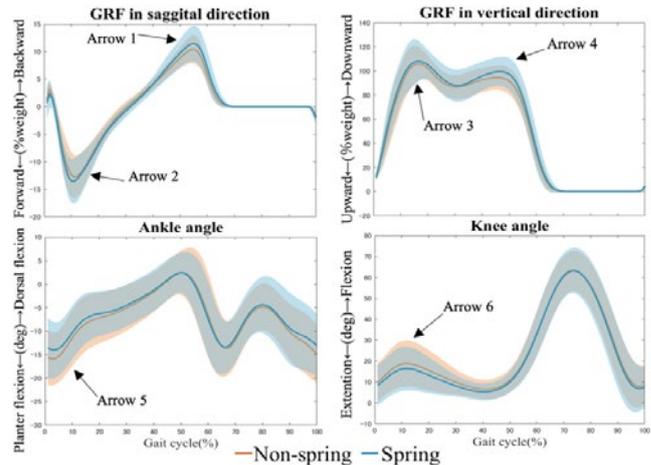

Figure 1: GRF of %weight and ankle and knee angle

Increasing GRF may mean Elastic force of the spring; increasing during Initial Contact to MSt indicate shortening of the spring and in releasing in PSw. Then, Increasing COM variation show elasticity of spring (Table 1).

Table 1: GRF of %weight and ankle and knee angle

±SD(%)	Elderly			Young			All Subject		
	Non spring	Spring	p-value	Non spring	Spring	p-value	Non spring	Spring	p-value
Stride	49.4±8.3	51.7±9.0	0.01*	55.0±7.9	59.4±8.4	<0.01*	52.5±8.4	55.9±9.4	<0.01*
COM variation(S)	1.3±0.4	1.7±0.5	<0.01*	1.5±0.3	1.7±0.4	<0.01*	1.4±0.4	1.7±0.4	<0.01*
GMED mean(LR)	55.3±34.8	60.5±35.2	0.20	61.4±28.4	67.8±30.8	<0.01*	58.6±31.1	64.5±32.6	<0.01*
BF mean(LR)	49.3±10.8	43.5±7.4	0.04*	42.4±35.0	39.8±31.4	<0.01*	45.5±23.3	41.5±23.9	0.20
RF mean(LR)	70.6±31.5	64.7±26.7	0.09	64.2±20.3	64.6±25.5	0.8729	67.8±26.8	64.7±25.7	0.18
MGAS mean(PSw)	66.0±16.4	69.1±18.3	0.09	44.6±13.1	45.2±10.0	0.7578	54.3±18.1	56.1±18.6	0.19

Additionally, expand the stride length without increasing the activity of lower limb muscle (Table 1) also strengthen the case for elasticity of the spring generates propulsive force. On the other hand, the activity of GMED is significantly increasing in young and all subjects. GMED may control the COM by braking the trunk in loading response (LR). Especially, young subjects showed a significant difference in GRF and a significant increase in GMED activity. Therefore, the young can handle spring shoes more effectively than the elderly by applying force to the spring.

### Conclusions

Spring shoes can invest gait with propulsive force with increasing of GRF, although there are differences of effect size depending on age.

### Summary

We developed that Functional biomechanics garments (FBG) with the function of the walking assistance based on the biomechanics of the gait. This study was to investigate the effect of FBG compared to other garments using a biomechanical method. The participants were divided into the FBG group, Compression garments (CG) groups, and Other brands garments (OBG) groups. The spatio-temporal data, the kinematics, kinetics, and Dynamic Joint Stiffness (DJS) during gait were calculated using three-dimensional gait analysis system. The walking speed was increased, and DJS of the hip decreased at Terminal Stance (TSt) by wearing the FBG.

### Introduction

Wearing compression garments (CG) not only enhance performance in various sports [1, 2], but may also be applied to walking training on a daily basis. We have developed a functional biomechanics garment (FBG) designed to support the kinematics and kinetics of the lower extremity based on the walking mechanism during the stance phase. The FBG is a compression garment that adheres from the buttock to the heel. The characteristics of the FBG are a mix of different elastic parts to support accurately lower extremity movement (i.e., lower extremity joint moment) at the stance phase during walking. The purpose of this study was to investigate the effect of FBG compare other garments using a biomechanical method.

### Methods

Forty-eight males (age 21.7±3.1 years, height 1.74±5.4 m, weight 64.1±7.3 kg) participated in this study. The participants were divided into of the FBG group, Compression garments (CG) groups and Other brands

garments (OBG) groups. All participants measured the baseline and each condition at the usual walking speed. The spatio-temporal data were measured, and the kinematics, kinetics and Dynamic Joint Stiffness (DJS) at the lower extremity during gait were calculated using a three-dimensional gait analysis system. A two-way ANOVA with repeated measurements was performed to compare groups among pre-walking with the post. ( $p < 0.05$ ).

### Results and Discussion

The walking speed was increased by wearing the FBG. The DJS of hip joint at Terminal Stance was FBG 0.033±0.014, CG 0.049±0.016, OBG 0.049±0.015 ( $p < 0.05$ ). The passive elastic moment by the high elasticity part of the hip joint front in the FBG supported the internal hip flexion moment. Therefore, the FBG was able to increase the hip extension angle while decreasing the internal hip flexion moment. Accordingly, the FBG decreased hip DJS in the TSt and affected walking speed.

### Conclusions

The FBG decreased hip DJS in the TSt and affected walking speed. The FBG has a biomechanical effect.

## Summary

Stair walking contributed to 26% of self-reported falls and became the leading cause of accidental death for the elderly[1]. The risk of falls increases while performing a physical-cognitive dual-task (DT). We aimed to investigate performance under DT condition during stair ascent among people with more than 10-years Tai Chi (TC) practices. It would be helpful for the elderly if TC can be proved to improve their performance under cognitive-related conditions.

## Introduction

Declining physical and cognitive functions increase the challenge of stair ascent among the elderly [2,3]. The ability to move while simultaneously performing a secondary cognitive task is essential to daily living activities. Still, there are more high fall risks under a stair ascent environment.

Tai Chi (TC) is a traditional Chinese conditioning exercise. It integrates training in balance, flexibility, and neuromuscular coordination with some cognitive components, resulting in benefits to body performance during stair ascent among the elderly. Therefore, this study was performed to investigate TC practitioners' performance under DT conditions during stair ascent.

## Methods

Thirty healthy elderly individuals recruited for the study, including fifteen 10-year regular Tai Chi (TC) practitioners and fifteen no exercise (NE) history.

A simulating staircase with six steps, two force platforms (KISTLER, Switzerland) embedded in the 3rd and 4th steps, was constructed for data collection. Force data, sampling rate at 1000 Hz, were collected synchronously with kinematic data, an eight-camera motion analysis system (Vicon, England), sampling rate of 100 Hz. The participants were asked to walk from the starting position to ascend the stair setup in a step-over-step manner under condition DT. Meanwhile, the participants were asked to subtract seven from a given three-digit number ranging from 100 to 999 at the starting position. A successful stair ascent trial was defined as a trial in which

the participant continuously ascended from the end to the top of the staircase.

The kinematics and kinetics variables include horizontal velocity, foot clearance, step frequency, head/trunk inclination angle, hip/knee/ankle angle, loading rate, medial/lateral/propulsive/ braking impulse. The confidence interval of mean difference values between groups was calculated by using independent T-tests comparison. Significant differences were confirmed if the respective 95% confidence intervals(CI) of mean difference did not cross 0. Effect size(Cohen's d) and statistical power were also calculated for each dependent variable. Thresholds for effect sizes statistics were: 0.2, trivial; 0.6, small; 1.2, moderate; 2.0, large; and over 2.0, very large.

## Results and Discussion

Selected descriptive statistics of the kinematic variables are presented in Table 1. Compared with the NE, TC practitioners had a lower trunk inclination angle (TC<sub>DT</sub>=10.08°, NE<sub>DT</sub>=19.12°; CI95%:-15.88/-2.19; moderate effect).

Compared with NE practitioners, TC practitioners had superior gait strategies to increase body stability and could perceive the potential risks brought from DT and changed their gait strategies to increase performance to prevent falls.

## Conclusions

1 Under DT condition, body stability decreased among NE and remained unchanged among TC practitioners.

2 TC practitioners performed better during stair ascent compared with NE practitioners.

## A Longitudinal Analysis of Change of Gait Stability in Older Adults with Dementia

Sina Mehdizadeh, Mohammadreza Faieghi, Andrea Sabo, Hoda Nabavi, Avril Mansfield, Alastair J. Flint, Babak Taati, Andrea Iaboni

KITE-Toronto Rehabilitation Institute, University Health Network, Toronto, ON, Canada

Email: [sina.mehdizadeh@uhnresearch.ca](mailto:sina.mehdizadeh@uhnresearch.ca)

### Summary

We measured changes in gait stability over a 10-week period in a group of hospitalized older adults with dementia to determine which factors were associated with its changes. Fifty-four individuals admitted to a specialized dementia inpatient unit participated in this study. A markerless motion capture system was used to record participants' natural gait. Multilevel growth models were developed with gait stability as the independent variable and clinical and demographic variables as predictors. Gait stability decreased over this period. Gait stability of men decreased more than that of women, associated with an increased sacrum lateral movement over time. The sacrum mediolateral range of motion decreased in those with mild neuropsychiatric symptoms, but increased in those with more severe neuropsychiatric symptoms. Our study provides evidence of worsening of gait stability, mainly due to difficulty in controlling the center of mass in older adults with dementia.

### Introduction

Mobility in older adults with dementia can be affected by factors such as hospitalization, and use of antidepressants [1,2]. Monitoring of mobility status in older adults with dementia is important, because a decline in mobility not only has an impact on activities of daily living such as walking, but also increases the risk for falls. Current tools of monitoring mobility provide clinical observations about mobility status, but do not reveal the underlying biomechanical changes associated with mobility decline. These approaches are also subjective and infrequent and miss subtle changes occurring slowly over long periods of time [3]. Recent advances in markerless motion capture allow for longitudinal, unobtrusive, and frequent daily-life assessment of gait over time in older adults with dementia. The aims of this study were, therefore, to i) describe changes in gait stability (as the main cause of falls in walking) over 10 weeks in older adults with advanced dementia and to determine which demographic and clinical factors were associated with its change over 10 weeks.

### Methods

Fifty-four individuals admitted to a specialized dementia inpatient unit participated in this study. A vision-based markerless motion capture system (incorporating a Microsoft Kinect v2 camera) was used to record participants' natural

gait. The estimated margin of stability (eMOS) was measured as the measure of gait stability in walking. In addition, participants' sacrum mediolateral range of motion (ML ROM) was measured as an estimation of their center of mass motion. Multilevel growth models were used with these two gait measures as the independent variables and clinical and demographic variables as predictors.

### Results and Discussion

Over the course of 10 weeks, gait eMOS decreased (coefficient= -0.09 cm per week,  $p=0.003$ ) indicating worsening of gait stability. In addition, the eMOS declined in men (Figure 1A) ~2 mm per week more than in women ( $p= 0.002$ ). Over this period, men's sacrum ML ROM also increased (Figure 1B) on average 1.1 cm per week more than women ( $p=0.02$ ). Moreover, while the sacrum ML ROM decreased for those with low neuropsychiatric symptoms, it was increased for those with higher neuropsychiatric symptoms (coefficient= 0.03 cm per week,  $p=0.02$ ).

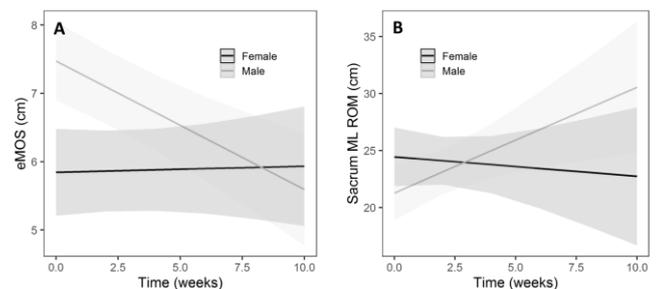

Figure 1: Plot of interaction effects A) sex on eMOS, B) sex on sacrum ML ROM.

### Conclusions

Our findings demonstrate the worsening of gait stability was due to inability of participants to control their lateral center of mass movement which itself was associated with neuropsychiatric symptoms.

# FUNCTIONAL INSOLES IMPROVE PLANTAR PRESSURE DISTRIBUTION DURING RACE WALKING

Xinrui Zhang<sup>1</sup>, Wei Sun<sup>1</sup>, Cui Zhang<sup>2</sup>, Li Li<sup>3</sup>, Qipeng Song<sup>1</sup>

<sup>1</sup>College of Sports and Health, Shandong Sport University, Jinan, China

## Summary

This study investigated the effectiveness of functional insoles on plantar distribution during race walking to reduce the high plantar pressure and force on race walkers, who tend to suffer from overuse injury. A total of 20 male race walkers were recruited as participants. Each participant completed a race walking with functional or regular insoles. Plantar pressure data collected. A two-way analysis of variance with repeated measure was used to determine the difference between the two conditions among ten different plantar regions. Results showed that functional insoles reduce the peak pressure in the metatarsophalangeal joints and heels. Functional insoles have the potential to reduce the overuse injury risks at these parts. Functional insoles could also reduce the risks of foot and leg injuries.

## Introduction

Fifty-kilometer race walking is the longest track and field event and involves distances that are approximately 7.8 km longer than those in marathons. A 67 kg individual walking 50 km must absorb about 2016 tons cumulative impact on each foot[1]. Thus, race walkers are prone to overuse injuries, such as blisters, metatarsalgia, stress fractures, and knee pains, in their lower extremities.

In this study, arch-supported functional insoles were used to reduce plantar pressure loading. We aimed to determine the effects of functional insoles on the plantar pressure distribution during race walking.

## Methods

A total of 20 male race walkers were recruited from the provincial race walking team of Shandong, China. Each participant walked at an average race walking speed (3.5–3.8 m/s) for 400 m in his or her race walking shoes under two conditions in random order: (1) with a functional and (2) with a regular insole. Two sets of timing doors of the Smartspeed system were used to calculate the walking speed. Insole data were collected for ten consecutive steps during the last 100 m of each 400 m walk[2].

Plantar pressure insoles were used to collect plantar pressure data. During the test, peak pressures of eight anatomical sub-regions and GRF of the whole foot were calculated. Ten anatomical sub-regions were identified as the medial heels (Hm), lateral heels (HI), medial arch (Vm), lateral arch (VI), five metatarsal-phalange joints (MPJs): M1, M2, M3, M4, and M5, and the hallux (T1). Two-way analysis of variance (ANOVA) with repeated

measures was used to compare plantar pressure among ten different parts of the foot and between the two conditions. The significance level was set at 0.05.

## Results and Discussion

This study demonstrated that the arch-support functional insoles reduce the peak pressure at all tested areas, except for the M5 and arch areas with increased pressure at the Vm area (Figure 1). The GRF exhibits a typical bimodal pattern (Figure 2). With functional insoles, the first peak decreased ( $P=0.034$ ), where the second peak remained unchanged ( $P=0.078$ ).

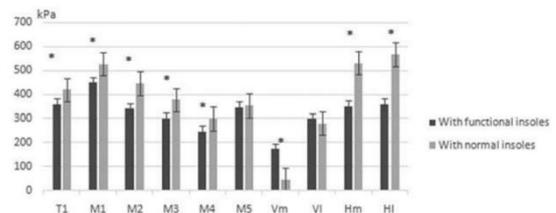

Figure 1: Peak pressures on plantar areas.

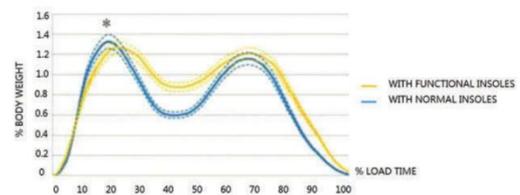

Figure 2: GRF in the vertical direction

## Conclusions

During race walking, the peak pressure in the MPJs (except M5) and heels were reduced by arch-supported functional insoles. The reduction in the first GRF peak also suggests that the insoles absorb the vertical shock during the heels' strike phase and thus prevent the potential injury risks in the foot and leg.

## Population Study of Kinematic Gait Parameters for Biometric Application

Gunwoo Park<sup>1</sup>, Seungbum Koo<sup>1\*</sup>

<sup>1</sup>Musculoskeletal Biodynamics Lab, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea

Email: skoo@kaist.ac.kr

### Summary

Studies on human walking as a behavior biometric have emerged with the advance of video processing methods. Among those, model-based procedures reconstruct motion from acquired images to compare it. Our work is about how motion data can be individualized. Kinematic parameters suggested by previous gait analysis were extracted from the captured motion of 488 subjects. Comparing total variance and intra-class variance of each parameter, we could explain how each feature remains invariant for different gait trials.

### Introduction

Gait kinematics has been studied for various aspects of its application for biometric systems. Since gait data is usually captured as a sequence of images, existing studies comprise both model-free and model-based approaches [2]. Gait shape reconstruction precedes model-based works, while model-free works directly extract features from an image. Model-based studies have quantified three-dimensional shapes introducing a set of biomechanical parameters [1]. We aimed to explain how the parameters are distributed and whether they are consistent for each identity.

### Methods

From a motion capture system with multiple optical cameras and markers, we captured the natural walking of sampled 500 subjects. Gait data from 12 subjects were excluded because of experimental errors such as missing markers. Gait data of 248 males (average age 36.8 (SD 17.2) years) and 240 females (average age 37.4 (SD 16.3) years) were used for the study. The time-series position of 17 landmarks was extracted. (Figure 1)

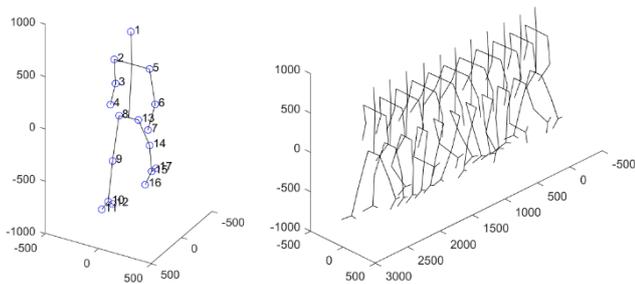

Figure 1: Gait data description

For each subject, we used four gait cycles. A gait cycle was set as a sequence of walking motion from a right heel strike to

the next right heel strike. The data contains information about the hip, knees, shoulders, and elbows. We extracted maximum flexion and extension for the joints as kinematic parameters, as well as overall shape such as stride length, width, and foot angles during the stance phase. The parameters were calculated from gait kinematics using scripts written at Matlab (2020a, MathWorks, Natick, MA, USA). Variation properties of each parameter were calculated. Total variance and intra-class variance are compared since how the feature is invariant depends on its intra-class and inter-class variation [3].

### Results and Discussion

The intra-class variance was calculated as the variance of four gait trials of each subject. The parameter could be directly compared by scaling intra-class variance with total variance. If a scaled value is lower, it can be regarded that the feature is robust. (Table 1) The scaled intra-class variance was in the range of between 2% and 8%, except for step width, which was 26.3%.

### Conclusions

The range shows that gait kinematics can be used for biometric individualization to some extent. Though stride and step width can be observed on the same scale, step width had much less total variance. Therefore, step width may not be discriminative in practice. Knee flexion showed the smallest scaled value of intra-class variance, which implies it may be a robust feature of gait. We showed that the gait model could be used for individualization by analyzing kinematic parameters. Many recent methods use machine learning algorithms to extract features from gait. This study will provide a useful baseline and information to analyze the resulting parameters.

# A Kinematic Comparison of Overground and Treadmill Walking Using AI-based Gait Controllers

Mingi Jung<sup>1</sup>, Young-Jun Koo<sup>1</sup>, Seungbum Koo<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea  
Email: skoo@kaist.ac.kr

## Summary

We used reinforcement learning to make gait controllers with two-layer neural networks for overground and treadmill walking in a dynamic simulation environment. Motion capture data of a subject was acquired during overground walking and used as a reference motion. Gait controllers were trained using an imitation learning technique to follow the reference motion during overground and treadmill walking simulations. First, we evaluated kinematic differences of the gaits with the trained gait controllers against the reference motions. Second, we compared the hip and knee angles between overground and treadmill cases.

## Introduction

A number of studies reported differences in the body kinematics during overground and treadmill walking. The treadmill motor power and the change in treadmill speed during different phases of walking have been studied as potential causes in the differences [1]. Meanwhile, there is still a lack of understanding on the physics and physiology behind it. As a first step toward it, we aimed to create three-dimensional gait controllers of a humanoid model that can walk on overground and treadmill to compare the kinematics during the two conditions eliminating physiological differences.

## Methods

Twelve motion capture cameras were used to obtain a subject's walking motion data, and it was processed into kinematic data by using OpenSim. The dynamic simulator RaiSim was used for reinforcement learning. The ground was made to learn overground walking, and a treadmill moving at a subject's average speed was made to learn treadmill walking. Each network was learned using the reward functions of DeepMimic [2]. Each controller network consists of 2 hidden layers of 256 units. This is shown in figure 1.

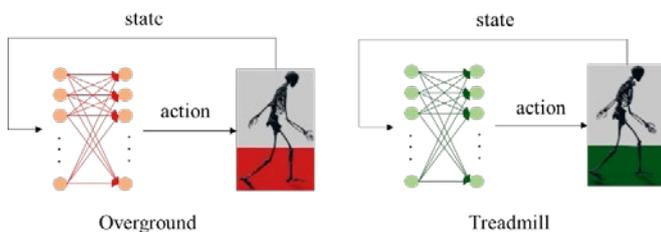

Figure 1: Training loops in both cases using neural networks

The human body model consists of joints with a total of 25 degrees of freedom (DoF). The hip joint has 3 DoF, and the knee joint has 1 DoF. The state has 86 dimensions (D): the pelvis's height, orientation, linear velocity, angular velocity (1D, 3D, 3D, 3D), the angle of each joint (25D), the angular velocity of each joint (25D), gait phase (1D), terrain

recognition (25D). The actions are the PD targets of each joint. The network parameters were updated using PPO.

When walking on the treadmill in the real world, the power of the treadmill is not infinite. Therefore, to make it similar to the actual walking, the noise between -0.1 m/s and 0.1 m/s was given every 0.01 seconds to treadmill velocity.

## Results and Discussion

For the comparison between the reference motion and the simulated motions, the root mean square (RMS) difference of the knee flexion angle and hip flexion angle were 2.1 degrees and 5.2 degrees, respectively, for the overground walking simulation. In the case of treadmill walking, the RMS difference of the knee flexion angle and hip flexion angle were 2.5 degrees and 6.2 degrees, respectively. The gait controller for overground walking had a slightly lower difference.

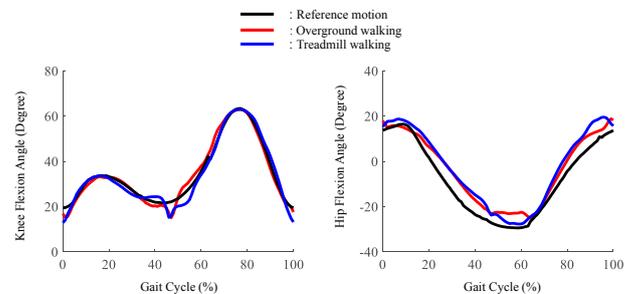

Figure 2: Knee and hip flexion angles

When the body kinematics during the two conditions were compared, the maximum knee flexion angles and the maximum hip flexion angles were both larger in the treadmill walking simulation by 0.1 degrees and 0.7 degrees, respectively. The knee ranges of motion and the hip ranges of motion were also larger in the treadmill walking by 2.3 degrees and 3.3 degrees, respectively.

## Conclusions

Gait controllers of the three-dimensional humanoid model were successfully trained for overground and treadmill walking simulations. This approach would help understand the underlying physics and physiologies for different gait kinematics during overground and treadmill walking.

### Summary

Whether adaptations in locomotor metabolic economy occur across an individual's life span remains unclear. Here, we used an avian bipedal model to assess the potential that locomotor economy responds plastically to altered loading history during growth. A remarkably low costs of carrying limb mass after chronic growth-period limb-loading demonstrate that locomotor economy may indeed be tuned to specific habitual conditions. Findings from this study have implications for understanding the impact of childhood activity level on locomotor energetics.

### Introduction

Over an evolutionary time scale, natural selection has resulted in specializations for animal locomotor economy [1]. Whether adaptations in locomotor economy occur across an individual's life span, however, remains less clear. For example, it remains debated how and if running economy in humans is altered due to training [2]. A recent study that eliminated high-intensity activity during the growth period in an animal model showed no effect on locomotor economy [3]. The results of this study suggest that locomotor economy might not respond plastically to altered amounts of exercise during growth and may be robust to changes in life history.

To understand better the scope of developmental plasticity of locomotor economy, we adopted a bipedal model (guinea fowl) that permitted drastic alteration of musculoskeletal loads across the growth span. We achieved this by increasing distal limb mass experimentally by a factor of ~ 2.5x over the maturation period. We hypothesized locomotor economy responds plastically to altered load levels during growth and adapts in a manner that is tuned to the habitual loading environment.

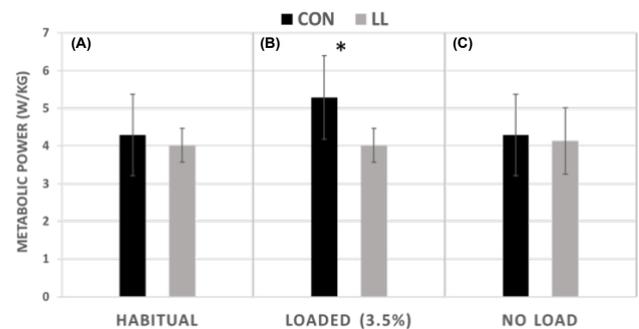

### Methods

Twelve 1-day old guinea fowl (*Numida meleagris*) were obtained (Privett Hatchery, Portales, NM) and raised in large circular floor pens. At one week of age, animals were randomly assigned to a control group (CON, n=6) and a limb-loaded experimental group (LL, n=6). A lead strip with mass equal to 3.3% of the individual's body mass was chronically added to the right leg of the LL group throughout growth (adjusted weekly). Starting at three weeks of age, each group was exercised three times per week by herding animals around a circular course in four 5-minute intervals for a total of 20 minutes.

Metabolic power was measured during standing and during treadmill walking ( $0.5 \text{ m}\cdot\text{s}^{-1}$ ) using a flow-through metabolic chamber system [2]. Metabolic power was measured in the habitual condition (CON= unloaded, LL=loaded) as well as in their novel condition where an equivalent leg mass (3.3% body mass) was added to the CON group and the load was removed from the LL group. Lastly, we used an interlimb design to investigate load carrying economy on the habitually loaded leg versus the habitually unloaded leg in the LL group. Between 3-5 trials were recorded per condition and the order of conditions was randomized.

### Results and Discussion

The LL group carried the added limb load more economically (26%) compared to the CON group (Fig. 1B). Surprisingly, the large addition in habitual limb mass in LL did not result in a difference in walking metabolic power compared to unloaded walking in the CON group (Fig. 1A). There was also a significant lower cost ( $p = 0.05$ ) associated with carrying the additional mass on the habitually loaded leg (right) compared to the habitually unloaded leg (left). These findings support our hypothesis that locomotor economy adapts to altered loading history during growth, and in particular highlighted by the remarkably economical load carrying in LL. Nevertheless, contrary to our hypothesis, the CON group did not have a lower metabolic cost than the LL group in the unloaded conditions (Fig. 1C).

**Figure 1:** (a) : Comparison of net body-mass specific metabolic power in the habitual conditions (CON =Unloaded, LL= limb-loaded), the 3.3% BM loaded condition, and the unloaded condition. \*  $p < 0.05$ .

Overall, our results support our hypothesis that locomotor economy responds plastically to altered amounts of load/functional demand during growth and is tuned to the habitual loading environment. The exception was the unloaded group comparison. The similar cost of unloaded walking between CON and LL may occur if the mechanical energy saving associated with removing the mass in the LL group is offset by muscles operating sub-optimally (e.g. unfavourable force-length-velocity effects). The musculoskeletal factors leading to altered economy are currently being explored.

### Significance

Here we provide new evidence that locomotor economy can be altered based on the loading history during growth. These data have important implications for understanding the long-term effects of childhood activity and inactivity. Further analysis may determine the importance of the growth period on permanent adult locomotor energetics and biomechanics.

### Summary

This study aimed to examine the relationships of the plantar fascia (PF) stiffness with the foot arch deformability and performance in single-leg drop jump. We found that PF shear wave velocity (an index of tissue stiffness: SWV) was related to the peak values of the foot arch deformation in the stance phase and jump performance. Our findings suggest that stiffer PF is associated with less foot arch deformability and superior performance in dynamic exercises.

### Introduction

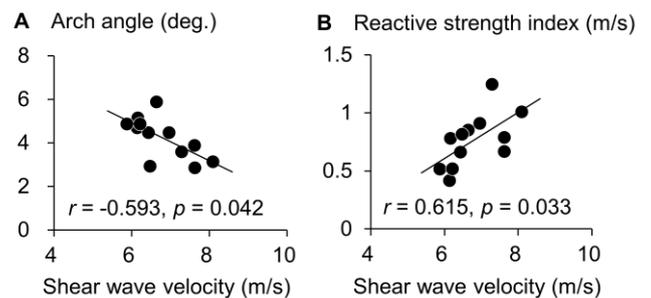

The foot arch is lowered and stretched out while bearing load in the stance phase, and then recoils as the load is removed. This spring-like property of the foot arch helps to attenuate impact forces and store/release elastic strain energy [1]. We previously found that the foot arch deformability during passive ankle and metatarsophalangeal joint angle changes depends on PF SWV [2]. Besides, a previous study reported that even when intrinsic muscles' contractions were inhibited by a tibial nerve block, the foot arch deformability during walking and running was not substantially changed [3]. These findings suggest that PF stiffness may regulate the foot arch deformability even in dynamic exercises, and thereby related to the exercise performance. To test this hypothesis, we examined the relationships of PF SWV with the foot arch deformability and performance in single-leg drop jump, which is a simplified bouncing-gait model.

### Methods

Twelve healthy males (age  $23.3 \pm 2.7$  years; mean  $\pm$  SD) participated in this study. PF SWV was measured at its proximal, middle, and distal sites in the longitudinal direction with supersonic shear imaging. Then, SWV values at the three sites were averaged to obtain the representative value of PF SWV over its length [2]. A three-dimensional motion capture system and a force plate were used to capture multi-segment foot kinematics and kinetics data during maximal single-leg drop jump. The peak values of the arch angle (the sagittal plane rotation of the metatarsal segment relative to the calcaneal segment) and arch length (Euclidean distance between the calcaneus and the second metatarsal head) in the stance phase were calculated as the measures of the foot arch deformability. The jump performance was assessed as jump height and the reactive strength index (jump height relative to contact time: RSI), which was calculated from the vertical component of ground reaction force. Pearson product-moment correlation coefficients were calculated to examine the relationship between measured variables ( $\alpha = 0.05$ ).

### Results and Discussion

PF SWV was significantly related to the peak values of the arch angle ( $r = -0.593$ ,  $p = 0.042$ , Figure 1A) and arch length ( $r = -0.652$ ,  $p = 0.022$ ), jump height ( $r = 0.623$ ,  $p = 0.030$ ) and RSI ( $r = 0.615$ ,  $p = 0.033$ , Figure 1B). There were no significant relationships between the measures of the foot arch deformability and jump performance ( $p > 0.05$ ).

**Figure 1:** Relationships of PF SWV with the peak value of the arch angle (A) and RSI (B) with the regression lines.

A negative correlation between PF SWV and the peak arch angle demonstrates that the foot arch deformability during single-leg drop jump can be partly explained by PF stiffness. Additionally, as PF is extending from the calcaneus to the proximal phalanges, the peak arch length is conceivable as a measure of PF lengthening as well as the arch deformability. Thus, the relationship between PF SWV and the peak arch length can be interpreted that stiffer PF results in less lengthening, and thereby leading to smaller deformation of the foot arch upon loading. Furthermore, the measures of jump performance were correlated with PF SWV but not with the foot arch deformability. These results suggest that stiffer PF is associated with superior jump performance whereas the foot arch deformability does not affect the jump performance.

### Conclusions

In this study, we found that PF SWV was related to the peak values of arch angle and arch length, jump height, and RSI in single-leg drop jump. Our findings suggest that stiffer PF is associated with less foot arch deformability and superior performance in dynamic exercises.

## Summary

Humans account for dissipative work performed by a damped surface by altering their leg mechanics and increasing the active contribution from muscle [1]. However, prior work has not considered the contribution of our feet. Here we examined the adaptations of foot and ankle function and the contributions of the intrinsic foot muscles to this mechanism.

## Introduction

Storing and returning energy is an important function of our feet; allowing us to redirect our centre of mass with great efficiency [2]. We have shown previously that humans modify this function to harness energy stored and returned from an elastic surface operating in series with the foot, reducing their active contribution to work [3]. This was at odds with prior work that showed contributions from the foot's intrinsic muscles to increase during shod gait in running shoes [4]. We propose that running shoes, in fact, act as a damper in series with the foot, rather than a spring as proposed previously. As such, here we tested the hypothesis that humans increase their active contribution to work at the foot and ankle to replace dissipated energy when hopping on a damped surface.

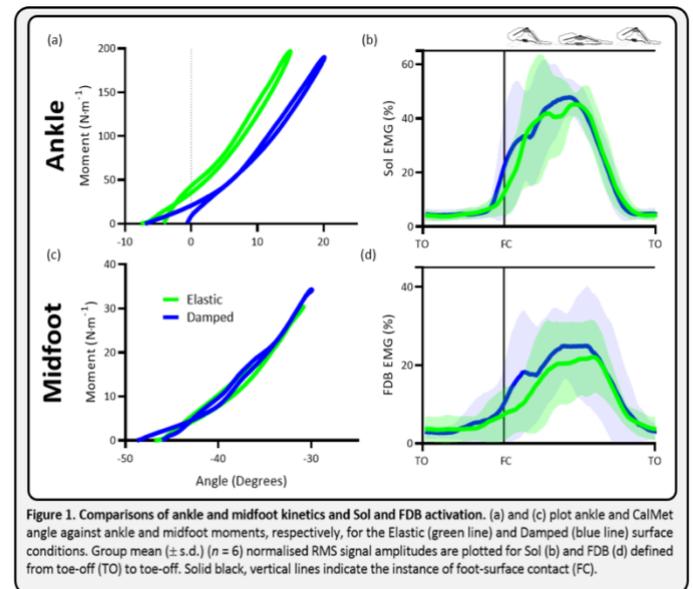

## Methods

Eight participants hopped in place at 2.2 Hz on an adjustable platform in two damping configurations; Damped, and Elastic. Because we were interested in examining the effect of surface damping, the surface stiffness of each condition was matched. Three-dimensional kinematic and kinetic data were recorded in Qualisys Track Manager (Qualisys) alongside muscle activation from abductor hallucis (AH), flexor digitorum brevis (FDB), soleus (Sol) and tibialis anterior (TA). Kinematic and kinetic data were processed in Visual3D (C-Motion) to calculate sagittal plane joint angles, moments and work of the ankle and midfoot using a multi-segment foot model. EMG data were processed in Matlab (Mathworks). Raw signals were band-pass filtered before root mean square (RMS) envelopes were computed and normalised for each participant to the peak amplitude recorded on the Elastic surface condition.

## Results and Discussion

In an effort to replace energy dissipated during the Damped platform configuration, positive work at both the ankle and midfoot increased

significantly with respect to hopping performed on the Elastic surface;  $t(8)=3.314$ ,  $p=0.001$  and  $t(8)=4.289$ ,  $p=0.004$ , respectively (Table 1). This burst of work is evident at the end of the propulsive phase of the hop in the moment versus angle plots presented in Figure 1 (panels a and c). The generation of work at both ankle and midfoot appears to be linked to signal amplitudes and greater integrated EMG during contact recorded in the Damped condition in Sol ( $t(7)=3.673$ ,  $p=0.014$ ) and FDB ( $t(7)=3.505$ ,  $p=0.017$ ) (Figure 1, panels b and d).

## Conclusions

Foot mechanics and muscle activations appear to be altered on a damped, compared to elastic surface to account for dissipated energy. This has applications for the design of wearable devices and footwear.

 Email: 226909999@qq.com

### Summary

The present study examined knee and ankle joint stiffness on both the cement runway and plastic runway. While the knee joint play an important role for shock attenuation, the ankle joint become stiffer when running in the same speed range. This significant change on the knee and the ankle may be related to the greater risk of the knee soft-tissue and the Achilles tendon injuries [1].

### Introduction

During running on a hard surface, the knee joint play an important role for shock attenuation, while the ankle joint is used much less in this capacity [2]. It is reasonable to expect that running on a cement runway requires less knee joint stiffness for shock attenuation than on a plastic runway. Therefore, the purpose of this study is to investigate the change in the knee and ankle joint stiffness during running on two surfaces.

### Methods

Eight healthy male rearfoot runners ( $22.63 \pm 3.74$ yr,  $65.65 \pm 4.76$ kg,  $172.75 \pm 2.92$ cm) completed three running trials at  $3.33 \pm 0.15$  m/s were recruited. Kinetic data and kinematic data were captured with a force plate and an 8-camera motion capture system. Cement runway and plastic runway were laid at least 8m from start point to the force plate. Stiffness ( $K$ ) for the ankle and knee joints was determined for the shock attenuating phase as the change in joint moment divided by the change in joint angle [3]. A paired  $t$  test at significance level  $\alpha = 0.05$  was used to determine effect of surface type for the joint stiffness.

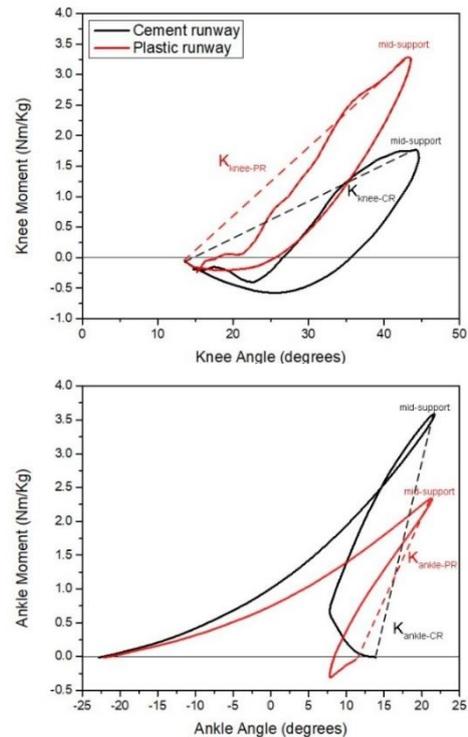

### Results and Discussion

Results are presented in Figure 1 and Table 1. For knee joint, cement runway significantly demands less  $\Delta$ moment and  $K_{knee}$  ( $p < 0.001$ ) than plastic runway, no significant change observed in  $\Delta$ angle ( $p > 0.05$ ). For ankle joint, cement runway significantly demands more  $\Delta$ moment and  $K_{ankle}$  ( $p < 0.001$ ) than plastic runway, no significant change observed in  $\Delta$ angle ( $p > 0.05$ ).

### Conclusions

To accommodate a harder runway, the knee joint was less stiffness to absorb shock and ankle joint were more stiffness to resistance lower limb folding than plastic runway. Our results provide insight into the role of lower limb joint

stiffness for running on different runways and may shed light on higher risk of the Achilles tendon injury [1].

**Figure 1:** Mean joint stiffness at knee (top), and ankle (bottom). Solid lines indicate the joint moment and joint angle relation, dash lines indicate joint stiffness. Black indicates cement runway, red indicates plastic runway.

**Table 1:** The change in joint angular and moment of knee and ankle ( $K$  in  $N \cdot m / kg / degree$ ) during running on cement and plastic runway.

	Cement runway		Plastic runway	
	Knee	Ankle	Knee	Ankle
$\Delta$ angle	$29.97 \pm 4.2$	$7.85 \pm 4.08$	$28.44 \pm 6.36$	$10.13 \pm 2.79$
$\Delta$ moment	$1.85 \pm 0.43$	$3.60 \pm 0.39$	$3.52 \pm 0.63$	$2.38 \pm 0.26$
Stiffness	$0.06 \pm 0.01$	$0.62 \pm 0.41$	$0.13 \pm 0.04$	$0.26 \pm 0.11$

# GaitSense: Estimation of knee joint angle for Sit-to-Stand (STS) movement activity in Osteoarthritis

Sitesh kumar<sup>1,2</sup>, Gunjan P.<sup>2,1</sup>

<sup>1</sup>Biomechanics Research Lab, SynerSense Private Limited, Ahmedabad, India

<sup>2</sup>Dept. of Biodesign Medical Technology, SynerSense Private Limited, Ahmedabad, India

Email: gpatel.sns@gmail.com

## Summary

Estimation of joint range of motion while performing dynamic activity day to day activity is important in diagnosing various musculoskeletal and neurological disorders. In this study we have used an inertial sensor based device developed by GaitSense to estimate and compare the knee joint angle of an Osteoarthritis (OA) patient with a healthy subject while performing dynamic STS movement activity. Results obtained for OA and normal subjects are compared to see variability in knee joint angle pattern in the sagittal plane while performing the same activity.

## Introduction

In India, there are an estimated 104 million elder age group population. Physical therapy in geriatrics helps to strengthen the muscles and reduce the risk of imbalance and individuals return to their prior level of functioning, and encourage activities and lifestyle changes as specific to Sit-to-stand (STS) activity. Conventionally, Opto-electronic motion capture and video camera based systems are widely used to characterise sit-to-stand motion activity [1]. Thus, Motion capture systems have high capital cost and are limited to controlled settings. Present time, wearable inertial measurement unit (IMU) based device which can be easy to use in indoor or outdoor settings and monitors the physical therapy exercises improvement that provides reliable and accurate outcome measures [2,3].

This study presents the wearable IMU based motion capture (GaitSense) device, which is wireless, markerless and automated joint kinematic evaluation during STS which could be applied to monitor physical therapy rehabilitation in a wide variety of musculoskeletal disorders. The STS study was performed in indoor and outdoor settings. The STS data accuracy of the knee joint range of motion estimated for a single Sit-to-Stand cycle activity within suggested range and differentiate between normal and OA orthopedic disordered that the GaitSense can be considered as alternative method for motion capture.

## Methods

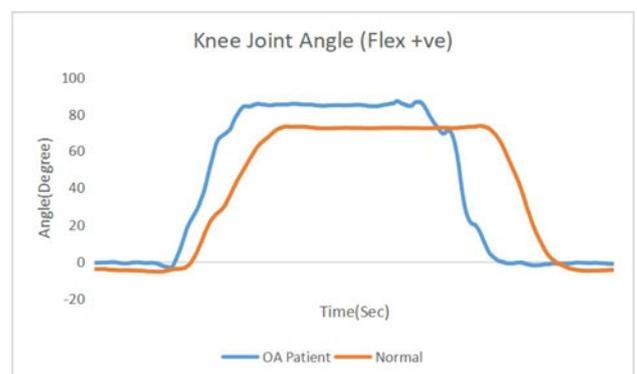

The developed GaitSense device's each node comprises 3-axis accelerometer and 3-axis angular velocity sensor. For obtaining knee joint angle range of motion during the performed activity of STS in the sagittal plane, we require to place 4 nodes on both the lower limbs. A pair of nodes are placed laterally on the left and right side of the shank and thigh segments. Goniometer reading of knee joint angles at sitting and standing position was recorded to calibrate device at same time.

The subject is then instructed to perform 5 cycles of STS activity and the IMU data while performing the activity is recorded wirelessly.

The recorded data is processed using GaitSense proprietary sensor fusion algorithm to estimate knee joint range of motion in the sagittal plane. Post-processing of the data was done using the GaitSense proprietary software to obtain and represent the joint range of motion in standard format. The data was collected in both indoor and outdoor settings on the leveled ground surface.

## Results and Discussion

The result obtained in the form of a joint angle graph replicates the goniometer readings of knee joint angle motion pattern in the sagittal plane during the dynamic activity of sit to stand. The output graph shows the difference of 13.6 degree in maximum knee joint angle between OA and normal subject.

**Figure 1:** Knee flexion/extension joint range of motion in OA and normal subject while performing STS movement activity.

## Conclusions

GaitSense device is capable of estimating joint range of motion of knee joint during dynamic activity like sit to stand, squat etc. This result could further be extended for joint angles about the other two axes i.e. in the frontal and transverse plane. Further clinical study is needed to validate the GaitSense system setup in healthy and pathological conditions.

## Predictive tracking of the knee position for mobile x-ray imaging

Seungwoo Yoon<sup>1</sup>, Seungbum Koo<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea  
Email: skoo@kaist.ac.kr

### Summary

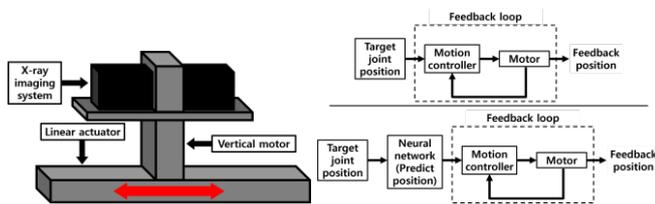

The mobile biplane X-ray imaging system requires imaging of a target human joint while it moves. This study proposes a control algorithm that reduces the tracking error between the X-ray system and the target joint. Since the target joints that move at a high speed must be tracked, the time delay causes a large tracking error. A neural network was designed to predict future joint position to compensate for the time delay. The neural network was trained with a treadmill walking data for 60 seconds, and the position of the knee after 130 ms was estimated with a 1.4 mm error. The servo motor was driven with the predicted value. The target joint tracking RMS error between the servo motor and the target joint was 5.6 mm.

### Introduction

Many biplane X-ray imaging systems have been studied to obtain accurate kinematics of human joints [1]. Among them, a mobile biplane X-ray imaging system was developed to capture a wider range of motion [2]. It was important for such equipment that the motor tracks the target joint position with little error. Since human joints moved at high speed around 1 m/s, there was a large error due to time delay. A neural network was designed to predict future joint position to compensate for the time delay.

### Methods

Reflective motion capture markers were attached on the lower limbs of subjects with the Plug-in Gait marker set protocol and walked on a treadmill at 5 km/h. The position of the marker attached to the knee joint was measured at 100Hz cycle using the motion capture system of the VICON cameras. The linear actuator (5kW, Mitsubishi) was driven according to the measured target joint position. The linear actuator was driven by loading a vertical motor of about 100 kg (Figure 1). The walking data was transmitted to the linear actuator at 10ms cycles, and the position is feedback controlled by the motion controller (MR-MC240, Mitsubishi).

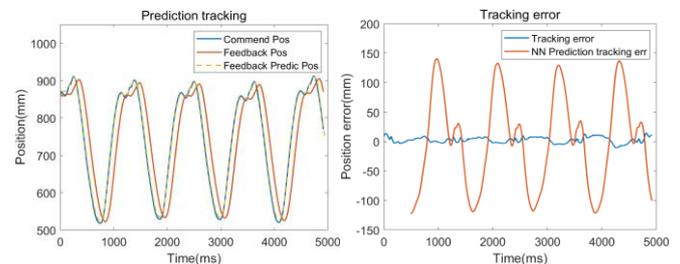

**Figure 1:** Mobile X-ray imaging system schematic design (left) and Feedback control loop (right, top) & Feedback control loop with neural network (right, bottom)

We designed a neural network to compensate for the error due to the time delay. The neural network had three hidden layers and 40 nodes. The neural network was trained using a

supervised learning algorithm to predict the future position after 130 ms by receiving 13 previous target joints position. The training data set consisted of 60 seconds of treadmill walking data captured at 100 Hz.

### Results and Discussion

The target joint position after 130 ms was estimated with the RMS error of 1.4 mm. The graph of driving the motor with the predicted positions using the neural network is shown in Figure 2. When only the feedback control of the motion controller was used, the tracking RMS error was 79.9 mm. When the neural network and feedback control were utilized, the tracking RMS error was 5.6 mm.

**Figure 2:** Compare trajectory between Motion controller & Motion controller + position Predictor (left) and tracking error (right)

In [2], when the Look-Ahead-Trajectory-Prediction and feed-forward control were applied for tracking the target joints, the tracking error was reported to be within 40 mm. Our equipment is not yet ready to take X-ray images, so a fair comparison is difficult, but we have confirmed that the tracking error can be reduced to 5.6 mm using a network-based predictive control.

### Conclusions

We developed and operated a system that accurately tracks the joint by predicting the position of the knee joint while walking. This study would be helpful in developing a mobile biplane X-ray system that acquires X-ray images of lower limb joints during walking.

 Email: [328083341@qq.com](mailto:328083341@qq.com)

## Summary

This study used functional data analysis (FDA) to understand hip-knee coordination patterns during instep and punt kicking. Three-dimensional kinematic data were obtained for 11 male soccer-majored college students performing the two kicking tasks. Bivariate functional principal components (BfPCs) for the hip and knee functions were extracted to determine key coordination patterns and the differences between kicking tasks and individual subjects. BfPC1 and BfPC2 suggested differences between individual subjects in the later portions of kicking movement, while BfPC3 and BfPC4 suggested differences between kicking tasks in the earlier portions. The relationships between these coordination patterns and hamstring length were explored to identify potential risk factors for hamstring injury.

## Introduction

FDA is a family of statistical techniques and has excellent applicability to biomechanical data since it considers the entire sequence of measurements in a time-series as a single curve rather than as a series of discrete parameters [1]. Hip-knee coordination during instep and punt kicking and its relationship with hamstring lengthening are still unclear.

This study aimed to use BfPCA to (1) identify hip-knee coordination patterns during instep and punt kicking and determine how they differ between the two kicking tasks, and individual subjects, (2) qualitatively examine the potential relationships between the hip-knee coordination patterns and hamstring lengths during the two kicking tasks.

## Methods

Eleven male soccer-majored college students with right foot dominance volunteered to participate. Reflective markers were attached. The participant then performed 3 successful trials for each of the instep kicking and punt kicking tasks. The sagittal hip and knee angles of each trial were calculated as the Cardan angles. The kicking movement was divided into the acceleration and follow-through phases. The muscle-tendon unit lengths of the biceps femoris, semimembranosus and semitendinosus were determined as the distance between the two attachment points of the muscle [2] and normalised to the respective muscle length in an upright posture.

BfPCs for the hip and knee angles of each trial were extracted. Angle-angle plots were used to visualise the BfPCs. A positive multiple of the BfPC was added to the mean hip-knee curve at equally spaced points and joined by an arrow. A positive score is indicated by '+ + +' and a negative score is indicated by '- - -'.

## Results and Discussion

The first 4 BfPCs accounted for 93% of the total variation. BfPC1 captured variation in the knee angle at later stages of the kicking movement (Figure 1), while BfPC2 described the coordinated range of hip and knee angle throughout the kicking movement. Differences in scores on BfPC3 suggested that individuals displayed greater hip flexion when performing punt kicking compared with instep kicking, particularly before ball contact. Results from BfPC4 indicated that individuals displayed greater knee flexion before ball contact when performing punt kicking compared with instep kicking.

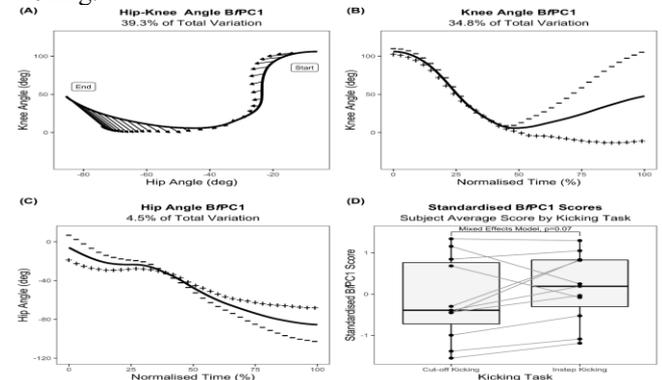

Figure 1: The first BfPC for hip-knee joint coordination.

Examining the impact of BfPC1 on hamstring muscle-tendon unit length, predictably a higher score meant that hamstrings underwent continued lengthening until the point of maximal hip flexion, reaching peak length later in the follow-through phase. A higher score on BfPC2 indicated that the hamstrings were at shorter lengths and thus at relatively lower potential risk for injury when kicking a ball.

## Conclusions

Task and inter-individual hip-knee coordination differences were found in the acceleration and follow-through phase respectively. Kicking with a greater peak knee flexion angle throughout the kicking movement especially in the later portion of the follow-through phase is a good kicking strategy for preventing a hamstring injury. This study demonstrates the potential that FDA possesses to provide novel insights for complex movements in sports biomechanics with pairs of kinematic variables that are time series in nature.

## Electromyography recordings of the tensor fascia lata muscle during dynamic tasks: A comparison of surface and fine-wire electrodes

Manuela Besomi<sup>1</sup>, Wolbert van den Hoorn<sup>1</sup>, Bill Vicenzino<sup>1</sup>, Paul W. Hodges<sup>1</sup>

<sup>1</sup>The University of Queensland, NHMRC Centre of Clinical Research Excellence in Spinal Pain, Injury and Health, School of Health and Rehabilitation Sciences, Brisbane, Qld 4072, Australia

### Summary

The tensor fascia lata (TFL) is a small fusiform muscle that is active during flexion, abduction, and internal rotation of the hip. Surface electrodes are usually used to make electromyographic (EMG) recordings from the TFL, which are more susceptible to crosstalk from surrounding muscles. Differences in the pattern of TFL activity between surface and fine-wire recordings have not been investigated. EMG was simultaneously recorded from the TFL muscle with surface and fine-wire electrodes during step-up and step-down tasks. Although the pattern of TFL activity was variable between participants for both electrode types, it was clear-cut that surface recordings revealed activity that was absent in the fine-wire recordings, which strongly suggests contamination of surface recordings by activity from adjacent muscles. However, some participants showed opposite results (higher activity with fine-wire recordings than surface). Fine-wire recordings were more prone to artefacts.

### Introduction

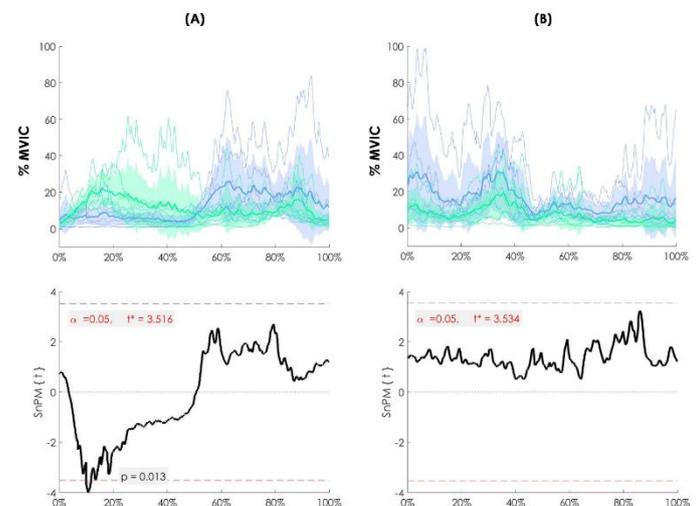

Although most existing studies have used surface electrodes to record EMG from the TFL muscle [Besomi et al., 2020], its small size and close proximity to other muscles make these recordings susceptible to crosstalk [Besomi et al., 2019]. Recent systematic review on muscle structure and activation of the TFL has identified that all EMG studies used surface electrodes for comparison of pattern of activity between participant groups [Besomi et al., 2020]. It is unclear whether the bursts of TFL EMG reported with surface recordings arise from TFL or represent crosstalk from underlying and surrounding muscles (e.g., gluteus medius and minimus, sartorius, rectus femoris, and iliacus).

### Methods

Eight healthy and physically active volunteers (5 females, 3 males; mean  $\pm$  SD age  $28 \pm 6$  years; height  $1.70 \pm 0.07$  m; mass  $65.6 \pm 10.3$  kg; BMI  $22.8 \pm 3.4$  kg/m<sup>2</sup>) participated in this study. EMG signals of the TFL muscle were recorded with surface and fine-wire electrodes (inserted under guidance of ultrasound). Participants performed five trials of step-up and step-down tasks wearing their preferred footwear, followed by three maximum voluntary isometric contractions (MVICs). EMG data were band-pass filtered (50–500 Hz for both electrode types) with a zero-lag fourth-order Butterworth filter. EMG signals for all trials were visually inspected for artefacts. EMG data were rectified and subsequently smoothed with a 10-Hz, fourth-order zero-lag low-pass Butterworth filter, and were subsequently amplitude-normalised to the MVIC (expressed as %). Statistical parametric mapping (SPM) was used to statistically compare the patterns of activation between electrode types.

### Results and Discussion

The pattern of TFL EMG from surface and fine-wire recordings varied between participants in both tasks. Some participants showed an additional major peak with surface recordings that was not apparent in the fine-wire recordings, and others showed the opposite. SPM revealed one supra-threshold cluster (between 10-15%) exceeding the critical threshold ( $t^* = 3.516$ ,  $p = 0.013$ ) during the step-up task. The MVIC normalised amplitude of surface recordings was significantly greater than fine-wire recordings during this period (Figure 1).

**Figure 1:** Comparison of EMG pattern of the TFL normalised to MVIC between surface (green) and fine-wire (blue) electrodes during step-up (A) and step-down (B). Bold line represents the group mean and shaded area the group standard deviation

During the step-up task, activation of other hip flexor muscles will be present and could have been recorded by the surface electrode. It is possible that fine-wire EMG recordings were greater during the late phase of the tasks because of the normalisation procedure. If MVIC for surface recordings included contribution of adjacent muscles, amplitude used for normalisation might exceed the muscle's true MVIC and thus lead to underestimating activation as a proportion of MVIC for that phase. Lower activation in surface EMG might also be explained by methodological issues from each electrode.

### Conclusions

Surface EMG recordings of TFL are affected by crosstalk. For studies that aim to understand the specific activation of TFL, fine-wire recordings are recommended considering the limitations of this technique.

## Removing artificial jumps from kinematic recordings with multiple cameras

Charlotte Le Mouel<sup>1</sup>, Marc H. E. de Lussanet<sup>1,2</sup>

<sup>1</sup>Movement Science, University of Münster, Münster, Germany

Email: lussanet@uni-muenster.de

### Summary

In standard marker-based motion capture systems, the 3D position of each marker is reconstructed from the 2D views of a set of cameras. When the subset of cameras viewing a given marker changes, the reconstructed marker position jumps suddenly from one frame to the next. Although these jumps are often small (0.1 – 1 mm), they cause drastic errors in speed estimates (up to 0.5 m/s), especially for high frame rates (120 – 500 Hz). The problematic of these artificial jumps requires heavy filtering of kinematic data. We propose and compare methods for identifying and removing such jump artifacts. We validate these methods on kinematic data of both static balance and running recorded at two different frequencies using two different motion capture brands. Both methods reliably remove jump artifacts while keeping the original signal intact, and largely improve estimates of marker speed.

### Introduction

The recording of kinematic data using modern high-speed cameras combines high spatial accuracy (typically 0.1 – 1 mm) with very high recording speeds (typical frame rates of 100-500 Hz). The 3D position of each marker is reconstructed from the 2D views of a set of cameras. The reconstructed marker position may be inaccurate if the initial calibration of the cameras' position is insufficient or the lens correction does not compensate fully for the nonlinearities of the cameras [1]. Although reconstruction errors are typically small (less than 1 mm), they depend on the subset of cameras viewing the marker. The subset of cameras changes the marker is obstructed from the view of one of the cameras or moves in or out of a camera's field of view. As a result, when the subset of cameras viewing a marker changes, a small jump in the reconstructed marker position (typically less than 1 mm) occurs from one sample to the next. Especially with rapid frame rates, this causes a drastic inaccuracies (spikes) in marker speed.

Typically, the problem is dealt with by severe smoothing of the data with a low pass filter that introduces real artifacts to the recorded kinematics. Thus, the kinematic jump problem represents a limiting factor to the effective accuracy of kinematic recordings.

We developed and tested numerical methods for removing artificial kinematic jumps without introducing artifacts into the kinematic signal. These artifacts involve transients, such as the heel-stroke during running, and drift due to the incomplete removal of jumps. Furthermore we test the stability of the filter with different measurement frequencies.

### Methods

The methods involve the following steps. First, possible steps in the raw kinematic recording are identified. Second, the appropriate threshold to include as many steps as possible while ignoring transients in the recordings such as

heel strike and very fast movements. Third, removing possible drift from the thus cleaned signal.

We validated the methods on four datasets: 1. Treadmill running recorded at 500 Hz and down-sampled versions of the same recordings. Special attention was given to markers with frequent jumps due to partial masking, to ones with transient kinematics due to the heel strikes and to the fastest ones. 2. Walking along a track of several meters with special attention with special attention given to moving in and out of camera view. 3. Static balance recordings with a dense placement of foot markers. 4. Simulated sinusoidal motion with the negative phases replaced by zeros, with added noise and jumps. The stability of the method was further tested by applying it several times on the already processed signal.

### Results and Discussion

The resulting method has an automatic threshold detection, providing objective criterions. Further, we got excellent velocity and acceleration signals by Savitzky-Golay differentiation.

The validation showed robust behavior of the new method, independent of the capture frequency, the movement velocity and kinematic transients such as heel strikes during running. At low frequencies, the new method became somewhat less selective for the heel strike. Steps due to calibration errors and nonlinearities of the cameras could be removed alike and irrespective of movement velocity, translation and partial occlusion.

The drift correction could keep the error with respect to the recorded signal below the size of the steps at all times.

### Conclusions

The proposed novel method for removing kinematic jumps is highly selective and reliable in all tested conditions. It is the first one available and is advised for kinematic recordings with multiple cameras.

Matlab and Python scripts are made available on Github [1].

## Micro-Biopsy Fiber Mechanics from the Medial Gastrocnemius of Dancers

Paige E. Rice<sup>1</sup>, Sophia Nimphius<sup>1</sup>, Kiisa Nishikawa<sup>2</sup>

<sup>1</sup>School of Medical and Health Sciences, Edith Cowan University, Joondalup, WA, Australia

<sup>2</sup>Department of Biological Sciences, Northern Arizona University, Flagstaff, AZ, United States of America

Email: [p.rice@ecu.edu.au](mailto:p.rice@ecu.edu.au)

### Summary

Human single muscle fiber and muscle fiber bundle mechanics have historically been performed on Bergström needle (5-6 mm) muscle biopsy samples (~60 mg). Here, we demonstrate that muscle fiber mechanics can be performed on muscle samples (~15 mg) from 14G micro-biopsy needles (2.1 mm), which are far less invasive, more feasible for laboratories that do not have access to a medical doctor, and pose less risk to the participant. To our knowledge, these are the first passive muscle fiber mechanics data from dancers.

### Introduction

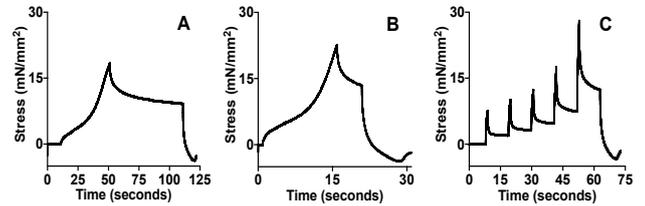

Muscle micro-biopsies are a practical technique for physiologists and biophysicists to further knowledge surrounding human muscle properties. Up until now, Bergström muscle biopsies have been the sole technique for researchers investigating human muscle fiber mechanics [1, 2]. The aims of this study were to 1) determine whether muscle fiber mechanics could be investigated using medial gastrocnemius (MG) micro-biopsy samples, and subsequently 2) report passive muscle fiber characteristics of dancers.

### Methods

Healthy female dancers (n = 15; age = 24.2 ± 5.0 yrs.; height = 163.8 ± 4.6 cm; body mass = 61.1 ± 8.9 kg; dance training = 19.6 ± 4.9 yrs.) volunteered to participate in this study and gave informed consent. Topical lidocaine was used to numb the area of the biopsy. Three muscle samples (~45 mg of tissue) were taken using a micro-biopsy needle (SuperCore™ Semi-Automatic Biopsy Instrument, with co-axial needle, 14 G, 6 cm, Argon Medical, Frisco, TX) from the dancers' MG.

Muscle samples were immediately placed in 2 mL of skinning solution and stored at -30°C for one month prior to permanent storage in -80°C until the day of the experiment [1]. On the day of experiments, muscle fibers (2-3 mm in length) were teased from samples in relaxing glycerol (50:50). Muscle fibers were attached with acetone-based glue to length lever controller (Aurora Scientific Inc., Model 315C, Ontario, Canada) and force transducer pins (Model 400A). A high-speed camera (Aurora Scientific Inc., HVSL 901C, Ontario, Canada) was used to adjust fibers to a starting average sarcomere length (SL) of 2.4 μm. Muscle fiber cross-sectional area (CSA) was determined with an ocular micrometer (50X).

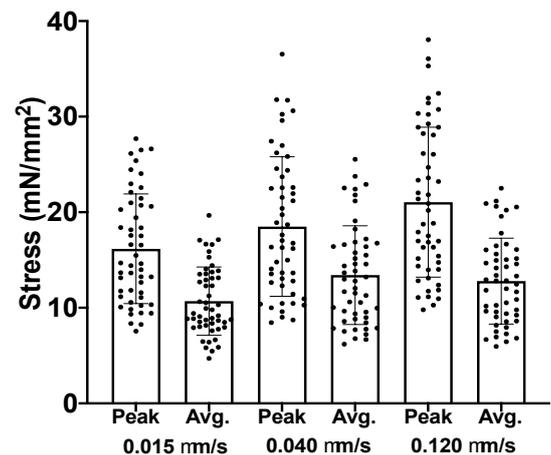

Muscle fibers (n = 50) were passively stretched from an average SL of 2.4 μm to 3.0 μm at 0.015 μm/s, 0.04 μm/s, and in five ramping increments at 0.12 μm/s (Figure 1). Trials were separated by three minutes of rest. Muscle fiber stress was calculated as force divided by muscle fiber CSA. Peak stress and average stress from the last second of each corresponding stretch-hold were reported.

**Figure 1:** Example data from a passive muscle fiber during A) slow (0.015 μm/s), B) moderate (0.04 μm/s), and C) ramp stretch (0.12 μm/s) from an average SL of 2.4 to 3.0 μm.

### Results and Discussion

Passive peak stress of muscle fibers increased with stretch velocity (Figure 2). The data are comparable to previous human MG fiber studies, and suggest that micro-biopsies can be used to investigate the intrinsic and adaptable properties of human muscle fibers [3].

**Figure 2:** Passive peak stress at an average SL of 3.0 μm after slow, moderate, and the fifth ramp stretch (see Fig. 1).

### Conclusions

Based on the comparable results of fiber mechanics between techniques, micro-biopsy samples are a viable alternative to Bergström biopsies to investigate fiber mechanics.

### Summary

The purpose of this study was to clarify the influence of intermittent blocking of visual information on walking parameters and corticomuscular coherence (CMC). Twelve healthy young persons participated in this study. Subjects walked at a comfortable speed for 10 minutes with and without intermittent blocking of visual information. The subjects' visual information was blocked intermittently by the liquid crystal shutter goggle with 10 Hz blinking frequency under the two conditions with the duty ratio of 30% and 70%. No blocking of visual information was the control condition. EEG was recorded from Cz, and EMG was recorded from the right tibialis anterior (TA). Walking parameters (speed, walking rate, step length) and the peak value of Cz-TA coherence in the beta band (13-30Hz) were evaluated. There was no significant difference in walking parameters at intermittent blocking of visual information with the duty ratio of 30% and 70%. The peak value of Cz-TA coherence in the beta band significantly decreased at intermittent blocking of visual information with the duty ratio of 70% compared to that of no blocking. These results suggested that intermittent blocking of visual information in young adults during walking mainly affected the modulation of CMC, but it did not even cause the change of walking parameters.

### Introduction

There is still little consensus on the influence of intermittent blocking of visual information on walking parameters and corticomuscular coherence (CMC) during walking [1]. This study aimed to clarify the influence of intermittent blocking of visual information on walking parameters and CMC.

### Methods

Twelve healthy young men (age:  $21.2 \pm 0.8$  years, height:  $169.8 \pm 6.9$  cm, weight:  $65.5 \pm 7.4$  kg) participated in this study. The study was approved by the ethics committee for Yamagata Prefectural University of Health Sciences (approval number 1809-19) and was performed by the Declaration of Helsinki. Subjects walked a 20m 8-shaped walking path at a comfortable speed for 10 minutes. Measurement conditions were the following three conditions. The liquid crystal shutter goggle blocked the subjects' visual information with 10 Hz blinking frequency under two conditions with the duty ratio of 30% and 70%. No blocking of visual information (without the liquid crystal shutter goggle) was the control condition. Walking parameters of speed, walking rate, and step length were evaluated above the three conditions. Electroencephalogram (EEG) and electromyogram (EMG) were measured during walking using a 4-channel Ganglion Board (Open BCI) at the 200Hz sampling frequency. EEG activity was recorded through unipolar silver electrodes placed

at Cz by the international 10-20 system. Surface EMG electrodes of Ag/AgCl (Kendal H124SG, 30mm×24mm, interelectrode distance 2cm) were placed at the proximal 1/3 of the tibialis anterior (TA) muscle of the right leg. EEG and EMG electrode impedances were kept below 5k Ohm. The Welch algorithm calculated EEG-EMG coherence (Cz-TA coherence) for Cz-TA in theta (4-8Hz), alpha (8-13Hz), beta (13-30Hz), and gamma (30-40Hz) bands (window width: 256 points, overlapping 128 points, resolution 0.78 Hz). Walking parameters and peak values of Cz-TA coherence in the four bands were evaluated in the above three conditions. The evaluation parameters were compared between no blocking and intermittent blocking with the duty ratio of 30% and 70% using repeated-measures ANOVA. Statistical significance was given for P-values smaller than 0.05.

### Results and Discussion

There was no significant difference in walking parameters during intermittent blocking of visual information with the duty ratio of 30% and 70%. The peak value of Cz-TA coherence in the beta band significantly decreased at intermittent blocking of visual information with the duty ratio of 70% compared to that of no blocking. These results suggested that intermittent blocking of visual information in young persons during walking mainly affected the modulation of CMC, but it did not even cause the change of walking parameters.

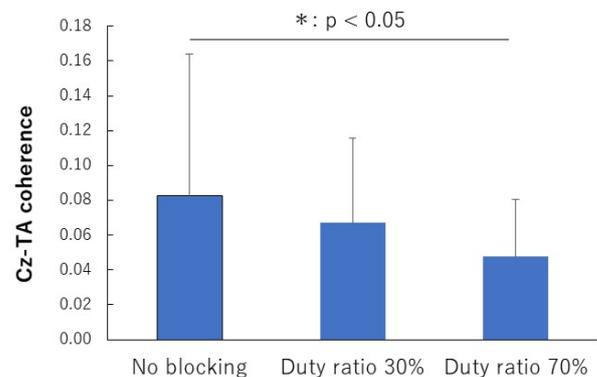

Fig. 1 Cz-TA coherence in beta band during walking

### Conclusions

Intermittent blocking of visual information with the duty ratio of 70% in young persons during walking mainly affected the modulation of CMC, but it did not even cause the change of walking parameters.

### Summary

This study explored trunk control during symptomatic and asymptomatic periods for individuals with recurrent low back pain (rLBP) and compared them with the back-healthy individuals using the Balance-Dexterity Task (BDT). Findings revealed that individuals with rLBP exhibited reduced center-of-pressure (COP) velocity when they were in remission compared to when they were in pain, and when compared to the back-healthy controls (CTRL).

### Introduction

Based on a former study, we hypothesized trunk kinematics during a dynamic balance task would be altered compared to the back-healthy individuals [1]. This motor control dysfunction may contribute to the recurrence of pain [1]. So it is necessary to explore task performance for people with rLBP when they are in pain and in remission. The purpose of this study was to investigate trunk control, dexterity, and steadiness in and out of an episode of rLBP and compare them to CTRL. We hypothesized that persons with rLBP in remission would have similar steadiness (COP velocity) and dexterity (ability to maintain compression force) and less frontal plane trunk coupling compared to CTRL. We also hypothesized that in active pain, individuals with rLBP would exhibit increased frontal plane trunk coupling compared to when they were in remission due to a “tighter” trunk control triggered by pain [2].

### Methods

19 individuals with rLBP (F=13, M=6; 25.3±5.2 years) and 19 matched CTRLs (F=13, M=6; 26.9±3.4 years) performed the BDT. rLBP group was first tested when they were in pain (rLBP-A, Visual Analog Scale (VAS) = 38.9±19.2 mm), then in remission (rLBP-R, VAS = 1.4±2.4 mm).

The BDT required participants to compress a stable block or an unstable spring with one limb (dexterous limb) to maintain an individualized force target while standing on the supporting limb [3]. With the recorded data from corresponding force plates under both feet (sampling frequency = 1500 Hz), COP velocity under the supporting limb and vertical force variability under the dexterous limb were analyzed. Frontal plane trunk coupling was calculated as the coefficient of determination ( $R^2$ ) between thorax and pelvis angles, which were modeled from marker-based kinematic data recorded by a motion capture system. The statistical analysis was conducted using linear mixed-effects models. The analysis was first conducted between rLBP-A and rLBP-R. If no differences were found, then rLBP-A and rLBP-R were pooled and compared to CTRL.

### Results and Discussion

Across rLBP-A and rLBP-R, participants had greater COP velocity ( $p<.001$ ), greater vertical force variability ( $p<.001$ ), and less trunk coupling ( $p=.0135$ ) when compressing the spring than the block (condition main effect). Trunk coupling was not statistically different between rLBP-A and rLBP-R ( $p=.695$ ) or between rLBP and CTRL ( $p=.327$ ). There were no differences in dexterity between rLBP-A, rLBP-R ( $p=.363$ ), and CTRL ( $p=.421$ ). rLBP-R had reduced COP velocity compared to rLBP-A ( $p=.029$ ) and CTRL ( $p=.011$ ) (Fig 1).

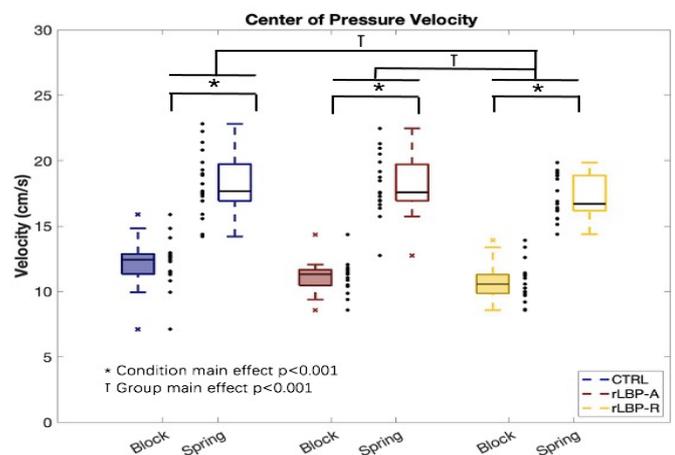

Figure 1: COP velocity during block and spring conditions in CTRL, rLBP-A, rLBP-R

### Conclusions

Contrary to our hypothesis, individuals with rLBP did not alter frontal plane trunk coupling in and out of a painful episode, nor were they different from CTRL. Instead, individuals in remission showed a lower COP velocity compared to when they were in pain and the CTRL. This may indicate that frontal plane trunk coupling was altered independently of task performance. These results suggest that persons with rLBP have greater steadiness during symptom remission, which may be attributed to psychosocial influences such as fear of movement.

### Summary

The mechanical arrangement of the human semitendinosus (ST), a hamstring muscle comprised of two anatomically in-series compartments, remains unknown. Using two-dimensional shear wave elastography (2D-SWE), we acquired the shear modulus of both ST compartments at ten knee joint angles. We found no differences in shear modulus-angle curve parameters between the two compartments. As shear modulus is linearly related to muscle force [1], our results suggest forces are equally distributed along the ST and thus the two ST compartments can be considered mechanically in-series.

### Introduction

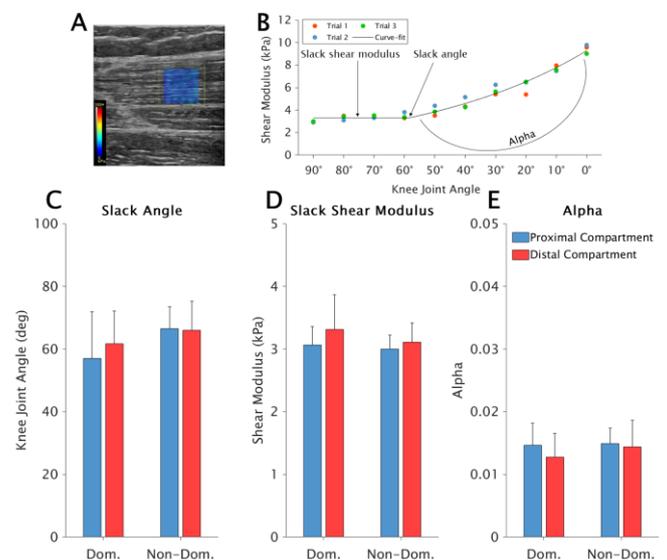

The ST is divided by a tendinous inscription into proximal (ST<sub>prox</sub>) and distal (ST<sub>dist</sub>) compartments, each with separate nerve branches [2]. As the two compartments are anatomically in-series, it is typically assumed they are also mechanically in-series in humans [3]. However, structures anatomically in-series do not necessarily bear identical loads and thus are not always mechanically in-series [4]. Further, potential imbalances in force between ST<sub>prox</sub> and ST<sub>dist</sub> may increase the risk of muscle injury [2]. As the shear modulus obtained with 2D-SWE can provide an indirect measure of muscle force [1], characterizing the passive shear modulus-angle relationship of ST<sub>prox</sub> and ST<sub>dist</sub> using 2D-SWE might suggest differences in force distribution between ST compartments. Thus, the aim of this study was to compare the passive shear modulus-angle curves of ST<sub>prox</sub> and ST<sub>dist</sub>.

### Methods

The Young's modulus of ST<sub>prox</sub> and ST<sub>dist</sub> was obtained from 14 prone-positioned participants ( $n=11$  bilateral,  $n=3$  unilateral) with a 44 mm linear ultrasound transducer (9L; Logiq E9, GE Healthcare) (Figure 1A). Following preconditioning, three 2D-SWE images from each of ST<sub>prox</sub> and ST<sub>dist</sub> were acquired at 10° intervals from 90° to 0° (full extension) of knee flexion. Knee joint angle and semimembranosus myoelectric activity (to verify hamstring passive state) were monitored in real-time (ME6000, Mega Electronics). Young's modulus values were divided by three to obtain shear modulus [1]. A piecewise exponential model was fit to the data to obtain parameters from the shear modulus-angle curve: slack angle (the angle at which shear modulus starts to increase), slack shear modulus, and "alpha" (the slope of the increase in shear modulus) [5] (Figure 1B). The effects of leg and compartment on slack angle, slack shear modulus, and alpha were assessed with a linear mixed model.

### Results and Discussion

There were no main effects of leg (slack angle:  $p=0.054$ ; slack shear modulus:  $p=0.319$ ; alpha:  $p=0.471$ ) or compartment (slack angle:  $p=0.480$ ; slack shear modulus:  $p=0.141$ ; alpha:  $p=0.220$ ) (Figure 1C-E). There were also no interactions between leg and compartment for slack angle ( $p=0.419$ ), slack shear modulus ( $p=0.564$ ), or alpha ( $p=0.370$ ).

**Figure 1:** Example elastography image (A) and piecewise curve-fit (B). Shear modulus-angle curve parameters of the semitendinosus compartments of dominant and non-dominant legs (C-E).

### Conclusions

The lack of differences in shear modulus-angle curve parameters between the proximal and distal ST compartments suggests an equilibrium of forces between the two human ST compartments and thus a mechanically in-series arrangement.

### Summary

Careful implant positioning during total hip arthroplasty (THA) is important to reduce muscle and joint forces during walking. However, current understanding of this relationship is based on simulation or mathematical models and often neglect true radiographical findings or fail to consider individual gait patterns. Here, we used pre-and post-operative computed tomography (CT) and 3D gait analysis to determine the effect of surgical placement of the hip joint center (HJC) during THA on hip abductor and hip joint reaction forces during walking.

### Introduction

Considerable research effort has focussed on reconstructing the HJC during THA to provide a mechanical advantage to the hip abductors, which contribute to the most of any hip muscle group to the hip joint reaction force [1]. The aim of this study was to determine the effect of HJC reconstruction on the hip abductor and hip joint reaction forces.

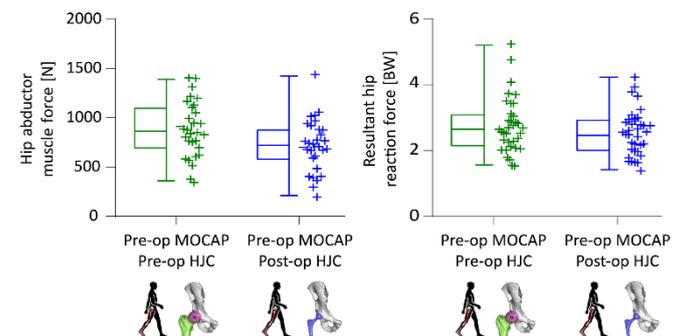

### Methods

Thirty-five patients undergoing primary THA for osteoarthritis (OA) were recruited from a single public hospital in Australia (mean age: 66 (SD 14) years, mean BMI: 24 (SD 5) kg.m<sup>-2</sup>). Subjects walked at a self-selected pace where a 10-camera motion analysis system (Vicon, Oxford, UK) system tracked marker trajectories and two force platforms recorded ground reaction forces. Pre-and post-operative CT of the pelvis and proximal femurs were obtained and reconstructed using the Scan-IP module (Simpleware,UK). The pre-operative hip HJC was determined using the center of a sphere fitted to the femoral head and its location was expressed relative to the center of a sphere fitted to the acetabulum. For the post-operative HJC location, the pre-and post-operative reconstructed models were aligned, where the post-operative femoral head location was expressed in the pre-operative acetabulum reference frame, allowing for the change in HJC location to be determined. To estimate muscle and joint reaction forces, a generic musculoskeletal model (Gait 2392) was scaled to the subject's anthropometry using the MAPClient [2], where the hip joint geometry was personalized from CT data. Muscle forces and hip joint reaction forces were computed using the available tools in OpenSim. To determine the effect of surgical change to HJC location alone paired samples *t*-test was used to test the

difference in the peak resultant hip reaction force when the pre-operative model was adjusted to represent the surgical change in HJC location, without any change in the pre-operative motion capture data.

### Results and Discussion

Surgical change to the HJC reduced the magnitude of hip abductor muscle force (mean difference: -162 N, SD 187, *p* <.001) and the resultant peak hip reaction force (mean difference: -151 N, SD 324, *p* = .009) (Figure 1). Medial and proximal location of the HJC had the greatest influence on hip joint reaction forces, explaining 52% and 40% of the variance, respectively. For each millimeter of medialization, the peak resultant hip reaction force reduced by 35 N, (SD 7) and for each millimeter of proximal change, the peak resultant hip reaction force reduced by 28 N (SD 9).

**Figure 1:** The effect of surgical change to the HJC on peak abductor muscle forces (left) and resultant hip joint reaction forces (right).

### Conclusions

Medial and proximal location of the HJC resulted in the greatest reduction in hip abductor and hip reaction forces. Changes in the medial direction were most influential to reduce hip joint reaction forces, indicating an emphasis is placed on HJC medialization to increase the hip abductor moment-arm and reduce hip joint reaction forces, with consideration of proximal placement if the available bone stock is sufficient to achieve implant stability.

## Optimal Design of Elastic Ankle Exoskeleton Using Optimal Control of Musculoskeletal Model

Karthick Ganesan, Abhishek Gupta

Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, India

Email: karthick.ganesan@iitb.ac.in

### Summary

Finding optimal stiffness is critical to the design of elastic ankle exoskeletons. Musculoskeletal simulations can be a promising alternative to laborious experiments in this regard. Here we use optimal control based musculoskeletal simulations to find the optimal stiffness of an elastic ankle exoskeleton. The stiffness found from simulations were similar to that found from experiments, proving the utility of this approach.

### Introduction

Elastic ankle exoskeletons are of light weight, simple in construction, yet have the potential for reducing the metabolic cost of walking. However the stiffness of these exoskeletons has to be chosen optimally, otherwise it can even have negative effect on the metabolic cost due to the interplay between the plantarflexor muscles and tendon [1]. Researchers have used springs of different stiffness values in experiments to arrive at the optimal stiffness. Musculoskeletal simulations can complement experiments. Although simple lumped parameter models have been used [2], they did not consider the dynamics of all limb segments and assume fixed kinematics. Optimal control based predictive simulations can overcome these limitations. Here we use this approach to optimize the stiffness of an elastic ankle exoskeleton.

### Methods

We used a 2D version of the Rajagopal's [3] musculoskeletal model, with 12 degrees of freedom and 28 muscles. Contact elements were defined on the plantar surface of each foot. The muscles were replaced by muscle model proposed by de Groote et al [4].

The goal was to determine the states and controls of the model, and the stiffness of the bilateral exoskeletons that minimized a cost functional subject to the skeleton and muscle dynamics, and task constraints with respect to the bounds on states, controls, stiffness (0 – 250 Nm/rad) and final time. The cost functional had a tracking term and a muscular effort term. The tracking term consisted of the squared difference between values of the model variables and the reference variables (generalized coordinates and speeds, and the ground reaction forces). For reference values we used the mean experimental values from the literature. The reference values for pelvic tilt and lumbar degrees of freedom were set as zero. The generalized speeds for the pelvis and lumbar degrees of freedom were not tracked. The weights for tracking and effort terms were tuned to produce realistic metabolic cost without exoskeleton.

We solved the optimal control problem numerically using direct collocation. The optimal control problem was

converted into a nonlinear programming problem through hermite-simpson transcription with 25 nodes. This was achieved using CasADi solver in OpenSim Moco [5]. IPOPT was used as the NLP solver. Stiffness of the exoskeleton was treated as a static parameter.

### Results and Discussion

The optimal stiffness found was 34 Nm/rad which is close to that found through experiments. The metabolic cost reduction at this stiffness was 3.2%. We also tested the metabolic cost with different stiffness values and found that they were less, compared to that of optimal stiffness. One of the limitations of our study is that we used a two dimensional model to reduce the computational time. Another limitation is that we used experimental gait data for tracking. By increasing the weight on the effort term we can do a predictive simulation.

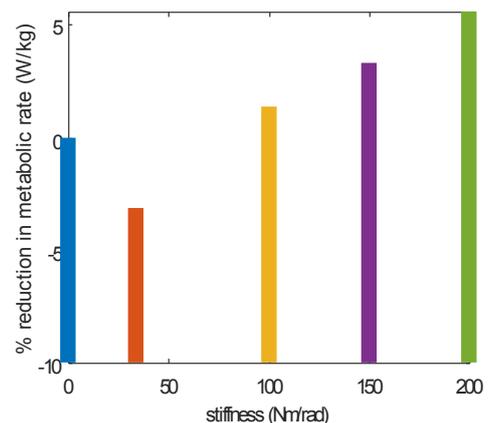

Figure 1: Percent reduction in metabolic rate for range of stiffness.

### Conclusions

We demonstrated the use of optimal control based musculoskeletal simulations to optimize the stiffness of elastic ankle exoskeleton. This approach can be extended to other exoskeletons and parameters. This approach will be particularly useful for designing exoskeletons for pathological populations since conducting many experiments on them is difficult.

Kieran.Bennett@adelaide.edu.au

### Summary

Estimations of joint loading are critical to evaluate joint disease and functional outcomes. However, the muscle recruitment strategy which best mimics joint loads measured *in vivo* remains unclear. This study compared the performance of three methods: (1) static optimization; (2) EMG-assisted, and; (3) an inverse EMG-informed stochastic method. Static optimization resulted in root mean square errors of 674 N and 196 N, while the EMG-assisted method errors were 413 N and 153 N. The stochastic method provided a spectrum of knee forces containing the *in vivo* target measurements and a spread consistent with the uncertainty on the inputs.

### Introduction

Joint loadings have been associated with onset and progression of musculoskeletal diseases, such as knee osteoarthritis. Musculoskeletal models can estimate joint loading, overcoming the inability to perform direct *in vivo* measurements. However, contention still remains around the optimal method to simulate muscle recruitment strategies that accurately estimate joint loading. Using data from instrumented knee replacements as ground truth, we compared three methods for simulating muscle recruitment to estimate internal joint loading at the knee during walking.

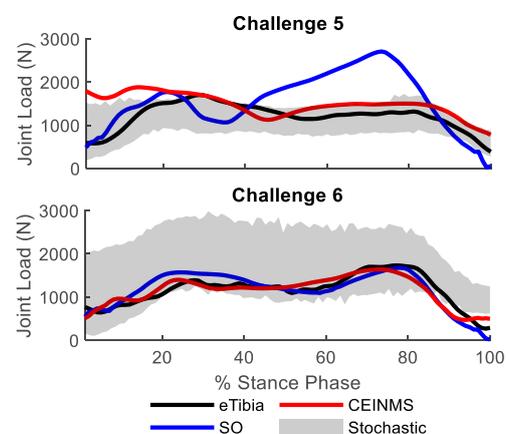

### Methods

Data were obtained from the Grand Challenge Competition to Predict *in-vivo* Knee Loads (challenges four, five, and six) [1]. Static and over ground gait trials were used. A generic full-body musculoskeletal model [2] was scaled using static marker data in MAPClient [3]. Musculotendon lengths [4] and muscle maximum isometric strengths [5] were tailored to subjects. Marker trajectories and ground reaction forces were used for inverse kinematics, inverse dynamics, and static optimization (SO) in OpenSim [2]. Electromyography (EMG) data were used for the Calibrated EMG Informed Neuromusculoskeletal Toolbox (CEINMS), and to inform constraints for the inverse EMG-informed stochastic method [7]. We used 8-11 EMG signals from large superficial muscles. In CEINMS, seven degrees of freedom were driven in EMG-assisted mode. In the stochastic method, one million solution samples were taken per frame, and muscles forces were constrained within one standard deviation of the CEINMS solution. Other muscles were constrained to half of their maximum possible force. The measured loading from the prostheses was used as the ground-truth for model validation.

### Results and Discussion

For datasets where subjects walked abnormally (Challenge 5, Fig 1), SO significantly over predicted second peak loading

(1390 N error), while CEINMS was able to account for altered neuromusculoskeletal control during late stance (182 N second peak load error). The stochastic method produced a solution space encompassing the measured load, except for between 27-32%. Root mean square errors (RMSE) for SO and CEINMS were 674 N and 413 N respectively. In challenge 6, both SO and CEINMS accurately predicted knee JCF with RMSE of 196 N and 153 N respectively. The stochastic method produced a solution space which includes the *in-vivo* target measurement up to 90% of stance.

**Figure 1:** Measured (eTibia) and estimated knee joint loading using SO, CEINMS, and the stochastic method of muscle recruitment.

### Conclusions

Estimations of joint loading were obtained using different methods of simulating muscle recruitment. Overall, CEINMS produced better estimates of joint loading compared to SO. The stochastic method provided a spectrum of knee forces containing the *in vivo* target measurements and can allow for further exploration into muscle recruitment and its effect on joint loading.

# Effect of sagittal alignment parameters on intervertebral compression forces in asymptomatic adolescent girls, during a pubertal growth spurt, using a thoracolumbar musculoskeletal model

Email: [mohammadaminshayestehpour77@gmail.com](mailto:mohammadaminshayestehpour77@gmail.com)

## Summary

Sagittal alignment of the spine alters during the pubertal growth spurt. Using a musculoskeletal model, we simulated these alterations by choosing Thoracic Kyphosis and Sagittal Vertical Alignment as variable parameters. Results indicated that, by increasing these parameters as the posterior inclination of the spine decreases through the growth spurt, the intervertebral compression forces of the thoracolumbar spine increase.

## Introduction

Adolescent Idiopathic Scoliosis (AIS) occurs most often in adolescent girls. This is a deformity in the frontal plane. However, this concurs with natural changes in sagittal plane alignment in their spinal pubertal growth. Previous studies indicate that the adolescent spine tends to be more posteriorly inclined earlier in the growth spurt, then Thoracic Kyphosis (TK) and Sagittal Vertical Alignment (SVA) increase in a way that posterior inclination decreases during further pubertal development [1, 2].

## Methods

We utilized a recently developed thoracolumbar musculoskeletal model [3] to obtain the variation of normalized intervertebral joint compression (NJC) force caused by alteration of TK and SVA, and then investigate the NJC trend through the growth spurt.

TK is the sagittal Cobb angle between the T4 and T12 vertebrae, and SVA is the horizontal distance between the C7 vertebra and the posterior superior sacrum. Positive SVA means C7 is placed posteriorly to Sacrum. Parameter values during the growth spurt were obtained from previous studies. [1, 2]. In this study, TK and SVA were simulated in the range of 28 to 39 degrees and -20 to 43 mm respectively.

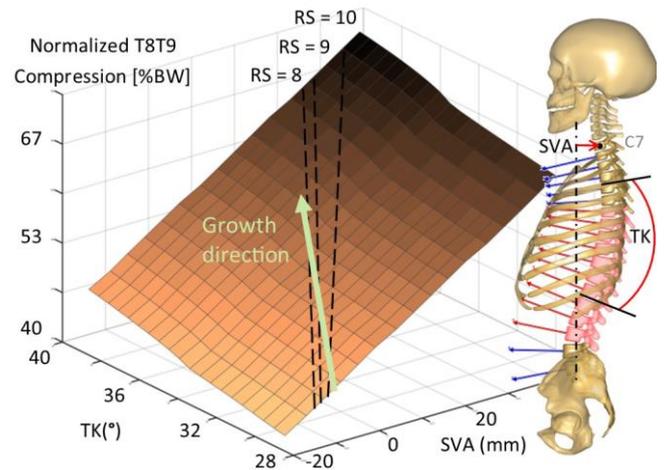

We represented the reclined segment (RS) of the spine by the number of vertebrae that are posteriorly inclined relative to the horizontal plane [1]. This parameter was employed to identify the proper growth direction line on the surface. Typical RS in growth is considered to be 8 to 10 posterior vertebrae, which were illustrated as dashed lines (Figure 1).

We acquired the growth direction line considering that TK and SVA increase and RS decreases, to describe typical TK, SVA and RS development in the growth spurt.

## Results and Discussion

We considered the T8-T9 NJC as a function of TK and SVA (Figure 1) because T8 is the most common apical vertebra in AIS. However, the trend was the same for all the lower

thoracic and lumbar regions. NJC increased with increasing TK and SVA but NJC is more sensitive to SVA than TK.

**Figure 1:** The T8-T9 NJC as a function of TK and SVA. The compression is normalized to body weight [BW]. TK and SVA are defined on the right and the reclined segment (RS) is shown in red. The spine arrows show the inclination of each vertebra. The dashed lines on the surface show constant RS of 8, 9, and 10 reclined vertebrae, which include L3 up to T8, T7, and T6, respectively.

Using the growth direction line, we infer that NJC is higher in the later stages of growth for adolescent girls. Moreover, we found a positive correlation between NJC and RS.

## Conclusions

The intervertebral joint compression in T8-T9 increases with TK as well as SVA, and the combination of parameter development typical for the growth spurt causes a net increase of joint compression. It may be speculated that the balance between increasing spinal compression forces and evolving resistance to load in the adolescent spine can play a role in the pathomechanism of AIS. The perspectives of this thoracolumbar musculoskeletal model may contribute to investigating this question in the future.

## Improving Muscle Geometry through Via-Point Optimization

C.V. Simon<sup>1</sup>, F.C.T. van der Helm<sup>1</sup>, T. Geijtenbeek<sup>1</sup>

<sup>1</sup>Biomechanics and Human-Machine Control, Delft University of Technology, Delft, The Netherlands

Email: t.geijtenbeek@tudelft.nl

### Summary

Accurate representation of muscle lengths and muscle moment arms is crucial for musculoskeletal modeling. A common approach is to model muscle geometry using via-points fixed to specific bodies. A downside of this approach is that the way in which moment arms change with motion is often unintuitive and leads to inaccurate or suboptimal moment arms – especially for joints with multiple degrees of freedom (DOFs). We used optimization to determine via-point placement so that moment arms matches reference data over a range of motion as closely as possible. We found this approach to drastically improve existing via-point models, approaching accuracy of more advanced methods that use wrapping surfaces.

### Introduction

The via-point method is a popular approach for modeling muscle geometry in musculoskeletal models [1]. It is easy to comprehend, visualize and implement, while being computationally far less expensive than more advanced methods based on wrapping surfaces [2]. The latter is specifically important for predictive simulations, where muscle lengths and moment arms are evaluated many times and often form a performance bottleneck.

Typically, the locations of via-points are tuned manually to match cadaver or imaging data. The downside of this approach is that selecting these points is unintuitive, since only segments that cross a joint are relevant. This leads to moment arms being inaccurate or suboptimal when considering the full range of motion of a joint. This problem is especially prevalent for multi-DOF joints that allow a large range of motion. The use of *conditional* via-points is an attempt to mitigate these issues [1], but this method instead leads to discontinuities with multi-DOF joints.

In our study we attempt to use optimization methods for determining via-point placement, in such a way that the resulting muscle moment arms match a ground truth over a specified range of motion, which is either based on real-world studies or models that use more advanced wrapping surfaces.

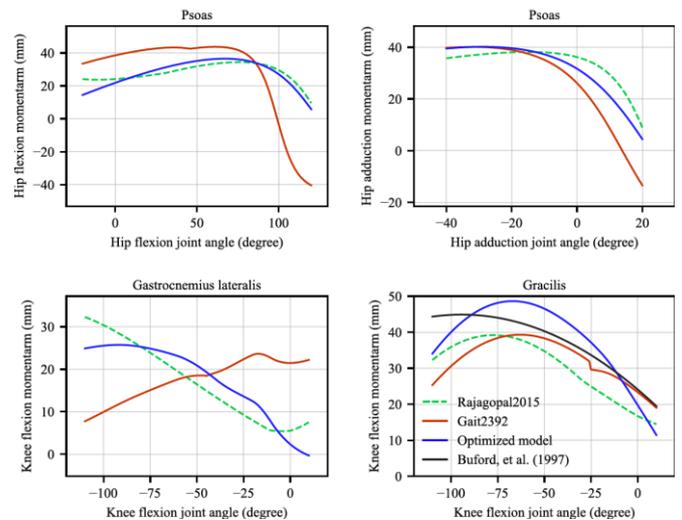

### Methods

The goal of our optimization is to optimize via-points  $V$  in such a way that the squared difference between the moment arms  $M$  and ground truth  $M_{ref}$  is minimized over the relevant range of motion, determined by the set of joints  $J$  and corresponding degrees-of-freedom  $Q$ . The error  $E(V)$  to be minimized corresponds to:

$$E(V, Q) = \frac{1}{|J||Q|} \sum_{j \in J} \sum_{q \in Q} \|M_j(V, q) - M_{ref,j}(q)\|^2$$

For our ground truth, we used data from experimental moment arm studies [3], supplemented by data from a musculoskeletal model that uses wrapping surfaces for muscle geometry [2]. We used the model from [1] as a starting point for our optimization, which was performed using Nelder-Mead [4], a non-differentiable optimizer based on the simplex method.

### Results and Discussion

**Figure 1:** Optimized muscle moment arms compared to existing models [1,2] and experimental data [3]

After optimization, the moment arms of muscle paths described by via-points are able to match our ground truth remarkably well (see Figure 1, blue lines). Especially the psoas and gastrocnemius muscles show significant improvement compared to [1]. A full statistical analysis will be presented in a separate study.

### Conclusions

The via-point method turns out to be remarkably capable for describing muscle moment arms over a range of motion. After using optimization methods to leverage their full capacity, via-point based models can approach the fidelity of more advanced and more computationally expensive methods based on wrapping surfaces.

## The difference of bilateral tibial load in patients with unilateral anterior cruciate ligament reconstruction during jogging

Ting Long<sup>1</sup>, Hanjun Li<sup>1</sup>

<sup>1</sup>School of Sport Sciences, Beijing Sport University, Beijing, China

Email: longting0817@163.com

### Summary

The risk of knee osteoarthritis is significantly increased after anterior cruciate ligament reconstruction (ACLR), and tibial contact force is associated with the development of knee osteoarthritis. Therefore, the bilateral tibial load of ACLR patients during jogging was calculated based on the neuromusculoskeletal model. The result showed the peak value of tibia compression force on the healthy side was significantly higher than that on the ACLR side, which may lead to insufficient recovery of articular cartilage or subchondral bone to withstand increased post-operative physical activity, leading to knee osteoarthritis.

### Introduction

The risk of knee osteoarthritis is significantly increased after ACLR, and tibial contact force is associated with the development of knee osteoarthritis. Therefore, the calculation of tibial contact force in daily activities can deepen the understanding of the pathogenesis of knee osteoarthritis in ACLR patients and provide a theoretical basis for the development of rehabilitation strategies.

The aim of this study is to calculate the bilateral tibial load of ACLR patients during jogging and to analyze bilateral differences.

### Methods

Seven ACLR patients were selected as subjects (3 males and 4 females, 1.5 to 3.5 years after surgery). The 14-camera Qualisys infrared motion capture system, Kistler 3D force measuring table and Delsys wireless EMG were used to synchronize the kinematics, dynamics and EMG data of the subjects when jogging.

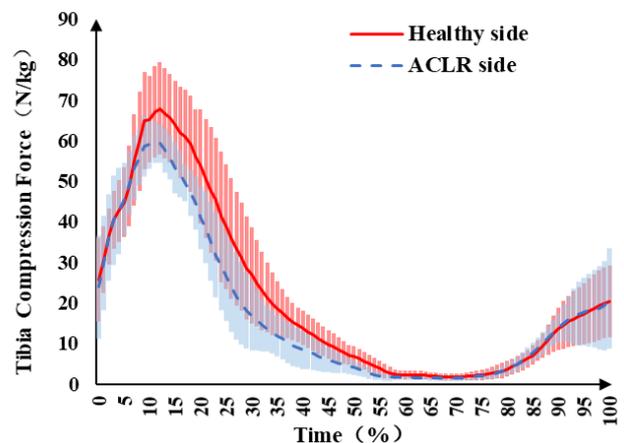

A personalized neuromusculoskeletal model was established by combining scaling in OpenSim and calibration in CEINMS [1]. The Inverse Kinematics tool and Inverse Dynamics tool in OpenSim were used to calculate the joint angle and joint net moment. In CEINMS software, the EMG-assisted model was used to calculate the muscle force during jogging. On this basis, the contact force of the knee joint was analyzed by the JointReaction tool in OpenSim and the tibial contact force was obtained.

The paired sample t test was used to analyze the difference between the healthy side and the surgical side of the subjects.

### Results and Discussion

The bilateral tibia compression force during jogging was shown in **Figure 1**. The peak value of tibia compression force on the healthy side was significantly higher than that on the

ACLR side ( $P=0.039$ ). At the peak value of tibia compression force on the healthy side, the muscle force of quadriceps femoris on the healthy side was significantly higher than that on the ACLR side ( $P=0.010$ ). The knee flexion angle on the healthy side was significantly higher than that on the ACLR side ( $P=0.042$ ), and the dorsiflexion angle of the ankle joint on the healthy side was significantly higher than that on the ACLR side ( $P=0.046$ ).

**Figure 1:** Bilateral tibia compression force during jogging.

The muscle force of quadriceps on the ACLR side was significantly less than that of the contralateral during the stance phase of jogging. This may be the reason why the tibial compression force on the ACLR side of the knee is less than that on the contralateral side.

In addition, the reduced compression force of the knee joint and tibia of ACLR may lead to insufficient recovery of articular cartilage or other joint tissues [2], so that the knee joint after ACLR surgery cannot withstand the gradually restored load intensity [3], leading to the occurrence of osteoarthritis.

### Conclusions

Patients with unilateral ACLR show less tibial compression force on the ACLR side than on the healthy side during jogging, which may lead to insufficient recovery of articular cartilage or subchondral bone to withstand increased post-operative physical activity, leading to knee osteoarthritis.

<sup>2</sup>Department of Physical and Rehabilitation Medicine, Helsinki University Hospital and University of Helsinki, Helsinki, Finland

Email: [williane.bernardes@uef.fi](mailto:williane.bernardes@uef.fi)

## Summary

Pain felt during exercises could be a reason for the reported low adherence of knee osteoarthritis (KOA) patients to the prescribed physical rehabilitation. Reducing the compressive loads on the knee regions affected by osteoarthritis may help to reduce the pain and improve adherence. In this study, the effect of functional knee alignment on the knee contact forces and external knee moments were evaluated during five exercises used in KOA rehabilitation. The alignment did not significantly affect the knee contact forces or external knee moments. Hence, alterations in the functional knee alignment may not be an effective strategy to unload specific regions of the knee in a rehabilitation setting.

## Introduction

Physical rehabilitation is often prescribed for the treatment of KOA but patient adherence is low [1]. Pain felt during the exercises may be an explanation [2]. Unloading the knee regions affected by osteoarthritis may reduce the pain, and consequently, improve adherence and ultimately lead to better treatment outcomes. Alterations in the functional knee joint alignment have been used to redistribute joint loading in the knee during gait [3], which may potentially provide a feasible strategy also during the performance of closed kinetic chain rehabilitation exercises. This study aimed to assess if the distribution of the compressive knee joint contact forces (KCF) is altered when different alignments are used during closed kinetic chain rehabilitation exercises.

## Methods

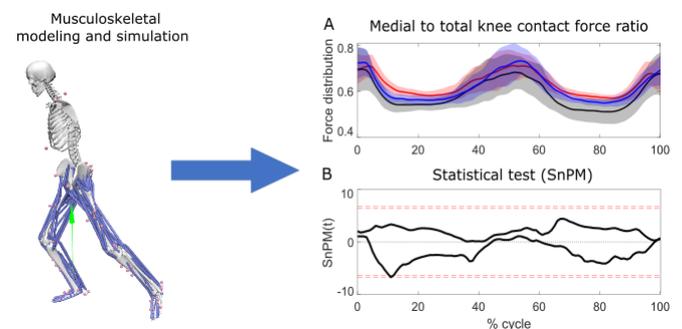

Eight healthy young adults (one female and seven males,  $23.9 \pm 5.2$  yr. old) executed five exercises in three sets of seven repetitions using their right leg. Each set was performed with a different knee alignment in the frontal plane: neutral, medial, and lateral while marker trajectories, ground reaction forces and electromyography of 12 lower limb muscles from the right leg were recorded.

A musculoskeletal model designed for movements with high lower limb joint flexions [4] was modified to replicate a recently proposed quadriceps moment arm [5] and to include medial and lateral knee compartment [6]. Five repetitions per alignment were selected for the analyses and the simulated muscle activations were compared against the EMG signals. Knee alignment was quantified as the frontal plane projection angle (FPPA), defined as the angle between the vector from the ankle joint center to the knee joint center and the vector from the knee joint center to the hip joint center. The

data was time-normalized and averaged within the participant, exercise, and alignment. Ensemble average data was used for comparing the KCF between the alignments with non-parametric repeated measures ANOVA using statistical non-parametric mapping (SnPM).

## Results and Discussion

The participants were able to perform the exercises with different knee alignments as evidenced by significant differences in the FPPA. However, the alignment had a minor to no effect on the magnitude and distribution of the KCF (Fig. 1), the external knee moments, and EMG activities.

**Figure 1:** Mean (SD) of the medial to total compressive KCF ratio during forward-backward stepping exercise with lateral (red), medial (black), and neutral (blue) knee alignments (A) and the pair-wise comparison between neutral-lateral and neutral-medial using SnPM in which the upper and lower thresholds for significant differences between the knee alignments are represented by the red dotted lines (B).

## Conclusions

Based on our results, different frontal plane knee alignments do not significantly alter the distribution of the compressive KCF, external knee moments, or lower limb muscle activities. Thus, altering the knee alignment may not be a successful strategy to unload the regions of interest of the knee while performing closed kinetic chain rehabilitation exercises.

## Finite element solver based full-body musculoskeletal model for multiscale biomechanics

Shihao Li<sup>1</sup>, Liming Shu<sup>1\*</sup>, Jiang Yao<sup>2</sup>, and Sugita Naohiko<sup>1</sup>

<sup>1</sup> Department of Mechanical Engineering, The University of Tokyo, Tokyo, Japan

<sup>2</sup> Dassault Systemes Simulia Corp., Johnston, RI, USA

\*Email: l.shu@mfg.t.u-tokyo.ac.jp

### Summary

Musculoskeletal modeling is a versatile computational method that gives a great insight into neuromuscular biomechanics of human movement. However, the calculation of subject-specific tissue-level mechanics with the musculoskeletal model is still an open issue. We proposed a finite-element-solver-based full-body subject-specific human musculoskeletal model which allows the synchronized calculation to provide the body and tissue level biomechanics with reasonable computation time and accuracy. Good consistency was found on knee joint rotations, muscle-tendon forces, and knee joint contact forces with experimental data.

### Introduction

Musculoskeletal (MS) models that are available in software packages such as OpenSim and AnyBody are widely used in investigating body level biomechanics[1]. However, MS models are limited on the investigation of tissue-level biomechanics for lacking the ability to take material deformation into consideration. On the other hand, finite element (FE) methods are widely used in tissue biomechanics analysis, but the load conditions were often fixed, which means the inter-subject variances cannot be properly reflected. Recently, researchers have developed combined workflows of the MS model and FE method. Instead of directly incorporate the MS model into finite element workflow, the MS model was used to generate subject-specific input and boundary conditions for the FE model. This limited combination which only incorporated the one-way interaction enhanced the authenticity of the simulation. However, because of the difference in the ability to deal with deformation, the kinematics in the MS and FE workflows are supposed to be different. The variance in kinematics has a comprehensive influence on the muscle and joint reaction force calculation, which may reduce the accuracy. In this research, we proposed a subject-specific full-body FE-MS workflow. The model can concurrently predict the tissue and body level biomechanics, which means the kinematic and dynamic alterations between the MS and FE models are synchronized.

### Methods

The generic FE-MS model developed in Abaqus CAE (Dassault Systems Simulia Corp., Providence, USA) is shown in Figure.1. The three-component Hill-type muscle model was modeled as 1D axial connector elements. The insertion coordinates and parameters were obtained from the ISB website[2]. The model was first scaled according to the motion capture data of each subject to obtain the subject-specific model. The inverse kinematics & dynamics were implemented using Abaqus Implicit Solver. Muscle optimization was performed to obtain the muscle force. With

all the initial state variables input into the model, the FE tissue is activated and the workflow starts iterating until the specified parameter converges. The data of the 6<sup>th</sup> grand challenge competition was used in the validation process. The patient data of DM who underwent total knee replacement with instrumented knee prosthesis were used to verify the proposed model from the aspects of muscle activation, joint kinematics, and joint contact force[3].

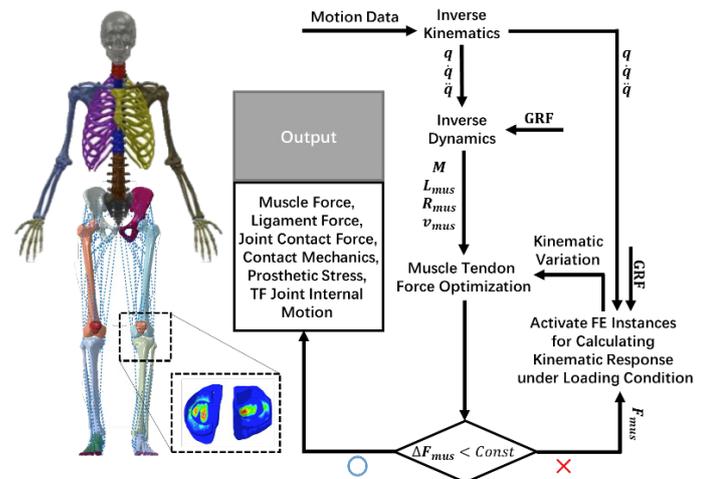

Figure 1: FE-MS model and workflow

### Results and Discussion

The computation time for a single gait cycle on a desktop computer took approximately 30min. The muscle activation results of flexor-extensor muscles showed good consistency on trend with electromyography. Good agreement on magnitude and trend were found in both medial and lateral sides of the knee contact force. The prediction accuracy of the FE-MS model ( $RMSE$ : 0.28,  $r^2$ : 0.90) was high among the recent publications[4].

### Conclusions

The proposed subject-specific FE-MS model presented a good prediction accuracy in terms of knee joint kinematics, dynamics, and muscle-tendon forces. It provides an approach for concurrent prediction of the body-level neuro-muscular biomechanics and the tissue-level biomechanics.

### Summary

We developed a novel technique to perform the high tibial osteotomy (HTO) based on prediction of the load sharing along the tibiofemoral joint. This work is a bridge between musculoskeletal modelling and the finite element analysis which provides required information and tools for surgeons to plan and perform HTO intervention.

### Introduction

HTO is a surgical procedure to delay the need for total knee replacement through correcting the frontal plane tibio-femoral alignment. A medial open wedge HTO is used for medial compartment osteoarthritis, whereby a surgeon makes a cut at the proximal tibia head and rotates the tibia in a valgus direction to offload the degenerated cartilage. Accurate pre-operative planning is essential to define the cut plane and valgus wedge angle in order to achieve the desired outcome. Frontal-plane x-ray is commonly used to define a correction angle, however, this does not account for the 3D articulating surface of the joint. We propose to provide a surgical plan by fitting a 3D model to the x-ray image and then simulating various cut orientations and predicting the changes in load distribution using a finite element model. Surgeons will be able to visualise the corrections and 3D print a wedge to accurately deliver the correct angle.

### Methods

A 48-year-old male (mass 86 kg) with early-stage medial knee osteoarthritis consented to being a participant in this study, which was approved by the Auckland Hospitals Research and Ethics Committee. Partial tibia, fibula, and femur bones and knee cartilage layers were segmented from magnetic resonance images with additional scans covering the knee, hip and ankle joints. Statistical shape models of each corresponding bone were used to generate complete bones [1]. The articulating region of the bone and cartilage were then fit to the segmented data using radial basis functions to sub-millimetre accuracy. Anatomical landmarks were identified on triangulated meshes and used to define the coordinate system and HTO cut plane agreed by surgeon. Bone meshes were registered to the patient's Frontal-plane and oblique x-ray images to reproduce the joint at its full extension standing position. A finite element model of the knee was developed using FEBio [2]. Bone and cartilage were treated as rigid bodies, with the femur fixed at 6 degrees of freedom and tibia-fibula allowed to rotate in varus-valgus with flexion-extension prescribed based on the weight-bearing x-ray. A set of interval force vectors, with magnitude of half body weight and upward were exerted to the tibia base and the contact pressure (CP) along the medial and lateral knee were predicted after the model achieved static equilibrium. CPs were then obtained for a range of virtual valgus cut planes. Optimal cut plane and correct wedge

angles were determined by surgeon after viewing the medial and lateral CPs changes resulting from various valgus cut planes.

### Results and Discussion

A range of valgus corrections and CPs were simulated and visualized on the tibial cartilage (Figure 1). By increasing the valgus angle, the peak CP along the medial articulation was gradually reduced. The surgeon received a spectrum of CP maps and selected the 8° valgus wedge (figure 1, left) to offload the medial compartment and equalise the forces through the medial and lateral tibial condyles [3]. A 3D template wedge was printed, sterilized, and used by the surgeon as a guide to deliver the correct valgus angle during the operation. Improvements to this workflow include the simulation of dynamic gait as boundary conditions to the FE model.

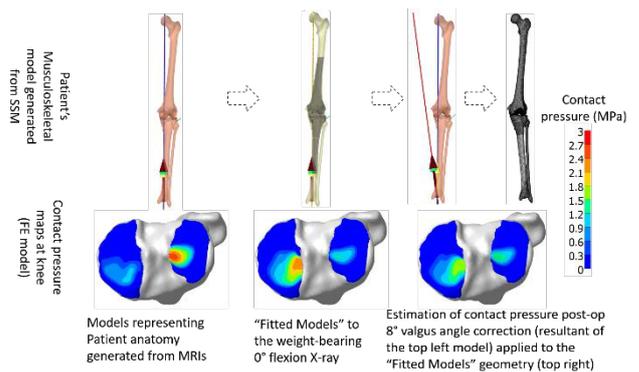

Figure 1: comparing the CP at the tibia cartilage. The pre-op mechanical axis (blue line), resultant post-op force vector (Red line) and its components (vectors).

### Conclusions

To deliver a patient-specific HTO correction plan, we developed a finite element model of the knee from standard clinical MR and x-ray images. Using this workflow, surgeons can easily visualise various HTO correction angles and their influence on predicted CPs. A custom designed and printed wedge ensured the surgeon delivered the desired correction angle.

### Summary

It is generally believed that the varus deformity of the first metatarsal occurs before hallux valgus (HV). To investigate the relationship between HV and metatarsus primus varus (MPV), the 3D bone position analysis by focusing on the alignment between the medial/intermediate cuneiforms and the first metatarsal was conducted. To evaluate the relationship between the MPV and HV, the correlation between the inclination angle of the first metatarsal and the HV angle was investigated. There was no significant correlation between them. The experimental results suggest that the MPV did not always occur before the HV.

### Introduction

HV is a common structural disease of foot deformity. Yasuhito et al. reported that the HV is primarily caused by the MPV and the MPV is a major factor in the development of HV [1]. X-ray images are usually used for the evaluation of HV in clinical site, while 3D bone alignment between the medial/intermediate cuneiforms and the first metatarsal is difficult to analysis by the X-ray image. Little is known about the correlation between the HV angle and the inclination angle of the first metatarsal in consideration of the alignment between the medial and intermediate cuneiforms in 3D position. The aim of this study is to investigate the correlation between the first metatarsal direction based on cuneiforms and the HV angle by using 3D bone position analysis. We hypothesis that MPV is responsible for HV; the HV angle and the inclination of the first metatarsal could have a positive correlation.

### Methods

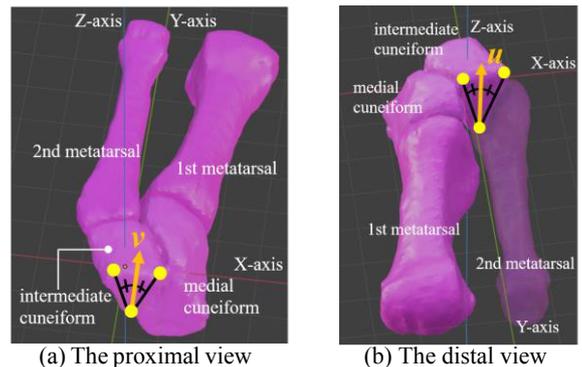

The study included seven female participants (10 feet: 5 right, 5 left; 5 HV, 5 no HV, aged  $70.9 \pm 5.4$  years) of whom five had ankle osteoarthritis. The 3D bone models were created from Computed Tomography (CT) image by using ITK-SNAP. A new coordinate system was proposed for the measurement of the MPV in consideration of the alignment between the medial/intermediate cuneiforms (Figure 1). The MPV was defined as the inclination of the first metatarsal from the Y-axis on the XY-plane.

### Result and Discussion

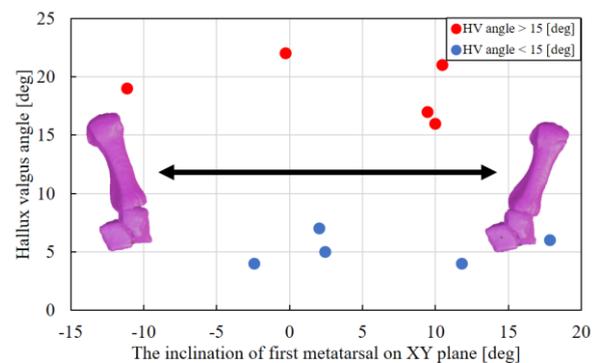

Figure 2 shows the relation between the inclination of the first metatarsal on XY-plane and HV angle. The HV angle and the inclination of the first metatarsal did not have a positive correlation (correlation coefficient: -0.20). The hypothesis was rejected. There is a probability that the hallux valgus

(HV) occurs before varus deformity of the first metatarsal [2] or the MPV is not always responsible for HV.

Limitations of the study are the number of subjects was small and some of the subjects had ankle osteoarthritis. There is a possibility that ankle osteoarthritis affected the first metatarsal.

**Figure 1:** The proposed coordinate system definition. Origin: The average of six points (ex. yellow circles) used by a triangular approximation in two planes, proximal/distal planes of the intermediate cuneiform. X-axis: Cross-product Y- and Z-axes. Y-axis: The axis parallel to the 2nd metatarsal long axis. Z-axis: The average of bisectors in each proximal/distal plane of the intermediate cuneiform. The  $v$  and  $u$ -vector in the figure are a bisector in the proximal and distal plane of the intermediate cuneiform, respectively.

**Figure 2:** The relation MPV and HV.

### Conclusions

The correlation between varus deformity of the first metatarsal based on cuneiforms and the HV angle was investigated. The experimental results suggest that the MPV did not always occur before the HV.

## Cartilage thickness is coupled to bone shape in healthy knees and varies with sex

Marco T. Schneider<sup>1</sup>, Nynke Rooks<sup>1</sup>, Thor Besier<sup>1,2</sup>

<sup>1</sup>Auckland Bioengineering Institute, The University of Auckland, Auckland, New Zealand

<sup>2</sup>Department of Engineering Science, The University of Auckland, Auckland, New Zealand

### Summary

The functional relationship between bone and cartilage is complex and is modulated by mechanical factors introduced by loading and motion. We investigated the coupled relationship between bone and cartilage morphology in a cohort of 51 knees as a function of sex, height, and body mass.

### Introduction

Mature bone and cartilage have a location-dependent histomorphology that is developed in response to its specific loading history [1]. Bone size and shape can affect the contact area and the lines of action crossing the joint [2], while cartilage thickness influences the mechanical properties of cartilage [3] and the stresses and strains experienced in the tissue [2]. Scarce data exist on the relationship between bone shape and the spatial distribution of cartilage thickness, in terms of how this varies in a population, which has important implications for understanding the onset of osteoarthritis, development of surrogate and predictive models, and design of implants.

This study has two aims: first, to characterise the coupled variation in knee bone morphology and cartilage thickness distributions in knees with healthy cartilage. The second aim was to investigate this relationship as a function of sex, height, and body mass.

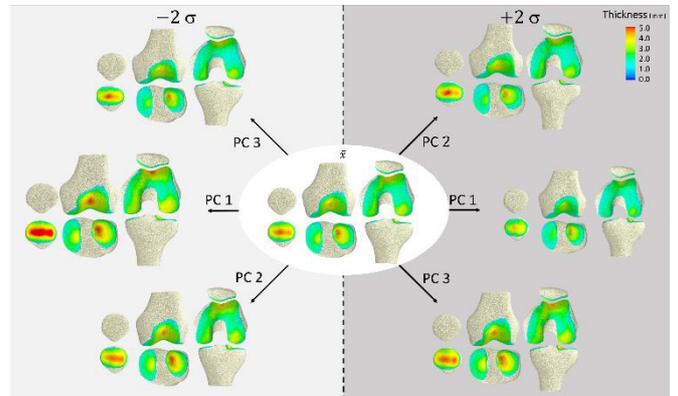

### Methods

MR images of 51 healthy adult knees ( $28.4 \pm 4.1$  years) were obtained from a previous study [4]. The bones, including the femur, patella, tibia, and their corresponding cartilages were manually segmented and a published method [5] was adapted to train a statistical shape model of the femur, tibia, and patella and their cartilages.

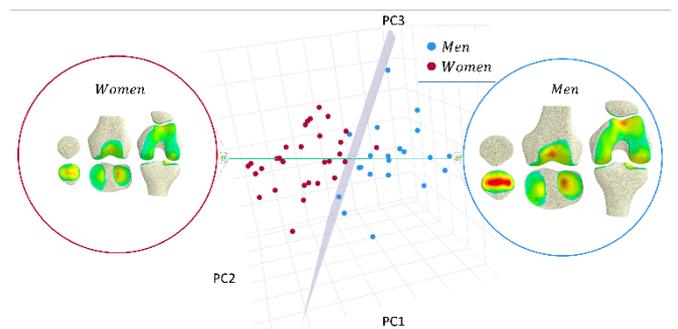

A logistic regression classifier was trained to characterise sex related features, and multiple linear regression models were trained to characterise features related to height and body mass. 10-fold cross-validation was performed to evaluate the models' performance.

### Results and Discussion

Cartilage thickness and its distribution was coupled to bone morphology, including both size (mode 1) and shape variations (mode 2 onwards). The first three modes described overall size, diaphysis size, femoral shaft angle, and corresponding spatial distribution of the cartilages (Figure 1). These modes were sex linked and could classify sex with an accuracy of 94.1% (95% CI [83.8%, 98.8%]) (Figure 2).

**Figure 1.** First three modes of coupled variation in the knee bones and cartilage.

**Figure 2.** 3D scatter of the first three modes of the training set by sex, showing the decision boundary plane (grey) of the logistic regression model, and, a vector (green) that passes through the average male and female knee.

Two modes could predict height to an error of 4.8cm, while four modes could predict body mass to an error of 5.4kg.

### Conclusions

Cartilage is thicker with increased bone size, diaphysis size, and decreased femoral shaft angle. Sexual dimorphism is present in these first three modes which can be used to classify sex. Shape features are also strongly correlated with height but weakly correlated with mass.

## How do Bone Measurements Change with Growth in a Paediatric Population?

Laura Carman<sup>1</sup>, Thor Besier<sup>1</sup>, Julie Choisine<sup>1</sup>

<sup>1</sup>Auckland Bioengineering Institute, The University of Auckland, Auckland, New Zealand

Email: lcar475@aucklanduni.ac.nz

### Summary

Understanding the change in bone shape and properties during growth is important for understanding how these factors deviate in children with movement disabilities, such as cerebral palsy. Statistical shape models (SSMs) of lower limb bones were built from a dataset of 333 children (aged 4-18 years). The aim of this study was to determine the changes in bone measurements with growth. No direct relationship was found between bone measurements and age, but relationships were found between bone measurements and the first principal component (PC) of the shape model.

### Introduction

Clinical bone measurements are usually performed on a 2D X-ray or partial 3D CT/MRI scans of the patient. This has been shown to be inaccurate due to different methods of measurement being performed and the requirement for the landmarks to be in the same plane [1, 2]. A more consistent and accurate method for calculating bone measurements is by reconstructing bone shape in 3D. The aim of this study is to generate a population-based growth chart for clinical bone measurements for a typically developed paediatric population.

### Methods

Post-mortem CT scans of 333 children (137 F, Age:  $12 \pm 5$  Y, H:  $148 \pm 24$ cm, M:  $49 \pm 22$ kg) were obtained from the Victorian Institute of Forensic Medicine (VIFM, Melbourne, Australia). The lower limb bones were segmented and aligned according to the ISB coordinate system [3]. A SSM was generated for the femur, tibia/fibula, and pelvis using principal component analysis [4]. Bone measurements were taken from 3D bone geometry using an automated process. Measurements were taken for each bone in the dataset as well as from geometries projected along the first PC (percent variation Femur: 98%, Tibfib: 97%, Pelvis: 91%) of the SSM between  $\pm 2$ SD at intervals of 0.1. The bone measurements taken were for the femur: anteversion, neck shaft, bicondylar, and mechanical axis angle. For the tibia: tibial torsion and tibial mechanical angle. The relationship between these measurements and demographic data (age, height, mass, sex) was compared.

### Results and Discussion

No definitive singular relationship between the measurements and anthropological factors were found. The relationship between femoral anteversion and age is shown in Figure 1 (top). When projecting along the first PC in terms of standard deviations (SDs), strong relationships were found between bone measurements and SDs for femoral anteversion, neck shaft angle, and tibial torsion.

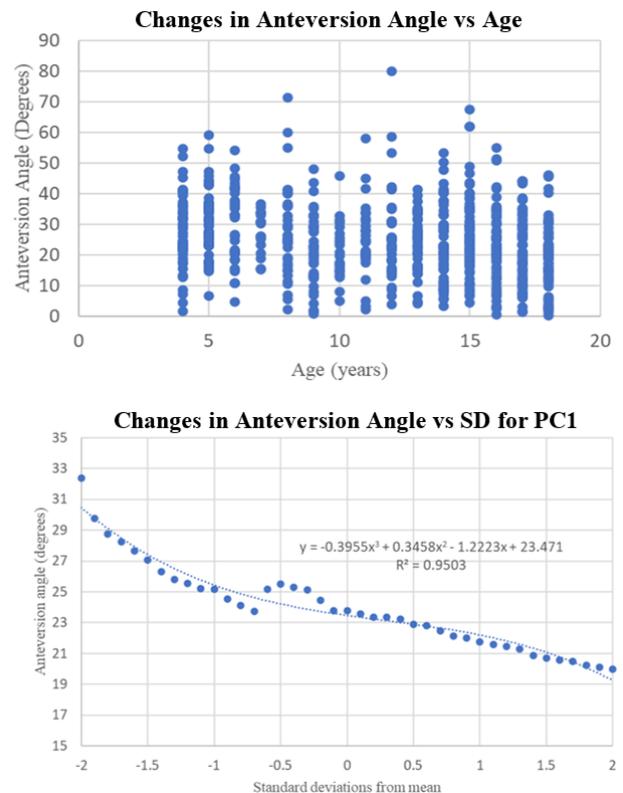

Figure 1: relationships of age and SDs with femoral anteversion

### Conclusions

The shape model was shown to capture the variation within the dataset of femoral anteversion, neck shaft angle, and tibial torsion. It is likely that these measurements depend on multiple demographic measures in a multiplicative relationship. This relationship needs to be further analysed to determine the plausibility of the generation of a growth chart for these measurements which could be used clinically to determine the range of normal development.

<sup>2</sup> Department of Orthopaedic Surgery, Chang Gung Memorial Hospital, Taiwan, R.O.C.

Email: agroup.lee@gmail.com

### Summary

The current gait analysis study identified the loading and unloading rates of the ground reaction forces (GRF) during gait, and their correlations with the hip morphology in twenty juvenile patients with surgically treated unilateral DDH during toddlerhood. The loading rates on both the affected and unaffected sides were highly correlated to the acetabular index on the unaffected side, which was also significantly correlated with the peak unloading rates on the affected side. These results suggest that apart from regular follow-up of the affected hip, routine assessment of the morphological changes and/or increased loading rates of the unaffected hip is also important for early identification of any signs of insidious hip dysplasia and risk of premature degeneration of the cartilage.

### Introduction

Abnormal loading rate was noted on affected side and unaffected side in the adolescent with unilateral DDH treated by Pemberton osteotomy [1]. So far as we know, no gait analysis study was about the correlation between the morphology and ground reaction forces during walking in the juvenile after DDH surgery. The purpose of the current study was to identify the loading and unloading rates of the GRF in the lower limbs during gait and their possible correlations with the bilateral hip morphology in juveniles who had been treated for DDH during toddlerhood.

### Methods

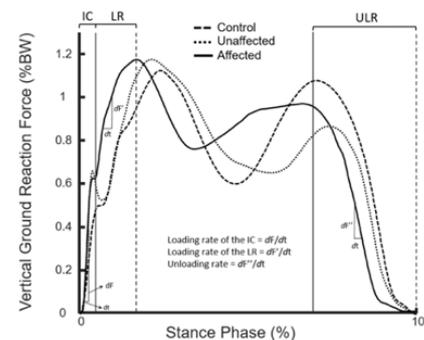

Twenty patients who had been treated for unilateral dislocation of the hip by reduction surgery at an age of  $2.2 \pm 1.7$  years participated in the current study. All subjects were able to walk without support. For each subject, the neck-shaft angle, acetabular index, and center-edge angle, femoral offset, acetabular depth ratio, articulo-trochanter distance (ATD), c/b ratio, and Alsberg angle were measured from anteroposterior X-ray images of the pelvis for both sides at the time of the gait study. Leg lengths of both sides were measured from a scenography. No leg length difference was found between left and right limbs (paired t-test,  $p = 0.019$ ).

Each subject performed level walking at a self-selected pace on a 10-m walkway in a typical gait laboratory. The ground reaction forces (GRF) were gathered from three forceplates. At least three successful trials were obtained for each subject for subsequent analysis. The 1st and 2nd maximum peak vertical GRFs of either affected or unaffected limb were extracted. A correlation analysis between GRF variables and radiographic measurements were conducted using SPSS 20.0 (IBM, Armonk, New York, U.S.A.). All significance levels were set at  $\alpha = 0.05$ .

### Results and Discussion

In the patient group, no significant differences were found in the morphological parameters between affected and unaffected sides. No significant between-side differences were found in the gait spatiotemporal parameters. No significant differences were found in the loading rates of vertical GRF between affected and unaffected sides (Fig. 1).

For the vertical GRF during initial contact, in general, the peak loading rates of both limbs were mainly correlated with the acetabular index of the unaffected side. The peak unloading rates of both limbs were also positively correlated with the acetabular index of the unaffected side. During loading response, peak loading rates of the affected limbs were positively correlated with the acetabular index and c/b ratio of the unaffected side, but those during both initial contact and loading response phases were negatively correlated with the center-edge angle of the unaffected side.

**Figure 1:** Curves of body-weight-normalized vertical ground reaction forces of the affected (solid line) and unaffected (dotted line) limbs of typical subjects in the DDH and Control group (dash line) during the stance phase of level walking.

### Conclusions

In this study, high vertical GRF in the affected limb is correlated to the morphology of the unaffected hip, especially acetabular index. It is important to monitor the contralateral hip morphology to improve the clinical outcome of children after DDH surgery.

<sup>3</sup>National Institute of Advanced Industrial Science and Technology (AIST), Tokyo, Japan

Email: hisano.g.aa@gmail.com

### Summary

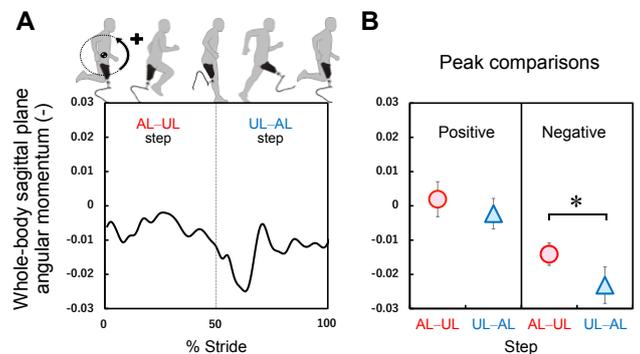

Maintaining dynamic balance is essential to achieve continuous running without a fall. However, little is known about how the whole-body sagittal plane angular momentum ( $L$ ) is regulated in unilateral transfemoral amputees (UTFAs) and the control of the affected (AL) and unaffected limbs (UL). We compared the positive and negative peaks of whole-body sagittal plane  $L$  between the AL–UL and UL–AL steps. No significant difference was observed in the positive peak, while the magnitude of negative peak during AL–UL step was significantly smaller than that of UL–AL step. These results suggest that UTFAs would require greater postural control demands to avoid the clockwise body rotation during UL–AL step than AL–UL step.

### Introduction

Although the UTFAs are progressively taking part in running activities, a fear of falling is a major barrier for those who wish to run. To maintain dynamic balance for continuous running without falling, the whole-body  $L$  about the body center of mass should be regulated [1]. Generally, the whole-body sagittal plane  $L$  during running is balanced between two legs [1,2]. However, owing to the morphological asymmetry between AL and UL in UTFAs, the control of whole-body  $L$  during running would be a challenging task for this population. Thus, this study aimed to evaluate the sagittal plane dynamic balance during running in UTFAs using whole-body  $L$ .

### Methods

Ten UTFAs participated in this study (age:  $32.6 \pm 10.6$  years, height:  $1.62 \pm 0.09$  m, mass:  $57.0 \pm 8.6$  kg, mean  $\pm$  SD). Each participant performed maximal sprinting on a 40-m of runway, where seven force platforms and optical motion capture cameras were placed approximately 22 m from the starting line. Whole-body sagittal plane  $L$  was calculated using a 15-segment model (head, torso, pelvis, upper arms, forearms, hands, thighs, shanks and feet). In the present study, the inertial properties of prosthetic components are modeled using the method described in the previous study [3]. A positive  $L$  indicates a counterclockwise rotation as viewed from the right side. Furthermore, whole-body  $L$  was normalized by participant height, mass, and average running speed ( $5.84 \pm 0.70$  m/s). All variables were averaged across the four trials to serve as representative values for each participant. A paired  $t$ -test was performed to check the statistical differences in the positive and negative peaks of whole-body  $L$  between AL–UL and UL–AL steps. Statistical significance was set at  $p < 0.05$ .

**Figure 1:** (A) A representative whole-body sagittal plane angular momentum during running over the AL stride cycle (recorded from one UTFA participant). (B) Shows the peak comparisons between AL–UL and UL–AL steps, where significant differences in the positive and negative peaks are indicated by the asterisk (\*).

### Results and Discussion

No significant difference was observed in the positive peak between AL–UL and UL–AL steps ( $p = 0.07$ ). However, the magnitude of negative peak during AL–UL step was significantly smaller than UL–AL step ( $p = 0.01$ ). A possible explanation for this phenomenon might be the mass difference between AL and UL. The larger magnitude of negative  $L$  with stance leg is counterbalanced by the smaller magnitude of positive  $L$  with swing leg throughout the running cycle in runners with and without transtibial amputation [1,2]. Because AL is the stance leg during AL–UL step, the reduced mass of AL might affect the smaller magnitude of negative  $L$  during AL–UL than UL–AL step.

A larger magnitude of negative whole-body  $L$  would lead to the clockwise body rotation. Therefore, current results suggest that UTFAs might require greater postural control demands for maintaining balance during UL–AL step than AL–UL step.

### Conclusions

UTFAs displayed a similar positive peak, but a smaller magnitude for the negative peak in whole-body  $L$  during AL–UL step than UL–AL step. These results suggest that UTFAs would require greater postural control demands to avoid the clockwise body rotation during UL–AL step than AL–UL step.

## Summary

Knee osteoarthritis (KOA) is a common disease associating with mechanical loading that causes limits functionality in older adults during daily activities. Proprioceptive neuromuscular facilitation (PNF) practices promote multiple-plane joint movements, which may improve medial loading distribution of the knee and increase joint range of motion (ROM). This study aims to examine the effects of a 6-week PNF intervention on joint ROM, and joint moments in the frontal plane in the elderly with KOA during walking. After the intervention, passive joint ROM increased in PNF participants. Peak external knee adduction moment decreased during walking. PNF could be recommended as one of the clinical treatments for KOA.

## Introduction

Knee osteoarthritis (KOA) is the most common chronic degenerative disease associating with ageing and mechanical loading, resulting in dysfunction. Over 40% of adults 65 and older are KOA symptomatic, who experience smaller maximum knee and hip flexion angles during walking than their healthy counterparts [1]. Increased the medial load distribution of the knee is a contributor to increase joint stress and cartilage degradation, affecting gait pattern [2]. The peak external knee adduction moment (KAM) is a surrogate for medial loading which are often elevated in older adults with KOA compared to healthy counterparts [2].

Traditional treatments for KOA are hard to cause the change of joint moments in the frontal plane. Proprioceptive neuromuscular facilitation (PNF) may be beneficial for people with KOA. PNF's spiral-diagonal patterns allow joints to move in multiple planes, may increase joint movement and ROM [3]. Therefore, we aimed to examine the effects of a 6-week PNF intervention on range of motion, and frontal plane joint moments in older adults with KOA during stair descent.

## Methods

Thirty-six people with KOA were randomly divided into the PNF and control (CTR) groups. The PNF group received PNF stretching, and the CTR group participated in a health lecture series, all for one-hour sessions, three times a week, for 6 weeks. Lower extremity passive flexion-extension joint ROMs from the affected leg were measured using standard goniometric procedures. Joint moments were measured using a motion analysis system with a force platform. Data were collected at weeks 0 and 6. Two-way (group by time) ANOVA with repeated measures was used to evaluate the intervention effects. Bonferroni-adjusted post-hoc pairwise comparison was used wherever appropriate. Cohen's d was used to represent the effect size of the post-hoc comparison.

## Results and Discussion

Our results showed a significantly time\*group interaction in the first peak KAM ( $p=0.004$ ,  $\eta^2p=0.291$ ), which decreased from week 0 to weeks 6 ( $p<0.001$ , Cohen's  $d=0.83$ ) in the PNF group. A decreased KAM indicated decreased stress on the knee's medial compartment and a favorable treatment outcome for KOA. In the spiral and diagonal patterns, the therapist's proximal hand exerts resistance on the medial/lateral of the participant's knee joint, thereby enhancing the knee joint's movement on the frontal plane, that is, knee adduction/abduction movement. The frontal movement promoted abductors/adductors' activity, which played an important role in regulating the load distribution of the medial-lateral knee joint [4]. Our study confirmed that PNF practice is an effective intervention to balance loads in the medial and lateral compartments.

As shown in Figure1, compared to the control group, the PNF group increased passive hip, knee, and ankle ROM. Autogenic and reciprocal inhibition has traditionally been accepted as the neurophysiological explanation for the superior ROM gains that PNF stretching achieves [5]. They refer to a reduction in the excitability of a stretched muscle because of the inhibitory signals sent from the GTOs of the same muscle (autogenic inhibition) or GTOs of the antagonist muscle (reciprocal inhibition), respectively [5]. Both conditions occur when the GTOs in the tendons of the stretched muscle or in the antagonist muscle to the stretched muscle detect harmful stimuli (maximum stretching).

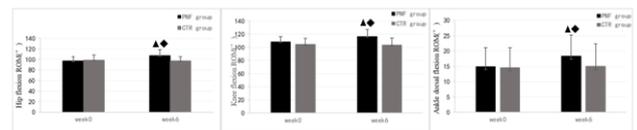

Figure 1. Passive joint range of motion of hip, knee and ankle.  
▲ Denotes significant difference in the PNF group between weeks 0 and 6; ◆ Denotes significant difference compared with the control group at week 6.

Figure 1: Joint range of motions of hip, knee and ankle.

## Conclusions

This study confirmed that a 6-week PNF intervention could decrease KAM and improve ROM in older adults with KOA during stair descent. PNF was an effective treatment for KOA to improve clinical symptoms.

### Summary

We have studied the effects of foot cutaneous sensation deficit on gait by testing foot plantar sensitivity and plantar pressure distribution during walking. The results indicated the input of foot plantar cutaneous sensation affected the plantar pressure distribution during walking on the treadmill. The heel and fifth metatarsal suffered more pressure, where less pressure with the hallux location, with the loss of foot sole sensitivity.

### Introduction

It was reported reducing plantar cutaneous causes no changes in plantar pressure distribution during walking in the healthy population [1]. And chronic sensory loss did not affect the plantar pressure distribution during walking in the peripheral neuropathy [2]. The effect of severity of foot sole sensitivity on plantar pressure is not clear. We aimed to explore the effects of impaired foot sole sensitivity on foot sole pressure distribution during walking.

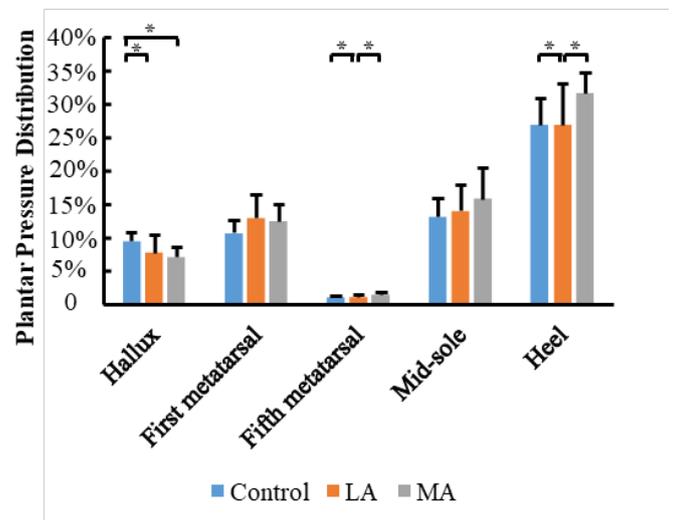

### Methods

Thirty-one participants were recruited and divided into three groups based on the foot sole sensitivity. Foot sole sensitivity was assessed in five locations of each foot (hallux, bases of first/fifth metatarsals, mid-sole, and heel) by 5.07-gauge Semmes-Weinstein monofilament. The Control group was scored at a full 10 on both feet. The less affected group (LA) ranged from 6 to 9 score. The participants with 0-5 scores named the more affected group (MA). Plantar pressure distribution of 10 walking steps was collected using the Novel system. The average pressure of the five areas corresponding to the monofilament testing over 10 steps was calculated. ANOVA with repeated measures was employed to exam the differences among the three groups.

### Results and Discussion

Significant group differences detect at the hallux, fifth metatarsal, and heel (See **Figure 1** for more details). The average pressure underneath the hallux decreased from the Control (9.51±1.29%) to LA (7.77±2.73%,  $p=0.021$ ,  $d=0.762$ ),

and MA groups (7.08±1.59%,  $p=0.002$ ,  $d=1.643$ ). The average pressure below the fifth metatarsals of the MA group (1.46±0.41%) was greater than that of Control (1.06±0.27%,  $p=0.005$ ,  $d=1.136$ ) and LA groups (1.11±0.34%,  $p=0.007$ ,  $d=0.940$ ). The average pressure beneath the heel of the MA group (31.53±3.26%) was greater than that of both the Control (26.90±3.93%,  $p=0.015$ ,  $d=1.303$ ) and LA groups (26.94±6.17%,  $p=0.008$ ,  $d=0.918$ ). Significant differential effects of the foot sole sensitivity impairments were observed. Less (more) pressure was associated with more impairments at the hallux (heel) during walking.

**Figure 1.** The plantar pressure distribution of five locations was showed. \* indicate significant difference detected ( $p<0.05$ ) between groups.

### Conclusions

Greater plantar pressure at the heel during walking was observed with severe loss of foot sole sensitivity. The opposite trend was detected at the hallux, where less pressure was detected with the most severely affected group.

### Summary

We have developed an assistive robot intended for shoulder rehabilitation after stroke. Our robot consists of a single novel direct-drive linear actuator providing gravity compensation in all arm orientations. Our experimental results suggest that, when the robot fully supports the arm against gravity, the deltoid and trapezius muscles' effort reduce by ~60 %.

### Introduction

Conventional rotary actuated assistive robots for stroke rehabilitation require complex mechanisms to be aligned with the instantaneous axes of rotation of the joint [1]. Although linear actuators offer a potential alternative, current off-the-shelf linear motors are unable to meet the main requirements for an assistive robot: back-drivability, high force density, compliance, and low mass. We have developed a novel linear motor [2] that is capable of meeting these requirements, producing a continuous force of 100 N from a 624 g device. Our assistive robot consists of one custom design direct-drive linear motor, attached to the arm and waist via two spherical joints (Fig 1) to lift the patient's arm in any directions. In this study, we present the results of using our assistive robot on healthy participants to investigate how robot assistance affects the shoulder muscles' effort during a series of abduction-adduction tasks.

### Methods

Ten healthy right-handed volunteers (5 males, 5 females, aged  $33.4 \pm 6$  years) with no history of shoulder injuries were selected for this study. The University of Auckland Human Ethics Committee approved this study, and all participants provided written informed consent before the experiment. All users wore the assistive robot supporting their right arms with only the supporting straps and waistband adjusted for each individual. We measured muscle activity from the anterior, medial, and posterior components of the deltoid (AntDel, MidDel, and PostDel, respectively), as well as the upper and middle components of the trapezius muscle (UPTrap, MidTrap respectively) using a Delsys Trigno electromyography (EMG) system (Natick, MA, USA) read with a National Instruments CompactRIO (Austin, TX, USA) at 1000 Hz. In the experiment, participants followed a predefined trajectory presented as a moving dot on a screen, by abducting and adducting their arm up to their shoulder height. The experiment was repeated under four conditions: a fixed assistive force of 0 %, 25 %, and 50 % of the participant's arm mass, and 100 % support using a position controller. The collected EMG data were high-pass filtered with a cut-off frequency of 30 Hz, fully rectified, and then

low-pass filtered with a cut-off frequency of 6 Hz; the average muscular activities are calculated for each trial.

### Results and Discussion

The robot reduced the deltoid and trapezius muscle efforts by ~60 % on average when providing 100 % assistance compared to when it was off (Fig 1). Furthermore, providing 25 % assistance from the robot resulted a ~20 % decrease in middle trapezius and deltoid muscle activities. However, when the robot increased assistance to 50 % of the arm weight, the upper trapezius and anterior deltoid activities reduced by ~17 %, whereas other muscle activity only decreased ~7 %. Hence, the participant used their middle trapezius, posterior and medial components of the deltoid muscles more during the experiment, which is likely to control their arm's speed [3]. Finally, 50 % support from the robot showed similar muscular activation to when the participants performed the experiment without the robot and visually matched the arm's speed with the moving dot on the screen.

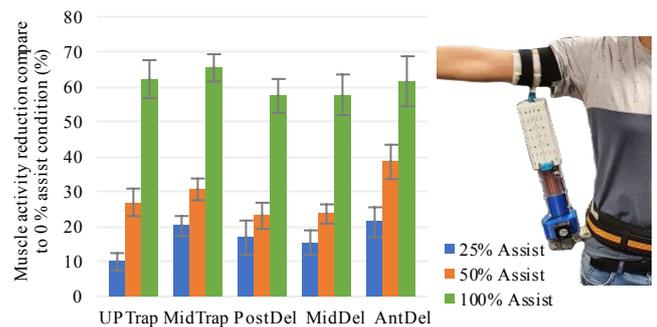

Figure 1: The robot illustration and its effect on the muscle effort.

### Conclusions

This study demonstrates that our robot can assist the shoulder joint by providing gravitational support. When the arm was supported, the muscular effort of deltoid and trapezius muscle reduced by ~60 % during the abduction-adduction task.

## Internal work could be used to estimate energy expenditure at various running intensities.

Bumjoon Kim<sup>1</sup>, Jung Kim, Suhyung Park<sup>1\*</sup>

<sup>1</sup>Department of Mechanical Engineering, Korea Advanced Institute of Science & Technologies, Daejeon, Korea

Email: [suhyungp@kaist.ac.kr](mailto:suhyungp@kaist.ac.kr)

### Summary

To estimate energy expenditure during running, heart rates were widely used. However, mechanical work was also used to estimate energy expenditure at moderate-intensity running. In this study, we compared the correlations between heart rate, two mechanical work (external work, internal work), and energy expenditure at various running intensities. As a result, overall, internal work showed a similar correlation to heart rate with energy expenditure. However, correlations are different depends on running intensity. In conclusion, not only heart rate, internal work could be used to estimate energy expenditure at various intensities. However, if running intensity is fixed, we have to consider the characteristics of intensity.

### Introduction

As running becomes a daily sport, many studies are being conducted to estimate energy consumption during running, which is one of the indicators of running performance. Of these, heart rate was the most used because it is related to oxygen supply [1]. However, some researchers had used mechanical work to estimate energy expenditure in certain intensity [2]. In this study, energy expenditure at various running intensities was measured and compared with heart rate and mechanical work (internal work and external work).

### Methods

Eight subjects participated in this study. They ran for 10 minutes on the treadmill at high-intensity speed (>75%VO<sub>2</sub>max), moderate-intensity speed (50~75%VO<sub>2</sub>max), and light-intensity speed (<50%VO<sub>2</sub>max). At the same time, metabolic energy, heart rate, ground reaction force, and lower limb motion were measured. Using these measured data, external work rate and internal work rate were calculated as follows; [3, 4].

$$\bar{P}_{ext} = \frac{\int_0^T \overline{GRF} \cdot \vec{v}_{com} dt}{T} \quad \text{Eq. (1)}$$

$$P_{int} = f \bar{s}^2 \left( 1 + \left( \frac{d}{1-d} \right)^2 \right) q \quad \text{Eq. (2)}$$

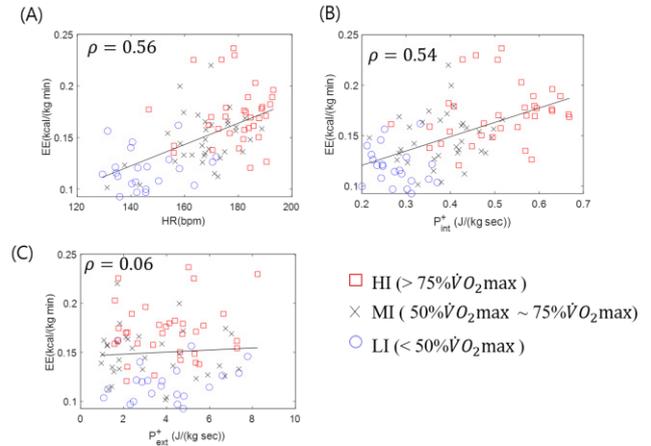

$\bar{P}_{ext}$  : average external work rate  
 $\overline{GRF}$  : ground reaction force  
 $\vec{v}_{com}$  : velocity of center of mass  
 $T$  : step duration  
 $P_{int}$  : internal work rate  
 $f$  : step frequency  
 $\bar{s}$  : progression speed  
 $d$  : duty factor  
 $q$  : compound dimensionless term

The average of the data 2 minutes before the end of each component was calculated to see a steady-state [2-4].

### Results and Discussion

As a result, Pearson's correlation coefficient for HR, internal work rate, and external work rate was 0.56, 0.54, and 0.06, respectively (Figure1). Even though external work is

larger than internal work, the correlation of internal work is higher and similar to heart rate. When looking at each intensity, the correlation with external work was high in light intensity, and the correlation with internal work was high in high intensity. (Table 1). In light intensity, external work is the main because the speed is slow, but as the speed increases, the step width and step frequency increase. Therefore, the correlation is high because the internal work increases relatively significantly compared to the external work.

**Figure 1:** Pearson correlation between energy expenditure (EE) and (A) heart rate, (B) internal work rate, (C) external work rate, respectively.

**Table 1:** Pearson's correlation coefficient with energy expenditure

	LI (<50% VO <sub>2</sub> max)	MI (50~75% VO <sub>2</sub> max)	HI (>75% VO <sub>2</sub> max)	Overall
Heart rate	0.12	0.38	0.05	<b>0.56</b>
Internal work rate	-0.21	0.16	0.19	<b>0.54</b>
External work rate	0.21	-0.08	0.05	<b>0.06</b>

### Conclusions

In order to estimate energy expenditure, internal work rate could be used like heart rate. However, if running intensity is fixed, we have to consider the characteristics of intensity.

## Summary

This study aimed to explore lower limb kinematics between elite marathoners with different training volumes at the speeds of 3m/s and 5m/s. The cadence, stride and sagittal plane lower-limb angles were collected during running. The results showed that hip and ankle angles at initial contact, and maximum hip flexion angle significantly increased in the HIGH group, but there were no significant differences on other kinematics variables. This study indicated that hip and ankle joints play a crucial role in controlling joint positioning at initial contact during running, and high-training volume may affect hip and ankle joints effectively.

## Introduction

Running is one of the most popular and accessible sport activities, with more runners participating in marathons and half-marathons [1]. High-training volume is related to a better marathon performance and finished time [1]. The running performance is associated with proper lower limb kinematics [2], but the effect of weekly training volume on lower limb kinematics for different running speeds is currently unclear. Thus, the purpose of this study was to determine whether different runners with vary training volume would show distinct running mechanics at different running speeds.

## Methods

Twelve healthy male elite marathoners (HIGH group: n=5, training volume: 180.0±40.0 km/week, age: 26.0±4.4 yrs, height: 172.8±4.7 cm, mass: 56.8±3.7 kg; LOW group: n=7, training volume: 88.6±32.2 km/week, age: 32.5±6.9 yrs, height: 174.9±5.7cm, mass: 64.9±7.3 kg). After warming up, all participants were asked to run over a treadmill at 3 m/s and 5 m/s for 3 minutes in a pair of running shoes (Li-Ning Boom, Beijing, China). The cadence, stride and sagittal plane lower-limb angles were collected by 8 VICON cameras during running. A 2×2 ANOVA was used to analyse lower limb sagittal kinematics (i.e., cadence, stride, joints angle at initial contact and maximum joint angle).

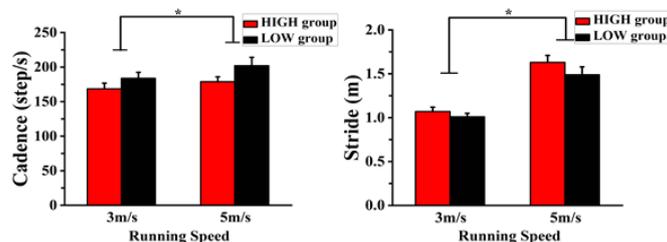

**Table 1:** Sagittal plane lower-limb angles between high-training and low-training volume groups.

Groups		Joint angle at initial contact (deg)			Maximum joint angle (deg)		
		Hip	Knee	Ankle	Hip flexion	Knee flexion	Ankle dorsiflexion
High-training	3 m/s	34.3±4.4*	-14.7±2.2	-3.2±4.4*	34.6±4.7*	33.7±4.2	14.9±2.5
	5 m/s	43.7±5.3*#	-18.0±1.9	-5.0±2.3*	44.6±6.8*#	38.9±4.7#	17.5±3.2
Low-training	3 m/s	29.4±4.4	-14.2±4	2.9±5	30.2±4.7	34.2±2.3	17.1±4.7
	5 m/s	36.5±5.1#	-13.7±4.1	0.74±7.8	37.2±3.9#	37.6±2.3#	17.4±6.1

**Note:** \*: main effect of training volume, #: main effect of running speed,  $P < 0.05$

## Results and Discussion

The main effect of training volume indicated that compared to the LOW group, the HIGH group runners had larger hip and ankle angle at initial contact, and maximum hip flexion angle ( $P < 0.05$ , Table 1). The main effect of speed revealed that compared to running at 3m/s, hip flexion angle at initial contact, maximum hip and knee flexion angles, stride and cadence significantly increased at 5m/s ( $P < 0.05$ , Table 1, Figure 1).

**Figure 1:** Cadence and stride between HIGH and LOW groups. \*: main effect of speed,  $P < 0.05$

## Conclusions

The significant differences due to training volume found in hip and ankle angles at initial contact, and maximum hip flexion angle indicated that hip and ankle joint play a crucial role in joints motion control at initial contact during running, and high-training volume may affect hip and ankle joints effectively.

### Summary

Runners may adjust their gait patterns and joint loadings during a half marathon. This study investigated the changes of lower limb joint kinematics, muscle activities, and tibiofemoral joint forces in fourteen runners undergoing a half marathon. The kinematic and kinetic data were collected every 2 km (from 2 km to 20 km) and processed by a musculoskeletal model incorporating medial/lateral knee compartments. The simulations reported unchanged joint angulation, muscle co-contraction index, ground reaction force, and medial tibiofemoral contact force. Knee adduction moment was lower at 18 km than at 2 km and 6 km ( $p = 0.001-0.002$ ). Lateral tibiofemoral contact force was reduced at 18 km, 16 km, 14 km, and 10 km compared to that at 2 km ( $p \leq 0.045$ ). The medial-shifted tibiofemoral force might result from lower limb realignment to maintain running efficiency. The injury potentials of such joint loading redistribution remained to be clarified.

### Introduction

Runners were thought to adjust their lower limb kinematics to cope with a prolonged run [1]. These body adjustments could influence loads on the tibiofemoral joint and thereby the injury risks. Joint contact force is the internal measure of the actual joint loading and is calculated as the primary variable in this study [2]. We also reported outcomes of joint kinematics and muscle activities at selected distance checkpoints.

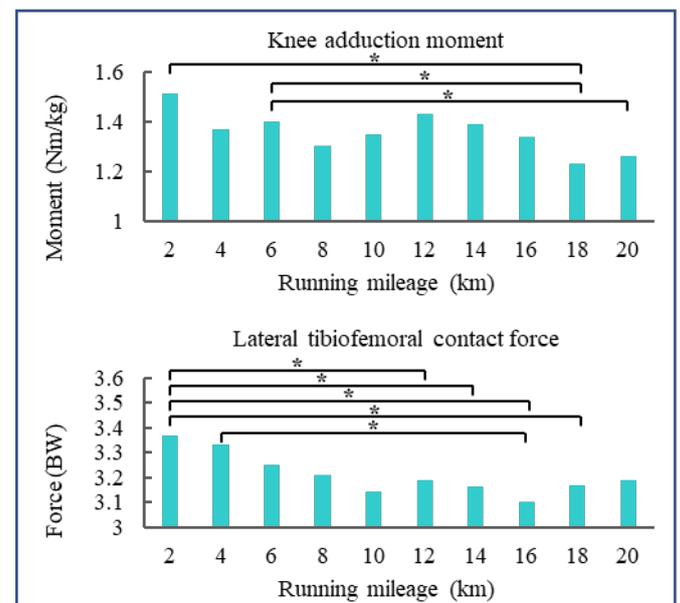

We hypothesized that the runners would increase the hip joint excursion and reduce the knee flexion, muscle co-contraction, knee adduction moment, and tibiofemoral contact force as the half marathon progressed.

### Methods

Fourteen experienced runners finished a half marathon on an instrumented treadmill. The kinematic and kinetic data were collected every 2 km (from 2 km to 20 km) and processed by a musculoskeletal model, which included an algorithm that calculated the distribution of the medial-lateral tibiofemoral contact forces. The computational simulations also reported lower limb joint kinematics, muscle activation, knee adduction moment. The co-contraction index of selected muscle pairs spanning the knee joint was calculated using a previously established method.

### Results and Discussion

No significant changes were found in joint angulation, muscle co-contraction index, ground reaction force, and medial tibiofemoral contact force. Knee adduction moment (Figure 1) at 18 km were significantly lower than those at 2 km and 6 km ( $p = 0.001-0.002$ ,  $\gamma = 0.663-0.813$ ). Lateral tibiofemoral contact force reduced from 2 km to 10 km, 14 km, 16 km, and 18 km, respectively ( $p \leq 0.045$ , Hedges'  $g = 0.216-0.859$ ). The results indicated that the external loads aligned closer to the lower limb's longitudinal axis as half-marathon progressed, whereby impacts during landing would be less absorbed by the works of soft tissue deformation but instead dispersed through segment collisions at the joint [3]. This may be an energy-saving strategy to increase race success while the injury risks behind it were unknown.

**Figure 1:** Knee adduction moment and lateral tibiofemoral contact force over the time course of a half marathon. \* significant difference in pairwise comparisons.

### Conclusions

Runners redistributed the knee joint loading during a half marathon to probably accommodate the effects of physical fatigue. Future studies were expected to explore its correlation with injury risks.

E-mail: [fuweijie@sus.edu.cn](mailto:fuweijie@sus.edu.cn)

## Summary

The purpose of this study was to investigate the Achilles tendon (AT) loading at different running speeds and footwear in elite marathon runners who trained with high- and low-training volumes (HIGH and LOW groups). All participants were instructed to run with two shoes at 3, 4, and 5m/s on an instrumented treadmill. The HIGH group had 1) greater ankle joint moment, AT force, average/peak loading rate, and less time to peak AT force than the LOW group; The HIGH group experienced greater AT force at 4 m/s and 5m/s, and ankle moment at 5m/s than those at 3m/s ( $p < 0.05$ ). These results suggested that greater AT force could be advantageous in elite marathon runners who performed high-training volume, regardless of footwear and running speed.

## Introduction

The Achilles tendon (AT) is the key anatomical structure to transmit the force from the triceps surae to the calcaneus. Elite marathon runners who performed high-training volume were demonstrated to have specific changes in morphologic and mechanical properties of AT (e.g. longer AT and greater AT force) [1]. However, it cannot be ignored the influence of footwear and running speeds on effective force transition by AT [2]. Thus, the purpose of this study was to investigate the effect of footwear and running speeds on AT loading in marathoners with different training volumes.

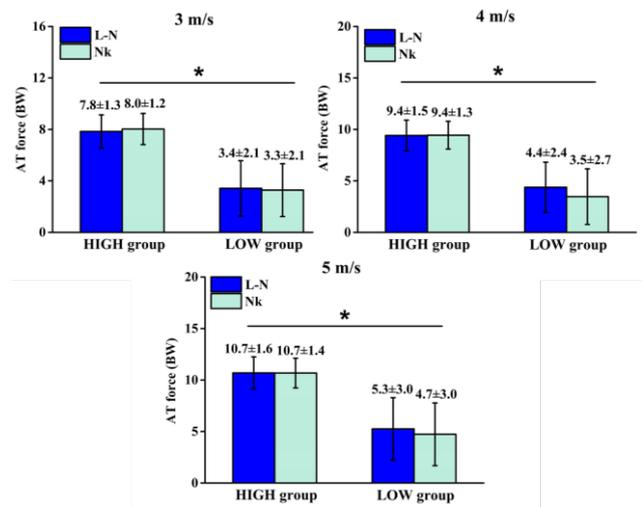

## Methods

Twelve healthy male elite marathoners (HIGH group: n=5, training volume: 180.0±40.0 km/week, age: 26.0±4.4 yrs, height: 172.8±4.7 cm, mass: 56.8±3.7 kg; LOW group: n=7, training volume: 88.6±32.2 km/week, age: 32.6±6.9 yrs, height: 174.9±5.7 cm, mass: 64.9±7.3 kg) participated in this study. They were instructed to run with two pairs of shoes [Li-Ning Boom (L-N), E-Pebax midsole, 6-mm heel-to-toe drop, 152g; Nike Zoom Vaporfly 4% Flyknit (Nk), foam middle sole and carbon fiber outsole, 10-mm heel-to-toe drop, 195g] for 3 minutes at each of the running speeds (3, 4, and 5m/s) on an instrumented treadmill (Bertec Corp., Columbus, Ohio, USA). The ankle joint moment ( $M_A$ ) and the mechanical properties [peak force ( $F_{AT}$ ), time to peak force ( $T_{AT}$ ), average ( $LR_{ave}$ ), and peak loading rate ( $LR_{peak}$ )] of the AT were calculated.

A mixed measures multivariate analysis of variance with an  $\alpha$  set to .05 was used to examine the effects of training volumes, footwear, and running speeds on the AT loading (21.0, SPSS Inc., USA).

## Results and Discussion

The ANOVA showed no interaction among three independent factors ( $p > 0.05$ ). However, the main effects of training volumes and speeds were observed ( $p < 0.05$ ). Specifically, the HIGH group had greater  $M_A$ ,  $F_{AT}$ ,  $LR_{ave}$ , and  $LR_{peak}$ , but smaller  $T_{AT}$  than the LOW group ( $p < 0.05$ , Figure 1). The HIGH group had greater  $F_{AT}$  at 4m/s and 5m/s, and  $M_A$  at 5m/s compared with the 3m/s, while  $F_{AT}$  only increased significantly at 5m/s in the LOW group ( $p < 0.05$ ). These results suggested that the AT was more effective to transmit the force from the triceps surae to the calcaneus in the elite marathoners with larger training volume.

**Figure 1:** Comparison of AT force between two shoes in HIGH and LOW groups at running speeds of 3, 4, and 5m/s (\*:  $p < 0.05$ ).

## Conclusions

The findings of this study suggested the similar acute effects between two tested shoes on the AT loading. The greater AT force and loading rate in marathon runners who trained with larger training volume training would benefit for effective force transition via AT.

## Foot motion analysis using a stretch strain sensor during gait and running.

Kodai Sakamoto<sup>1</sup>, Toshinori Miyashita<sup>2</sup>, Masashi Kitano<sup>1,3</sup>, Shintarou Kudo<sup>1,2,4</sup>

<sup>1</sup> Graduate school of health science, Morinomiya University of Medical Sciences, Osaka, Japan

Email: kudo@morinomiya-u.ac.jp

### Summary

The purpose of this study was to develop methods for the foot motion analysis using stretch strain sensor (STR). Foot kinematics during both walking and running on the treadmill were measured using both STR and optical motion capture system. STR was mounted over the skin between the navicular tuberosity and the sustentaculum tali. Difference from initial contact to maximum stretching value was defined as the S1, and difference from maximum and minimum value was defined as S2. Forefoot and hindfoot angular excursions with the same timing as S1 and S2 were calculated. Both S1 and S2 were assessed what angular excursion of the foot was reflected using multiple regression analysis. We found both S1 and S2 significantly related forefoot eversion/inversion excursion.

### Introduction

Multi-segment foot analysis has acceptable reproducibility and accuracy. However, it is difficult to measure the foot kinematics with footwear and foot orthoses due to the need to mount the reflective markers on directly to the skin. We had proposed a measuring method using a stretch strain sensor (STR), thin enough to be inserted into the footwear, and it may provide an alternative solution for gait studies. The purpose of this study was to develop methods for the foot motion analysis using stretch strain sensor (STR).

### Methods

The twenty-one normal volunteers were participated in this study. Foot kinematics during both walking(4km) and running (12km/h) on the treadmill were measured using the STR (C-stretch, Bando Chemical Industries, Japan) and a three-dimensional motion capture system(3DMocap) (Vicon MX system, Oxford Metrics Ltd., Oxford, England) sampling at 100 Hz, respectively. STR was mounted over the skin between

the navicular tuberosity and the sustentaculum tali. Difference from initial contact to maximum stretching value was defined as the S1, and difference between maximum and minimum value was defined as S2. Forefoot and hindfoot angular excursions with the same timing as S1 or S2 were calculated using the Oxford Foot Model using 3D Mocap. Both S1 and S2 were assessed what angular excursion of the foot was reflected in both walking and running using multiple regression analysis. Only items significantly correlated with S1 and S2 were used as independent variables. The significance level was  $p < 0.05$ .

### Results and Discussion

The results of the multiple regression analysis were shown in table 1. Both S1 and S2 were significantly associated with forefoot eversion/inversion excursion, the STR most strongly reflected the forefoot frontal motion.

The previous study suggested that the talonavicular joint motion was largest in the foot, and it mainly occurs in the frontal planes with loading condition [1]. In this study, the STR was attached to straddle the talonavicular joint. The STR may be most strongly related to the forefoot frontal motion because the talonavicular joint motion stretched and shortened the STR.

### Conclusions

The STR most strongly reflected the forefoot frontal motion. This method may be used in the future for measurement of foot kinematics while the subject is wearing the footwear and foot orthosis.

## Summary

This study aims to explore the patellofemoral joint (PFJ) loading in elite marathoners with different training volumes when wearing different running shoes. The results found that running shoes had a similar effect on the PFJ loading. Marathoners with high-training volume experienced a lower peak knee extension moment ( $M_{EXT}$ ) and peak patellofemoral joint stress ( $S_{PFJ}$ ) compared to marathoners with low-training volume, which recommended a high-training volume for lowered risk of patellofemoral pain (PFP).

## Introduction

PFP is one of the most frequently reported chronic injuries in runners [1]. Marathoners usually require a high volume of training. It is worth exploring whether the training volume can affect the load of PFJ in marathoners. Furthermore, high-end marathon racing shoes have been marketed and proven to have a better running economy and enable marathoners to achieve better athletic performance [2]. However, it remains unclear whether high-end shoes can prevent marathoners from a high loading of PFJ. Therefore, this study aimed to determine the PFJ load of marathoners with different training volumes when wearing different running shoes.

## Methods

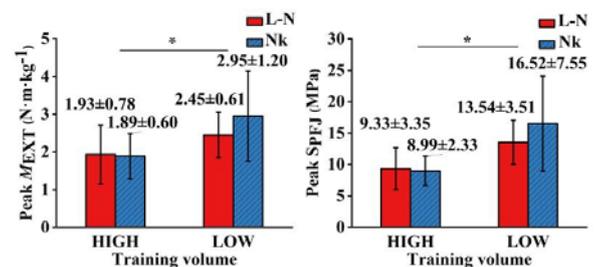

Twelve healthy male elite marathoners (HIGH group: n=5, training volume: 180.0±40.0 km/week, age: 26.0±4.4 yrs, height: 172.8±4.7cm, mass: 56.8±3.7kg; LOW group: n=7, training volume: 88.6±32.2 km/week, age: 32.5±6.9 yrs, height: 174.9±5.7cm, mass: 64.9±7.3kg) were recruited. Each participant randomly wore Nike Vaporfly 4% (Nk) and LI-NING Boom Marathon Racing Shoe ELITE (L-N) and ran at a speed of 5 m/s for 3 minutes on the Bertec instrumented treadmill (Bertec Corp., Columbus, Ohio, USA). Kinematic data was collected using Vicon T40 cameras (Oxford Metrics, UK).

Kinematics and ground reactional forces (GRF) of the right lower limb were processed using Visual 3D software (v5, C-Motion, Inc., USA). The peak  $M_{EXT}$ , peak knee flexion angle ( $\theta_{FLX}$ ), peak patellofemoral joint force ( $F_{PFJ}$ ), and peak  $S_{PFJ}$  under different running shoes conditions were calculated. A

two-way ANOVA (Training volume × Shoe) was performed on all tested variables (21.0, SPSS Inc., USA).

## Results and Discussion

There were no significant differences between the two groups in the peak  $\theta_{FLX}$  and peak  $F_{PFJ}$  regardless of shoe types. However, there was a main effect of training volumes for peak  $M_{EXT}$  ( $F=4.972, P=0.037$ ) and peak  $S_{PFJ}$  ( $F=8.339, P=0.009$ ). Specifically, the HIGH group performed a lower peak  $M_{EXT}$  and peak  $S_{PFJ}$  compared to the LOW group (Figure 1).

**Figure 1:** Comparison of the peak  $M_{EXT}$  and  $S_{PFJ}$  between high-training volume (HIGH) group and low-training volume (LOW) group with two types of shoes (L-N: LI-NING Boom Marathon Racing Shoe ELITE, Nk: Nike Vaporfly 4%) (\*  $P < 0.05$ ).

## Conclusions

High-training volume marathoners experienced a lower peak  $M_{EXT}$  and peak  $S_{PFJ}$  compared to low-training volume marathoners, which indicated a lower risk of PFP via high-training volume regime [3]. Different high-end marathon racing shoes have minimal effect on PFJ loading (i.e., peak  $F_{PFJ}$  and  $S_{PFJ}$ ) during running.

### Summary

An arched-shank design in a running shoe's midsole could facilitate energy return and improve running performance. The study investigated how different arch spans of the midfoot-shank would affect the shoes' energy flow during running through computational simulations. A runner performed running trials using a commercial running shoe, which featured an arched and carboned shank at the midfoot. Both of the runner's right foot and the shoe were finite-element modeled. The shoe model received virtual modifications on the shank's arch span and assembled with the foot model. Running simulations were conducted on the foot-shoe assemblies using the measured movement data. The results showed that increasing the arch span led to higher foot propulsive speed, shank energy return, and midsole energy return during gait propulsion. From the running efficiency perspective, we suggest that a running shoe including an arched midsole architecture considers a longer arch span to enhance its performance.

### Introduction

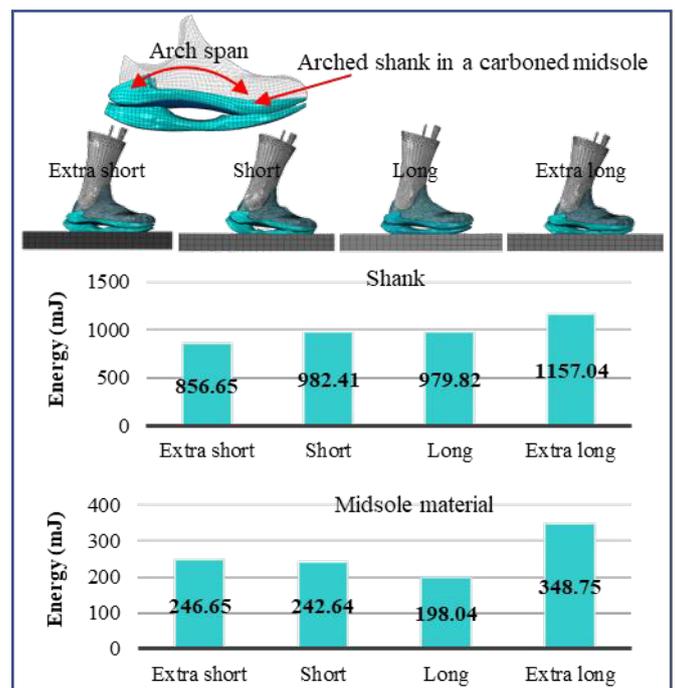

A carbon shank in the midsole has been a mainstream design feature for high-performance running shoes recently. An elastic shank could reduce energy loss for the runners [1]. Despite the varied shank designs, most of the research attention has been paid to the stiffness of the shank material [2]. The effects of shank geometry were rarely examined, particularly for an arched shank. An arched shank recycles energy through a compress-decompress process, which could be influenced by changes in the arch spans. We hypothesized that a longer arch span would produce higher foot speed, increase shank deformation and midsole energy return during propulsion.

### Methods

A finite element foot model was reconstructed from the MRIs of a healthy runner's right foot. A commercial running shoe (Jueying ARHQ245, Li Ning, China) with an arched shank was modeled and modified in virtual to produce four different arch spans (extra-short: 51 mm, short: 62 mm, long: 77 mm, extra-long: 92 mm). Thereby four foot-shoe model assemblies were created. The runner performed several running trials, which were processed with musculoskeletal modeling to generate a set of secondary movement variables. These variables served as the boundary conditions to set up the finite element analyses of running using each of the four model assemblies.

### Results and Discussion

Since this study focused on the shoe's performance, we analyzed the energy transformation of 50% to 75% stance phase, during which the midsole bounced back for propelling the gaits. The extra-long arch span increased peak foot propulsive speed (by 22.6%–39.3%), shank energy return (by 41.4%–76.1%), and midsole material energy return (by 17.7%–35.0%) compared to the other three conditions. A longer arch span could reinforce the bending motion on the shank at midstance, which resulted in increased shank deformation and energy recycling. The reduced volume of cushioning material in the midsole for accommodating a longer shank design was offset by increased material strains and energy release during propulsion.

**Figure 1:** Energy return for propulsion (shank and midsole).

### Conclusions

A running shoe using an arched-shank midsole system for energy saving/returning could consider a long arch span to enhance its performance during running.

### Summary

We have developed a functional foot supporter (FS) that the foot is thin and can be worn with various shoes. The purpose of this study is investigated influence of the FS on the foot motion during the locomotion. The strain of the foot which reflected on the eversion excursion of the foot during 3 trials which are walking(4km/h), running (12km/h) on the treadmill and over ground walking with comfortable speed were recorded using the Stretch strain sensor (STR). All trials were performed on barefoot without any supporter (BF) and with both FS and sham supporter (SS) at random. Strain of the foot with FS are significant difference with that of both BF and SS in all trials. The FS show to decrease eversion of the foot during loading phase of locomotion.

### Introduction

Flatfoot deformity increase the risk of the overuse running injuries. The custom-made foot orthosis is known to be one of the effective footwears for running injuries, however, there is a need for something devices to prevention foot problems in every situation. We have developed a functional foot supporter (FS) that the footwear is thin and can be worn with various shoes. However, there are no evidence that FS can be influenced on the foot motion during the locomotion. The purpose of this study is investigated influence of the FS on the foot motion during the locomotion.

Figure 1: photograph of the functional supporter

### Methods

The thirty feet of the thirty normal young volunteers with flatfoot deformity were participated in this study. Foot

motion during 3 trials which were walking(4km/h), running (12km/h) on the treadmill and over ground walking with comfortable speed were recorded using the STR (C-stretch, Bando Chemical Industries, Japan) with 100Hz. The STR was mounted over the skin between the navicular tuberosity and the sustentaculum tali. The difference strain from initial contact and maximum strain were calculated as loading strain reflected on eversion excursion of the foot with respected to the hind foot. All trials were performed on barefoot without footwear (BF) and with FS, sham supporter (SS) without supporting function at random. Difference strain each locomotion among the 3 supporters were assessed using repeated ANOVA with the Bonferroni test.

### Results and Discussion

Strain value at each trail with 3 difference condition are shown in table1. Strain with FS are significant difference with that of both BF and SS in all trials. Thus, the FS can be decreased eversion of the forefoot during locomotion. The effects of the foot orthosis worn footwears can be assessed using footwear removing the window, because reflective markers can be captured by the infra-red cameras [1,2]. However, it decreases a rigidity of the shoes. Therefore, there is no evidence that foot orthosis can be influenced on the foot kinematics during locomotion with normal footwear. In this study, the FS we developed is designed to be reinforced the arch of the foot by thin and hard to stretch materials, and foot motion during locomotion is assessed using STR with thin and light. Therefore, FS showed to decrease eversion of the foot during loading phase of locomotion.

### Conclusions

The FS can prevent to collapse the foot arch during the locomotion.

### Summary

Foot insoles are frequently prescribed in routine clinical practice to prevent or treat foot deformities or functional alterations. Currently adopted procedures for foot insoles manufacturing vary among clinical practitioners and manufacturers and decisions are mainly left to the experience of the ortho-prosthetic technician. Design frequently involves the use of cad-cam systems and, in the best case, static or, better, dynamic plantar pressure maps are considered. The aim of this contribution is to devise a simplified pipeline to provide ambulatory monitoring of dynamic foot function and to use this information to optimize plantar orthosis prescription for diabetic subjects. To this end both subject specific finite element models of the foot and of the plantar orthosis were developed.

### Introduction

Diabetes mellitus is an epidemic disease: more than 422 million people worldwide presently suffer from T2DM and 10 years after disease onset, between 20 and 50% T2DM patients develop diabetes neuropathy, a major risk factor for diabetic foot problems. This represents the most common cause of non-traumatic amputation (Armstrong et al 2017). Although the use of optimized footwear combined with foot orthotics is inherently implemented in the clinical care path [1], foot orthosis prescription is currently based on clinical experience and static measures. With a re-ulceration risk of 65% in 5 years [1], there is an important potential to optimize foot orthosis prescription by accounting for dynamic foot biomechanical function [2]. As multi-scale modelling has proven to accurately predict both high plantar pressure and even more important internal tissue stresses [3] the aim of this contribution is to devise a simplified pipeline to apply this methodology in ambulatory conditions without the constraints of a gait laboratory.

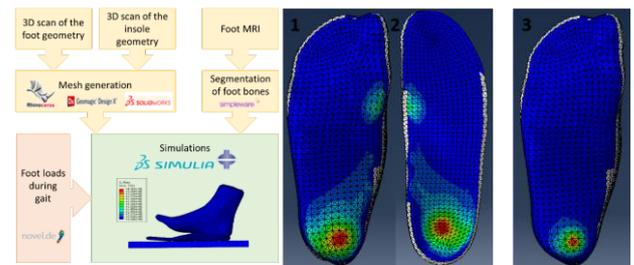

### Methods

The foot geometry of a cohort of 9 neuropathic diabetic subjects ((mean (SD) age 60.89(17.37) years and BMI 29.36(5.41) Kg/m<sup>2</sup>) was captured with a 3D scanner. Foot bones geometry was segmented from a database of neuropathic subjects foot MRI [4]. The foot bones were scaled based on every subject foot morphology (Abaqus). Each subject insoles geometries were scanned and meshed with tetrahedral elements (pipeline in Figure 1) and material properties were assigned according to the literature [3-4] and to the material characteristics declared by the insole

manufacturer. The vertical loads acquired during gait on a treadmill (2 km/h) through a PP insole system (PedarX, Novel gmbh) were applied in the FEM as boundary conditions. Loading response and midstance phases of the gait cycle were simulated [3] in 2 conditions: with and without the insole (see example in Figure 2). The comparison between the experimental PP and the simulated ones (peak and distribution) was used for validation purposes. Both simulated PP and internal Von Mises stresses in plantar soft tissues were compared across the different conditions (Root Mean Square Distance).

### Results and Discussion

A good agreement was reached between the experimental and the simulated PP. Simulated insole did not completely succeed in assuring a better distribution of the PP but they reduced the Von Mises stresses.

**Figure 1:** Left, the pipeline for the FEM creation; Right, the FEM simulation with (1,2) and without (3) the insole.

### Conclusions

The behaviour of the insole was successfully simulated through the proposed pipeline by adopting a simple experimental protocol applicable in ambulatory condition. This approach can be used to predict the effects of the produced insole on the foot function thus resulting in an efficient tool for optimizing its design.

### Summary

Recently patient-specific Computational Fluid Dynamics (CFD) simulations have provided important insights to understand the flow behavior under diseases such as atrial fibrillation (AF), which tends to facilitate thrombus formation in the left atrium appendage (LAA). The mechanical relationship between the LAA geometry and the thrombosis risk is still unclear. Many LAA variables have been related with an increased risk, performing parametric CFD studies to evaluate the influence. However, less attention has been paid to the pulmonary veins (PV) orientation, which is known to have an important effect on left atrium (LA) flow patterns. The aim of this work is to present a computational framework to perform parametric studies for the evaluation of the influence of the PV orientations in LAA flow patterns during AF conditions.

### Introduction

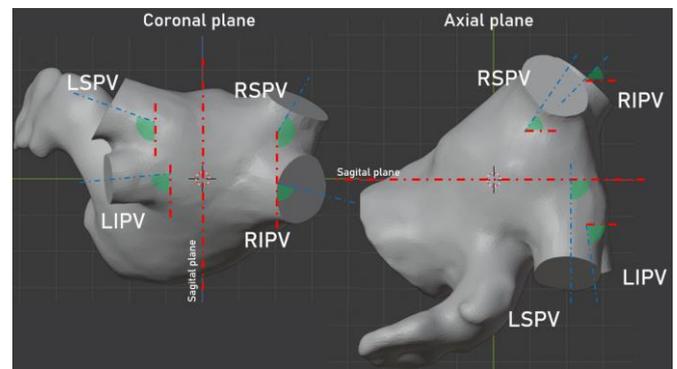

CFD techniques applied to patient-specific cardiac geometries in AF conditions aims to extend the existing knowledge about the thrombus formation process in the LAA, but the relationship between the thrombosis risk and the morphology of the LAA remains still unclear. Some of the previous CFD works have studied the influence of the dimensions of the LAA, the number of lobes, the ostium area, etc. However, the geometry and disposition of the PV, which present significant variations between patients and is known to affect to the left atrial flow patterns [1], has not been studied parametrically. The aim of this work is to find a convenient PV parametrization, providing a framework to perform parametric CFD studies from a patient-specific basis to evaluate the influence of the PV orientations in a physiological range.

### Methods

In this study a CT imaging dataset and Doppler-echocardiogram of a cardiac patient has been provided by Hospital Puerta de Hierro of Madrid, acquired during sinus rhythm. The endocardial surface of the LA has been segmented, computing each slice through intensity thresholding, generating a 3D model compatible with CFD simulations. Doppler measurements granted patient-specific boundary conditions, making possible at the same time to validate the simulation.

The parametrization of the PV orientations is based in the angle projection of each PV in the projective planes, more specifically in the coronal and axial plane with respect to the sagittal plane (Figure 1). Since there are measurements of these angle projections available in previous clinical works

[2], the election of the angle projections as input variables for the parametric study allow us to generate a range of different physiological geometries. These eight variables were thus selected - the coronal and axial projection angle of each of the four PV - in order to launch a Design of Experiments (DOE). This way a range of different physiological PV orientations has been generated from a patient-specific basis. Then, CFD simulations have then been run by generating tetrahedral meshes from these geometries and the Doppler measurements as boundary conditions.

**Figure 1:** Sample of the projective angles employed to perform the parametrization. Coronal plane and axial plane are shown.

### Results and Conclusions

This fully automated framework is able to generate a range of different physiological geometries from a patient-specific basis, opening the door to study the PV orientation influence on the LA flow patterns, and more specifically in the LAA thrombus formation process. Moreover, the workflow is valid to perform CFD simulations for both rigid and flexible atrium models.

**Summary:** A finite element analysis (FEA) based method for estimating strain distribution in the acetabulum with peri-prosthetic osteolytic (PPO) lesions was developed. The traditional total hip arthroplasty (THA) FEA approach of mapping material properties to trabecular bone geometry from patient CT scans is unfeasible for this method due to metal artefact. Therefore, five alternative approaches to assigning material properties to trabecular bone were tested and analysed. Analysis took into account; variability in acetabular strain values and distribution between approaches, simulation time and physiological validity of the values obtained. We consider applying constant generic material properties throughout trabecular bone geometry to be the most suitable of the five approaches tested.

**Introduction:** Published FEA THA models featuring acetabular PPO lesions use traditional methods of assigning material properties to trabecular bone [1] despite the effect of metal implants on CT clarity and Hounsfield Unit (HU) values [2]. The aim of this study was to perform a sensitivity analysis to determine which of five considered approaches of assigning trabecular material properties, whilst avoiding metal artefact, was most suitable within such models.

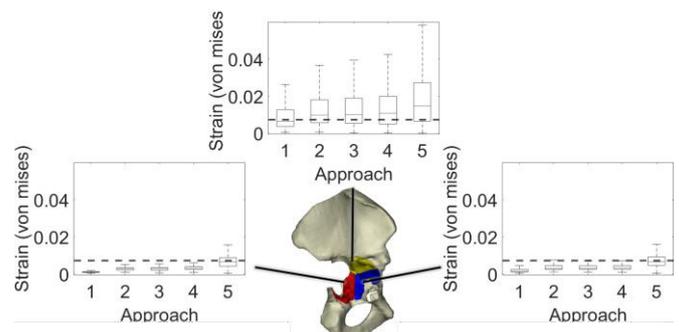

**Methods:** Two patients suffering from acetabular PPO (one with a unilateral THA implant *in situ* and one with bilateral THA implants *in situ*) were recruited and underwent both gait analysis and a CT scan. CT scans were segmented with a combination of thresholding, manual segmentation and Boolean operations. Volume meshes were generated from segmentations. FEA models were ran using these meshes and joint reaction forces were obtained from musculoskeletal modelling.

Five trabecular modelling approaches were outlined and tested. The first and second approaches involved assignment of one constant material property throughout the trabecular geometry aiming to represent generic healthy trabecular bone and 1+ years post-operative trabecular bone respectively. Approaches 3-5 were theoretically more physiologically realistic as trabecular bone material properties were assigned to three separate regions relative to the cup; superior, inferior and adjacent. Approach 3 assigned generic material properties to the superior and inferior regions and 1+ years material properties to the adjacent region. Approach 4 mapped material properties from the CT scans for the superior and inferior regions (as they were mostly unaffected by artefact) and assigned 1+ years material properties to the adjacent region. Approach 5

mapped material properties from the CT for all three regions however the material properties of the adjacent region were mapped from the contralateral side. Therefore, approach 5 was not possible for the bilateral THA patient.

Variability in acetabular strain values and distribution between approaches, physiological validity of the results and assembly and simulation time were all analysed.

**Results and Discussion:** There was little variance in strain values for approaches 2-4 implying no advantage to assigning different material properties to the superior, inferior and adjacent regions. For approaches 2 – 5 there were strain values that were considered physiologically unreasonable in the ilium with regards to theoretical yield (Fig. 1). There was consistency in the order of mean von Mises strain (lowest to highest) between the ilium, ischium and pubis for all approaches. This outcome was observed for both the unilateral and bilateral THA patient (with approach 5 excluded for the latter).

**Figure 1:** Box and whisker plots to demonstrate variability and in von Mises strain results between approaches for the unilateral THA patient. Dotted line indicates compressive yield value used to assess the physiological validity of the results.

**Conclusions:** Approach 1 (applying constant generic material properties throughout trabecular bone geometry) was considered the optimum approach of the five tested.

**Acknowledgments:** This study was supported by National Health and Medical Research Council (ID: 1126229)

### Summary

Although a finite element (FE) foot model could assist the insole design, the modeling construction process is time-consuming and costly. This study aimed to assess and validate a simplified FE modeling method using merely the information of scanned foot surface. The foot surface and bone geometries from the Glasgow-Maastricht foot model were used as the template geometry. A set of anatomic landmarks was defined on the template foot surface and the target foot surface (the scanned foot). By matching the landmark position, a morphology-mapping algorithm was applied to scale the template foot surface and the encapsulated bone geometries to the target foot and create a subject-specific foot model. The scaled foot model was validated by comparing the predicted foot pressures with measurement. The proposed foot FE modeling approach could provide a fast and reliable foot pressure prediction, which would facilitate the orthotic design and optimization.

### Introduction

A FE foot model could predict internal foot loading and verify the performance of an orthotic design. However, subject-specific foot modeling is challenging on a clinical basis because the modeling procedure can be time-consuming and costly. A simplified modeling method is needed to give quick but informative feedback on an orthotic treatment. This study proposed and validated a potential solution based on a foot surface scan and a model-scaling algorithm.

### Methods

The right foot of a young male adult (height: 175cm, weight: 64 kg) was scanned under a minimal weight-bearing condition to construct the target foot model. Meanwhile, the Glasgow-Maastricht foot geometries in the Anybody software (AnyBody Technology, Aalborg, Denmark, version 6.0.5) was used as the template foot model [1]. To reduce the scaling complexity, we merged the bony segments in the template foot. The template foot model was scaled to the target foot geometries by matching predefined landmarks on the foot surface. The scaling process can be divided into two parts: affine transformations and built-in radial basis function (Fig. 1) [2].

The scaled foot model was meshed in Abaqus 6.14 (Dassault Systèmes, Vélizy-Villacoublay, France) with linear tetrahedral elements. The foot-ankle complex material properties were adopted from the literature [3]. The ground plate was loaded with 310N in against the plantar foot, and a 155N Achilles force was assigned to simulate a balanced standing condition.

### Results and Discussion

The foot pressure distributions of balanced standing between model prediction and in-vivo measurement were compared (Fig.2). The predicted foot pressure showed a profile similar to the measurements. The peak foot contact pressures in model prediction and measurement were comparable (0.171 MPa and 0.163 MPa, respectively).

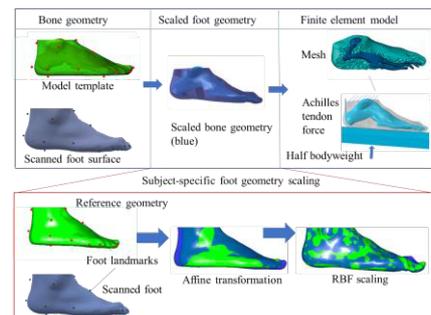

Fig. 1. Subject-specific foot geometry scaling for finite element model

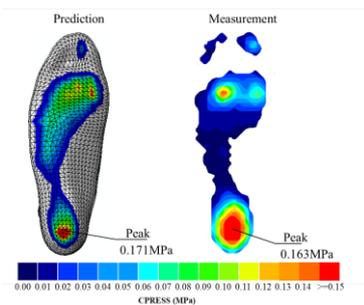

Fig. 2 Validation of the foot modeling with measurement during balancing standing

### Conclusions

We proposed a quick and validated FE modeling method that could potentially be used for orthotic assessments in the clinic.

## Summary

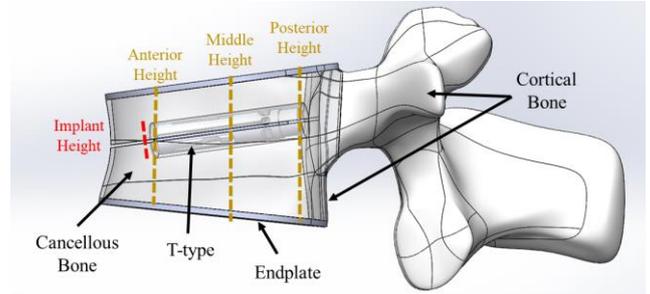

We used finite element model (FEM) to simulate and evaluate the restored vertebral height result of using bone expandable implant in the state of osteoporosis vertebral compression fracture (OVCF) and verified our results with cadaveric experiment.

## Introduction

With the aging society, osteoporosis has become the second most common endocrine disease in the world. It is characterized by low bone mass and microarchitectural degradation of bone tissue, which leads to a high chance of bone fragility and fracture susceptibility [1]. Patients with osteoporosis would be prone to have OVCF. The new minimally invasive surgery uses expandable implant to restore vertebral height. However, lack of biomechanical evidence on how the design of bone expandable implant affects the result of vertebral height restoration. It also takes considerable costs to refine the design and verify the functionalities through cadaveric experiments in the early stage of medical device development. This study established OVCF finite element model to verify the functionality of bone expandable implant and shorten the R&D process during initial design stage.

## Methods

This study was divided into three parts. The first part was to establish a L1 OVCF finite element model. The second part was to verify our FEM model using a commercial device (T-type) with cadaveric experiment in device expansion. We primarily examine the implant height of T-type and the vertebral at the anterior, middle, and posterior height restorations (Figure 1). Lastly, we simulated the stress acting on the vertebral components in the state of OVCF.

**Figure 1:** Vertebral components and height restoration. The black solid arrows are the vertebral components, yellow dotted lines are vertebral height restorations and red dotted line is implant height.

## Results and Discussion

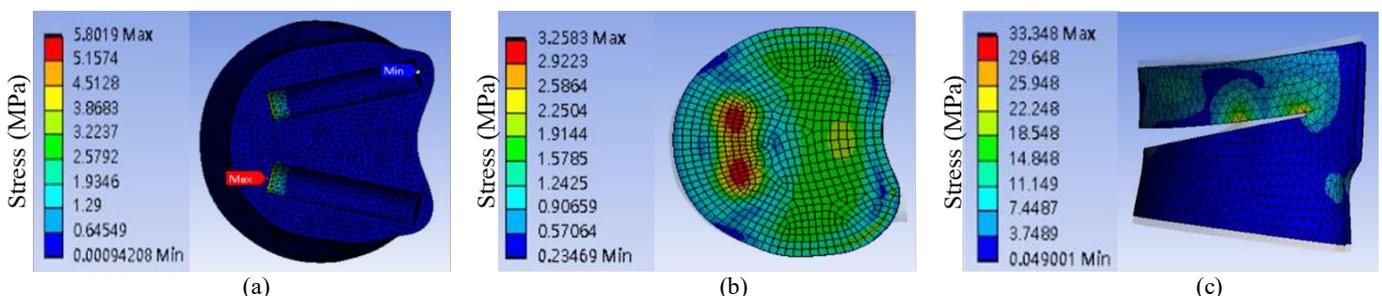

In the verification, the error of FEM simulation as compared to cadaveric experiment was 3.9%. The anterior, middle, and posterior height restorations in our FEM model were all overestimated with 1.283mm, 0.352mm, and 0.167mm respectively. The maximum stress in the cancellous bone caused by the bone expandable implant was 5.810 MPa; the maximum stress of the endplate stress at the front end was 3.258 MPa; the maximum stress of the cortical bone at the gap was 33.345 MPa (Figure 2).

## Conclusions

We established an OVCF finite element model that can help the R&D team to evaluate the effectiveness of the bone expandable implant for intervening vertebral compression fracture.

## Summary

We used surface electromyography and musculoskeletal simulation software, OpenSim, to obtain the muscular data in wrist flexion and extension, and analyze the correlated level between two data.

## Introduction

When tremor patients are having a botulinum toxin injection, it is important to define target muscle group and needle placement for the treatment [1]. However, there is a lack of ways to help doctors define which muscle causes tremor. Musculoskeletal simulation is a useful tool that can be used for biomechanical study. There are many studies used the muscle analysis tools in musculoskeletal simulation, OpenSim, such as computed muscle control (CMC), to simulate the muscle activation or muscle force, and surface electromyography (sEMG) signal was used for verification [2]. Nevertheless, sEMG signal is necessary when simulating the muscle activation or muscle force. According to the Hill-type muscle model, muscle generate force when muscle fiber contract, accompanied by the increase in muscle excitation. Huang and his colleagues [3] used optical motion capture system to capture the motions of upper arm, and evaluate shoulder disorder by simulating the muscle-tendon length in OpenSim without sEMG. However, simulation data in forearm muscles has not been verified. In this study, we aim to use OpenSim muscle-tendon length to develop a method for obtaining forearm muscle data without sEMG.

## Methods

We recruited five healthy subjects (20-25 years old) for the experiment. In this study, concentric and eccentric contraction motions in extensor carpi radialis longus (ECRL) and flexor carpi ulnaris (FCU) would be measured with two sEMG sensors placed on the anatomy positions of these two muscles. Each subject outstretched his right arm, extended and flexed the wrist as much as they could. The movement

would be captured by optical motion capture system, and be imported into OpenSim for simulating muscle-tendon length. The electromechanical delay (EMD), which sEMG signal will happen about 30-100 (ms) earlier than the change in muscle-tendon [4]. To compare the profile of two data, the EMD would be considered by aligning the onset time of the sEMG data to the onset time of the muscle tendon length data of each subject. The Pearson correlation coefficient then be calculated using sEMG signal and muscle-tendon length varying with time.

## Results and Discussion

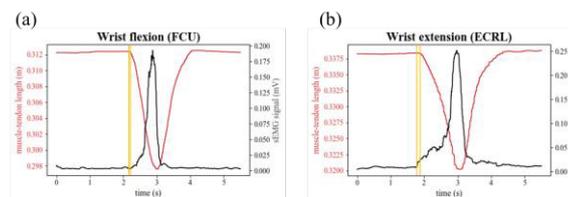

According to the data, sEMG signal increase when muscle-tendon length decrease. The average Pearson correlation of the ECRL and FCU were both higher than 0.70 between OpenSim muscle-tendon length data and sEMG signal. These results represent that the OpenSim muscle-tendon length data is highly correlated ( $r > 0.69$ ) with sEMG signal.

## Conclusions

Our method successfully simulated the muscle-tendon length data of wrist flexion and extension using musculoskeletal simulation, and verified the simulation data with sEMG signal. Further research can be performed on tremor patients to explore the clinical applications.

## An OpenSim-Based Musculoskeletal Model Controlled by Neural Oscillators That Generates Human Gait Patterns

Makoto Yoshida, Kazunori Hase

Dept. of Mechanical Systems Engineering, Graduate School of Systems Design, Tokyo Metropolitan University, Tokyo, Japan  
Email: yoshida-makoto@tmu.ac.jp

### Summary

In the investigations of human gait patterns, automatically generated patterns are useful because they are not affected by subjectivity by actual humans. Although a system that generates such patterns has been developed almost a couple of decades ago, it had not been used as widely as it deserves, probably due to the difficulty in data conversion. This system has been rewritten to be based on OpenSim, a widely used platform for biomechanical studies. A musculoskeletal model is controlled by a set of neural oscillators, a neuromimetic system capable of generating periodical signals suitable for gait control. A pair of neuron models acts as a neural oscillator, to which each rotational degree of freedom of the joints is assigned. The implementation of genetic algorithm to optimize the parameters of the set of neural oscillators with the criteria of maximizing the locomotive energy efficiency is underway.

### Introduction

A significant difficulty in human gait analyses arises from the subjectivity of the participants of experiments. Automatic algorithms that generate gait patterns, free of subjectivity, play an important role to overcome this problem. Hase and Yamazaki developed a forward-dynamics simulation system employing a set of neural oscillators, and successfully generated three-dimensional human gait patterns [1].

In spite of the usefulness of the system, it had only been used by a limited number of researchers, probably because it did not offer the compatibility to any of the well-known data formats. We have ported the system to OpenSim 4.1 [2], a well-known platform for biomechanical studies, to make this system accessible to a wider population of researchers.

### Methods

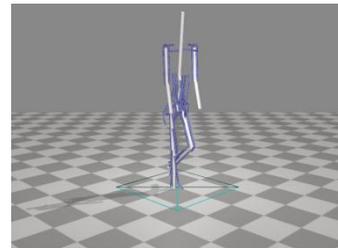

An OpenSim musculoskeletal model that reproduces the whole body of a human is constructed (Figure 1). Each joint was modeled as a single or a combination of rotational degrees of freedom.

This musculoskeletal model is controlled by a network of neuron models constructed according to that of Taga [3]. This neuromimetic controller that serves as a rhythmic pattern generator consists of paired neuron models. Each pair of neuron models acts as a neural oscillator, due to mutual inhibition of the neuron models in the pair. Each pair of neuron models is assigned to a rotational degree of freedom of a joint, where the state of a neuron model in a pair represents either the positive or the negative torque acting on the rotational degree of freedom, thus driving the

musculoskeletal model periodically. The states of the neuron models are modulated by a proportional-derivative feedback system employing some of the somatic senses, i.e. the joint angles, the ground reaction forces and the positions and the angles of the body segments with respect to the global coordinate system. The muscle force calculation is applied to the motion thus generated.

### Results and Discussion

The implementation of genetic algorithm that optimizes the parameters of the set of neural oscillators with the criteria of maximizing the locomotive energy efficiency is underway. Although this system has not generated a single successful gait pattern so far, the authors are optimistic in completing the optimization by the date of the presentation, thanks to the experience on implementing a similar system [4].

**Figure 1:** The musculoskeletal model. A neural oscillator is assigned to each rotational degree of freedom of the joints.

Since this system is not affected by subjectivity, this system may be used to find an optimal motion for walking in a variety of situations, e.g. that carrying some loads, that of a pregnant woman, that with prosthetic equipments, that with some pathology, the so-called Namba walking etc. This system may also be modified to simulate motions other than walking, e.g. skating, brachiation, cycling etc.

### Conclusions

A system capable of generating three-dimensional human gait patterns has been rewritten as an OpenSim-based system. Implementation of the code to optimize the parameters of the neuromimetic controller is underway.

# Estimation of Knee Ligament Forces During Non-resisted and Resisted Pedaling Using Finite Element Analysis

Yu-Ting Chen<sup>1</sup>, Tzu-Yu Chou<sup>1</sup>, Tung-Wu Lu<sup>1,2\*</sup>

<sup>1</sup>Department of Biomedical Engineering, National Taiwan University, Taiwan

<sup>2</sup>Department of Orthopedic Surgery, School of Medicine, National Taiwan University, Taiwan

Email: twlu@ntu.edu.tw

## Summary

Cycling is regarded as a gentle rehabilitation exercise for patients with knee ligament injury or surgery. However, improper pedaling conditions may cause damage on the knee musculoskeletal system damage. This study quantifies the forces transmitted in the anterior cruciate ligament (ACL), posterior cruciate ligament (PCL), medial collateral ligament (MCL), and lateral collateral ligament (LCL) during non-resisted and resisted pedaling using three-dimensional finite element analysis. According to the results, load on the PCL was much higher than the other ligaments for both resisted and non-resisted pedaling. It is recommended that patients with ACL injury or reconstruction but without PCL injury to perform pedaling as rehabilitation.

## Introduction

Cycling is a common exercise in rehabilitation programs. It not only improves physical fitness, muscle strength, and function after treatments or surgeries but also avoids excessive ligament load [1]. Attempts were made to measure the strain in the knee cruciate ligament during cycling [2]. However, no method has been developed to measure the forces in the ligaments without employing invasive instruments. Due to the development of computer technology, finite element method has been widely used to achieve non-invasive estimation of *in vivo* joint soft tissue mechanics. This study aimed to compare the effects of resistance during cycling by analyzing loadings on the knee ligaments and to act as a reference for patients undergoing rehabilitation.

## Methods

Twelve healthy subjects (age: 22.7±1.4 years; BMI: 22.6±3.6 kg/m<sup>2</sup>) were recruited and took CT and MRI images. They performed non-resisted and resisted pedaling under a speed rate of 30 rpm while the three-dimensional (3D) kinematics of the bones was measured using a 3D fluoroscopy method [3]. The resistance was set at 20 Nm to simulate the rehabilitation conditions. Laxity test was also performed on the subjects with KT-2000 arthrometer to obtain the displacement and force relationship.

In the finite element analysis process, models of the bones and ligaments were first constructed from CT and MRI images respectively. The attachments of ligaments were identified via a CT-to-MRI registration procedure. The bones were assumed to be rigid bodies and the material properties of the ligaments were assigned according to the data of laxity tests. Boundary conditions were obtained from the kinematics of 3D fluoroscopy. Resultant forces in the ligaments were then calculated by commercial finite element analysis software.

## Results and Discussion

From the results (Figure 1 and 2), it was observed that the PCL bore forces 7-8 times greater relative to the other ligaments for both resisted and non-resisted cycling. Maximum loadings of the PCL occurred at crank angle of 0° while minimum loadings appeared at approximately 135°. The forces PCL transmitted in the process of 0° to 180° during non-resisted cycling were greater than that of resisted cycling. On the contrary, the results reversed from crank angle of 180° to 360°.

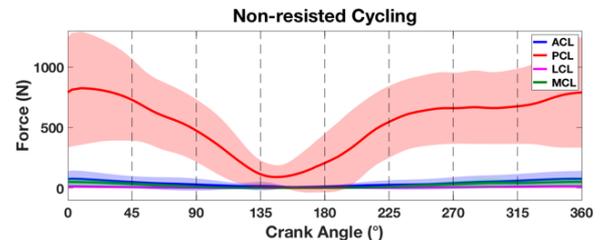

Figure 1: Ligament forces during pedaling without resistance

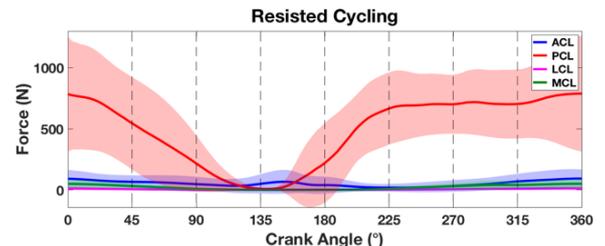

Figure 2: Ligament forces during pedaling with resistance

From the perspective of kinematics, since the position of the tibia was relatively posterior to the femur during the entire cycle of pedaling, the PCL would be stretched much more than the other ligaments to sustain joint stability. The lower forces in the PCL from 0° to 180° during resisted cycling compared to non-resisted cycling could be interpreted by the greater degree of internal rotation of the tibia obtained from the results of fluoroscopy, causing the PCL to become looser.

## Conclusions

This study estimated and compared the forces in the knee ligaments during pedaling. The results indicated that non-resisted and resisted cycling could serve as appropriate rehabilitation exercises for patients with ACL injury, however, not suitable for patients with PCL injury or reconstruction due to the excessive loadings on the PCL.

## Simulating Subject-Specific Spine Mechanics: An Integrated Finite Element and Neuro-Musculoskeletal Modelling Framework

L. Meszaros<sup>1,2</sup>, M. Hammer<sup>2</sup>, J. Riede<sup>2</sup>, P. Pivonka<sup>1</sup>, J. Little<sup>1</sup>, S. Schmitt<sup>2</sup>

### Summary

The aim of the current study is to integrate two different types of computational models (finite element and neuro-musculoskeletal) to simulate spinal motion in order to gain a greater understanding of the impact of spinal muscles on the mechanics in the thoracolumbar spine during forward flexion. All relevant structures were successfully included in both modelling workflows to directly simulate physiologically inspired motions. Analysis of the resulting finite element simulation shows a displaced spinal motion in the finite element model that was compatible with the simulated motion in the neuro-musculoskeletal spine model.

### Introduction

Finite element (FE) analysis and multi-body (MB) modelling are computational methods commonly used as an effective tool in simulating human spine motion. The aim of the current study is to develop an integrated framework that allows to combine two different spine modelling methods. When combined, a more intrinsic understanding of spine biomechanics is provided, giving insight into the internal tissue mechanics for physiologically authentic motions. We adapted an established muscle-driven neuro-musculoskeletal (NMS) spine model developed in the in-house modelling framework *demoa* [1] to match the mechanical properties of a subject-specific osseoligamentous FE model of the spine [2] in order to provide temporal data for muscle forces.

### Methods

The following sections detail the specific steps employed in order to generate models with compatible anatomy, soft tissue characteristics and initial conditions.

**Anatomy:** Both the NMS and FE models were personalised to include thoracolumbar spine, ribcage and pelvic anatomy for the Visible Man (VM) [3] using custom-developed image processing software, *Dicomtilt* [2]. The in-house preprocessor *calcman*, a tool for the calculation of 3D anthropometric data [1], was extended to allow the creation of subject-specific MB models based on CT-derived landmarks.

**Muscles:** A series of user-selected landmarks defined muscle attachment and deflection points in the thoracolumbar spine, sacrum and pelvis. Using custom-developed FE pre-processing software, *VirtuSpine* [2], these landmarks were used to create an osseoligamentous FE spine model with individual muscle threads modelled using axial connector elements (tension-only).

**Ligaments:** To match the nonlinear stiffness properties of the ligaments, an optimisation was performed using the

objective function of Least Squares on the literature-based stress-strain characteristics used in the FE model. The optimisation-derived characteristic points of the ligament stress-strain curve were implemented in the nonlinear modelling algorithm of the MB model.

**Intervertebral (IV) discs:** In order to equalise the models' IV coupling behaviour the 6D mechanical response of isolated IV discs from the FE model was encapsulated in different loading conditions and used to build individual surrogate models based on kernel methods for multiaxial non-linear approximation. These surrogate models mimic the forces and moments an IV disc exerts onto the endplates of adjacent vertebrae in the MB model.

Muscle forces were computed for a flexion movement using the developed subject-specific NMS model in a forward dynamics simulation. The NMS-derived temporal changes in muscle forces were applied via force amplitude data linearly ramped over the load step at the muscle connector elements in the FE model resulting in quasi-dynamic loading conditions.

### Results and Discussion

The NMS modelling workflow was successfully adapted to simulate subject-specific anatomy and soft tissue properties. Similarly, the FE capability was advanced to define a subject-specific NMS loading regime using >200 individual muscle threads. Analysis of the FE model with NMS-derived muscles forces for a forward flexion motion, predicted a displaced spinal motion in the FE model that was compatible with the simulated NMS motion.

### Conclusions

With the established framework, we have the capability to simulate NMS-derived, physiologically inspired motions in a FE model of the spine. This allows us to investigate the influence of spinal motion and muscle activation patterns on tissue level mechanics. All significant and relevant structures are now included in both modelling workflows to create identical models on FE and NMS level that together provide a finer resolution in discovering the influence of muscle synergies on joint mechanics. In future studies the developed approach will be applied on spinal pathologies.

Email: [zimi.sawacha@dei.unipd.it](mailto:zimi.sawacha@dei.unipd.it)

### Summary

Injuries related to the practice of field hockey are very common, especially those regarding the lower limb joint biomechanics. The goal of this study is to understand whether females are more prone to lower limb injury risk than males while performing a hockey specific task, like a sprint done with an implement (the hockey stick). For this purpose, we have assessed two cohorts of subjects on field and compared the biomechanical variables related to the lower joint joints.

### Introduction

Field hockey is a sport in which speed is the most important aspect in order to succeed. For this reason, hockey athletes are typically required to do several short sprints at high speed with the constraint of holding a hockey stick. Using the hockey stick while playing has been proved to affect players in terms of body posture and metabolic demand [1]. It should be further considered that injuries result not only in individual cost and can compromise the success of the team over the sporting season [1]. Furthermore, it has been shown that the joint kinematics was negatively affected by the use of the stick [2]. This study aims to compare female and male athletes in two different sprint conditions, and through the assessment of their lower limbs kinematics and kinetics, to evaluate their risk of injuries.

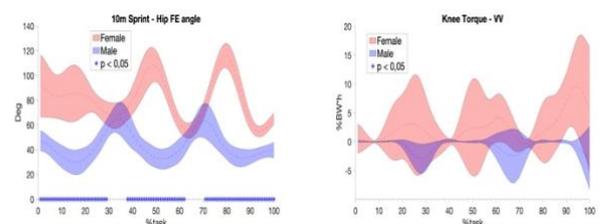

### Methods

After signing informed consent, sixteen subjects (9 athletes of the female hockey team: mean (SD) age 21,56 (4,67) and BMI 22,01 (0,99) kg/m<sup>2</sup>, 7 athletes of the male hockey team: mean (SD) age 22,00 (2,83) and BMI 23,71 (1,67) kg/m<sup>2</sup>) were acquired while performing two consecutive 10m sprints in two different conditions: one carrying the hockey stick with one hand and the other one carrying the hockey stick with two hands. Data were acquired by means of four GoPro Hero 3 cameras and plantar pressure insoles (Pedar X, Novel). An automatic tracking of feature software (TrackOnField, BBSof S.r.l.) and self-developed Matlab (R2017a) codes were used to estimate lower limbs (hip, knee and ankle) angles and moments [3]. The acquisition was performed directly on the field, while the athletes were performing the task. Seventeen retro-reflective markers were applied on each athlete according to a simplified version of the IORgait Marker Set

[4]. Only sagittal plane kinematics was considered. Normative bands were created (mean and standard deviation) of each variable for each tested condition and subject's cohort. Student T-test ( $p < 0.05$ ) was applied (Lilliefors Test evaluation of normal distribution) in order to compare the biomechanical variables between the female and male cohort.

### Results and Discussion

Statistically significant differences were observed between the two cohorts, especially in terms of lower limbs' hip joint rotations and knee moments. Higher hip flexion angles were observed in female athletes (Fig 1-left). An opposite trend was observed in the male athletes and higher knee moments were measured; female athletes recorded very high knee varus moments differently from male athletes that recorded low valgus moments (Fig 1-right).

**Figure 1:** Left: Comparison between the hip angles of the two teams. Right: Comparison between the knee moments of the two teams.

### Conclusions

Results of the present study highlighted differences between female and male hockey athletes while performing a sport specific task on field. A higher risk of lower limb injuries was assessed on the female athletes by considering the higher knee moment values on the coronal plane associated with higher flexion angles on all the lower limb joints.

## Intra-Subject Repeatability of Joint Angle Measurement During Skating on Synthetic Ice

Aminreza Khandan, Ramin Fathian, Jason Carey, Hossein Rouhani\*

Mechanical Engineering, University of Alberta, Edmonton, Alberta

Email: hrouhani@ualberta.ca

### Summary

High intra-subject repeatability in hockey players' kinematics is a requirement for athletic performance assessment based on joint angles; it, however, has not been studied yet for skating on synthetic ice. The objective of this study is to investigate the intra-subject repeatability of the joint angles during forward skating on synthetic ice. To this end, reflective markers were attached on four participants, and they were asked to skate forward on a synthetic ice area built on a motion capture lab. Using the marker trajectories, hip and knee joint angles were obtained. Then, the intrasubject repeatability of the joint angles was investigated. Good to excellent intra-subject repeatability was observed in the recorded joint angles during forward skating. Further studies with a higher number of participants on the real ice arena are required to reach a general conclusion.

### Introduction

The key assumption in kinematic performance assessments for ice hockey is the high intra-subject repeatability of the measured joint angles. This assumption directly affects the reliability of the obtained angles to indicate the player's performance in a measurement session, and it has not been comprehensively investigated yet. This study aimed to investigate the intra-subject repeatability of the measured joint angles during forward skating on a synthetic ice area.

### Methods

Four participants (age:  $28 \pm 1$  years, body height:  $176.5 \pm 0.7$  cm, body mass:  $77.0 \pm 7.7$  kg, all male) were recruited to skate on a 14m-long synthetic ice area built on a motion capture lab. A 12 infrared camera motion capture system was used to measure the three-dimensional (3D) joint angles of the participants' lower limbs during skating. The 3D joint angles were obtained using the markers placed on anatomical landmarks following an experimental protocol suggested by Cappozzo et al. (1995) [1]. However, the markers on lateral and medial malleolus were attached to similar locations on the participant's skates to be visible by the cameras. Using the recorded marker trajectories, 3D hip and knee joint angles were calculated and expressed based on the joint coordinate system (JCS) in all captured strides in 20 skating trials, i.e.,

five strides for each participant. Following Kadaba et al. (1989) [2] and Growey et al. (1997) [3], the coefficient of multiple correlations (CMC) was utilized to investigate the intra-subject repeatability of the 3D joint angles during forward skating.

### Results and Discussion

Intra-subject repeatability was excellent for the joint angles in the sagittal plane ( $CMC = 0.93 \pm 0.03$ ) and good to excellent in other planes ( $0.77 < CMC < 0.87$ ). The most repeatable joint angle was hip flexion-extension with  $CMC = 0.96 \pm 0.01$ . On the other hand, relatively lower repeatability in the hip internal-external rotation was observed ( $CMC = 0.77 \pm 0.07$ ). Intra-subject repeatability of the 3D hip and knee angle measurements during skating on synthetic ice is presented in Table 1.

### Conclusions

Although more data are needed before a general conclusion can be provided, the current observation confirmed good to excellent repeatability of the recorded joint angles during forward skating in a session. Also, the source of lower repeatability in some of the measured angles can be further studied; using other motion capture devices like inertial sensors will eliminate the errors due to marker reconstruction and marker misplacements. Finally, similar studies on real ice are required to investigate skaters' joint angle intra-subject variability during forward skating on ice.

## Looking for the ideal sprint stride: how would sports results change if all strides were perfect

Andrey Pomerantsev

Institute of Physical Education and Sports, Lipetsk State Pedagogical P. Semenov-Tyan-Shansky University, Lipetsk, Russia

Email: [a.pomerantsev.1981@gmail.com](mailto:a.pomerantsev.1981@gmail.com)

### Summary

World Athletics registers records in sprint running. Sprint race is a series of unique and non-repeating strides. Each step is a function of the previous steps and defines the next steps. The ideal step is the step that motor potential is realised to the greatest extent. Identifying the best step can serve as a running benchmark for a particular athlete, as well as an example for all athletes.

### Introduction

If the best stride is considered as an ideal (reference) step, then it is possible to determine the time losses at each step due to the deviation from this one. The ideal strides of various sprinters can be compared to determine the best stride in the sport history.

### Methods

The research is based on momentary velocity analysis in men's 100 m final at the 2009 IAAF World Championships in Berlin. The intracyclic velocity charts are taken from the IAAF official website [1]. Momentary velocity data is obtained by laser measurement system. We don't have the original numerical values of the momentary velocity, so we quantized the existing graphs. The quantization included mapping, scaling and interpolation points. It allows us to describe all features of the original curve in high degree of similarity. Based on this data momentary velocity graphs is reconstructed.

The graph shows that each oscillation corresponds to one running stride. The maximum peaks and the minimum troughs of the intracyclic contribute to a high average intracyclic speed [2]. We analysed the momentary speed of 3 outstanding sprinters in the history: Usain Bolt, Tyson Gay and Asafa Powell. These athletes won medals in the final race of the 2009 IAAF World Championship in Berlin and remain the best sprinters in history. One of them is the owner of the ideal sprint stride very likely. To determine the best stride we determined the average intracyclic speed for all running cycles.

### Results and Discussion

Ideal stride is one that allows the highest average intracyclic speed in accordance with individual athlete's characteristics. Analysis reveals that the ideal step for all athletes is determined beyond of the starting acceleration and is not included in the final strides number (Figure1).

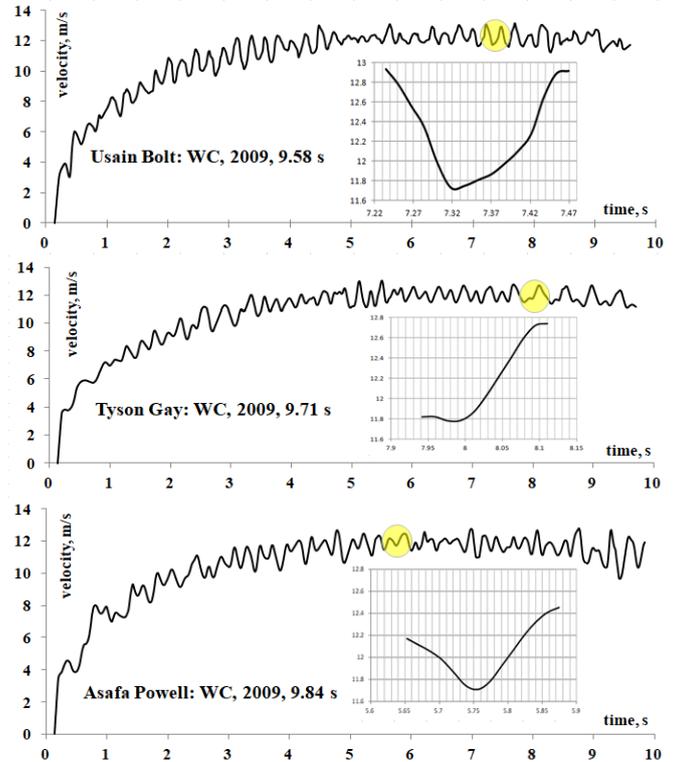

Figure 1: Momentary velocity vs time for medalists of 100m final at the 2009 IAAF World Championships in Athletics (quantized).

Computer calculation let to estimate the athletes' hypothetical results. In our cases we simulated that all strides would be identical and similar to the ideal stride after start acceleration (Table 1).

Table 1: Results of graphs analysis

Athletes	Velocity (average) of the ideal stride, m/s	Hypothetical results, s
Usain Bolt	12.30	9.42
Tyson Gay	12.19	9.50
Asafa Powell	12.08	9.54

### Conclusions

The sports result in the sprint largely depends on athlete's motor potential realisation. Any deviation from the ideal stride will worsen sport performance.

### Summary

It has become popular for team sport players to wear grip socks, which are marketed to reduce in-shoe slipping, and enhance speed and agility. We assessed these claims by quantifying in-shoe foot sliding using 3D motion capture, and measuring performance during change of direction manoeuvres. Foot sliding reduced in the tested grip socks, which was perceived by players to increase stability, comfort and speed. Yet, grip socks did not increase the coefficient of friction change or reduce time to complete a slalom course.

### Introduction

Team sports necessitate frequent and rapid whole body changes of direction during matches [1], enabling players to evade opponents to perform a certain action that can influence the result of the game. Few studies have investigated the role of friction at the foot-shoe interface during changes of direction. Yet performance depends upon the foot position being maintained on the midsole platform to prevent time being lost from foot sliding whilst transitioning from deceleration to acceleration [2]. The aim of this study was to investigate if grip socks enhance actual and perceived change of direction performance by increasing the coefficient of friction and reducing in-shoe foot sliding.

### Methods

Male recreational team sports players completed maximal effort change of direction manoeuvres (n = 10): a side cut (45°) and a complete turn (180°). Kinematic and kinetic data were collected with a 7-camera motion capture system (200 Hz) and a force plate (1000 Hz). In a separate visit participants (n =12) completed a slalom course to assess performance. Two sock conditions were tested: a regular athletic sports sock (RS) and a grip sock (GS) with rubber pads (7 x 9 mm) on the inside and outside sock material (LUX Sports). A standardised indoor football shoe was fitted to players that had holes in the shoe upper (30 mm Ø), and reflective markers attached to the midsole. The socks were cut in corresponding locations so markers were attached directly onto the dorsal foot skin overlaying the regions of the fifth metatarsal head (MH5) and base (MB5), and the lateral calcaneus (LC). During the change of direction manoeuvres, in-shoe foot sliding was determined from the maximum range of displacement between the foot and shoe markers between two frames after initial foot contact and two frames before toe-off, adapted from a previous study [3]. The mean coefficient of friction was calculated as the ratio of the horizontal to vertical ground reaction force during the loading and propulsive phase, defined as the first and second 50% period that in-shoe sliding was computed. The time taken to complete a 26 m slalom course was monitored [4] and subjective perception of

in-shoe grip, stability and comfort were measured with a 150 mm visual analogue scale [3]. Variables for each sock condition were averaged for each participant and compared statistically by paired t-tests (p<.05).

### Results and Discussion

The GS tended to reduce in-shoe sliding across foot regions in both change of direction manoeuvres compared to the RS (Table 1). No differences were observed in the coefficient of friction during the loading or propulsive phases during the side cut or complete turn (Table 1).

**Table 1:** Maximum foot marker to shoe displacement (sliding) and coefficient of friction (COF) across participants.

Variable	Manoeuvre	RS	GS	p-value
MTH-shoe sliding (mm)	Side-cut	7.3 ± 2.0	5.8 ± 2.0	0.073
	Turn	13.7 ± 4.7	11.8 ± 1.9	0.096
MB5-shoe sliding (mm)	Side-cut	8.1 ± 2.7	6.7 ± 2.5	0.070
	Turn	11.6 ± 2.4	9.4 ± 1.2	0.002
LC-shoe sliding (mm)	Side-cut	7.0 ± 1.8	6.3 ± 1.8	0.465
	Turn	8.8 ± 2.6	6.2 ± 1.3	0.012
Loading phase COF	Side-cut	.40 ± .06	.39 ± .05	0.311
	Turn	.59 ± .06	.58 ± .06	0.350
Propulsive phase COF	Side-cut	.52 ± .03	.51 ± .06	0.654
	Turn	.61 ± .05	.60 ± .05	0.255

There was no difference in the time to complete the slalom course (p = .175), but participants' perceived in-shoe grip (p < 0.001), stability (p < 0.001) and comfort (p = 0.022) increased in GS compared to RS

### Conclusions

Grips socks reduced in-shoe foot sliding during change of direction manoeuvres and were perceived to be more stable and comfortable. Future research needs to explore if this influences movement control and injury risk. The magnitude of foot sliding that grip socks reduced compared to regular socks is not sufficient to influence performance.

## Reproducing the characteristics of muscle fatigue change through sEMG analysis based on joint mechanical work during upper limb repetitive rotation

Jinsung Jung<sup>1</sup>, Jung Kim<sup>1</sup>, Sukyung Park<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Korea Advanced Institute of Science and Technologies, Daejeon, Republic of Korea  
Email: jinsungjung@kaist.ac.kr

### Summary

In this study, a model capable of estimating the mean power frequency(MPF) of the sEMG from joint mechanical work data was proposed to reproduce the characteristics of muscle fatigue changes. sEMG signals and kinetic data of the upper limb were measured. The change characteristics of the estimation result through the proposed model were compared with the change characteristics of the sEMG MPF. Estimation using the proposed model showed lower NRMS error and a more similar  $\Delta MPF$  value than linear regression. This result implies that the proposed model is more suitable than linear regression to estimate the sEMG MPF.

### Introduction

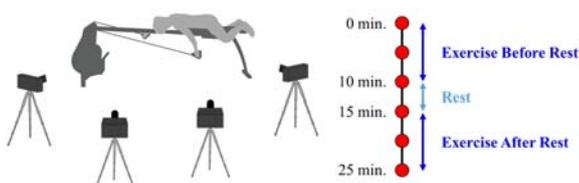

Muscle fatigue, which can be measured through blood lactate concentration or sEMG[1], is widely used in human movement studies, including sports. However, it's challenging to obtain by a general user because of an invasive measurement method and the high price of measurement equipment. Therefore, unlike the previous methods, we tried to estimate the sEMG MPF, which means muscle fatigue, based on kinetic changes, and to reproduce the characteristics of the change due to muscle fatigue of the data.

### Methods

The sEMG MPF of the upper arm muscles was modeled based on the upper limb joints' mechanical work, which can be obtained with inverse dynamics. From the fact that fatigued muscles' muscle fatigue decreases exponentially[2], a model for estimating the sEMG MPF was proposed.

$$\text{Estimated MPF}(\%) = 100 - \sum_{i=1}^{n_c} (c_s W_{s,i} + c_e W_{e,i}) e^{a(i-n_c)}$$

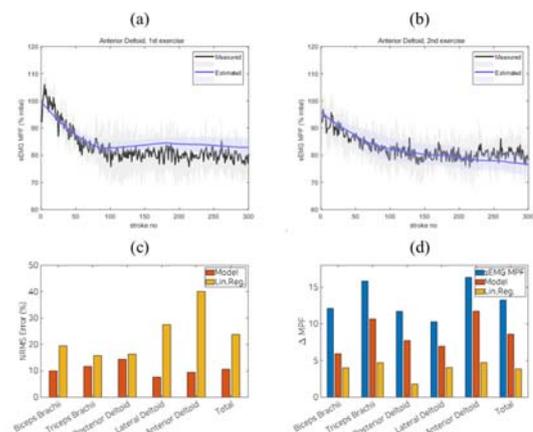

The model's parameters were determined through a nonlinear optimization that minimizes the objective function, which is defined as the square of the difference between the sEMG MPF and the estimated value. Nine subjects were recruited, and each subject performed six trials. In a single trial, subjects performed a crawl for 25 minutes with a 5 minutes break in the middle. The experiment was conducted on a swim bench (Figure 1). sEMG of the five upper arm muscles was measured, and the upper arm's kinetic data were collected from cameras and a force sensor.

**Figure 1:** Experimental setup and protocol.

### Results and Discussion

As a result of estimation through the proposed model, NRMS error of  $20.48 \pm 8.45\%$  was shown for the measured sEMG MPF (Figure 2a, 2b). Two characteristics of change were observed: muscle fatigue progression speed (numerical differential) and the rise due to recovery ( $\Delta MPF$ ). Since the correlation between sEMG MPF and joint mechanical work was shown through linear regression in the previous study[3], the estimation was attempted through linear regression with the same number of parameters as the proposed model. The NRMS error of the numerical differential value was  $23.82 \pm 109.73\%$  for linear regression estimation and  $10.62 \pm 27.10\%$  for the estimate using the proposed model at the exercise after rest (Figure 2c). For each data, the difference between the data values at the start of exercise after rest and the end of exercise before rest was calculated ( $\Delta MPF$ ).  $\Delta MPF$  of sEMG MPF was  $13.26 \pm 11.28$ , the linear regression was  $3.86 \pm 11.85$ , and the proposed model showed  $8.60 \pm 6.29$  (Figure 2d). The proposed model reproduced  $\Delta MPF$  value closer to the sEMG MPF.

**Figure 2 :** (a) sEMG MPF and proposed model estimate result before rest and (b) after rest. (c) The numerical differential error of the proposed model and linear regression estimates. (d)  $\Delta MPF$  of sEMG MPF, proposed model, and linear regression estimate.

### Conclusions

As a result, the proposed model can estimate sEMG MPF with an error of about 20% and better reproduce sEMG MPF change characteristics than linear regression estimation.

## Feedback-based running retraining for impact reduction: The relationship between peak tibial acceleration and step frequency

Pieter Van den Berghe<sup>1\*</sup>, Rud Derie<sup>1\*</sup>, Veerle Segers<sup>1</sup>, Marc Leman<sup>2</sup>, Dirk De Clercq<sup>1</sup>

<sup>1</sup>Dept. of Movement and Sports Sciences and <sup>2</sup>IPEM, Ghent University, Ghent, Belgium

\* Equal contribution, Email: pieter.vandenbergh@ugent.be, rud.derie@ugent.be

### Summary

This study evaluated the feedback-induced effect of axial peak tibial acceleration (APTA) reduction on step frequency in two test centers. Ten runners with high APTA followed 3 weeks of gait retraining via auditory feedback on an athletic track at ~2.9 m/s. We developed a wearable system that stimulated a reduction in APTA of 30% via music-based biofeedback on the momentary APTA. Runners could freely explore biomechanical adaptations for lower impact running. Despite the substantial reduction in APTA observed in the athletic facility ( $\Delta\bar{x}=-25.5\%$ ) and the laboratory ( $\Delta\bar{x}=-26.9\%$ ), the relative changes in APTA and in step frequency were not linearly correlated. A retraining program based on auditory feedback can be completed outside the laboratory, with reproduction of lower impact running in the laboratory without the real-time feedback on APTA. Our data showed that altering step frequency was no generic motor strategy for APTA reduction in this sample of high impact runners.

### Introduction

An increase in step frequency of 8.6% has decreased impact loading in high impact runners [1]. This impact loading was measured as the vertical loading rate of the ground reaction force, which correlates with the APTA during level over-ground running [2]. A strong negative linear relationship has been observed between the relative changes in step frequency and in APTA when varying the step frequency in running [3]. Hence, when stimulating a reduction in APTA with the use of biofeedback, we expected to observe a relationship between the relative changes in APTA and step frequency. The data were deliberately collected in two centers designed for over-ground running to improve confidence in the results.

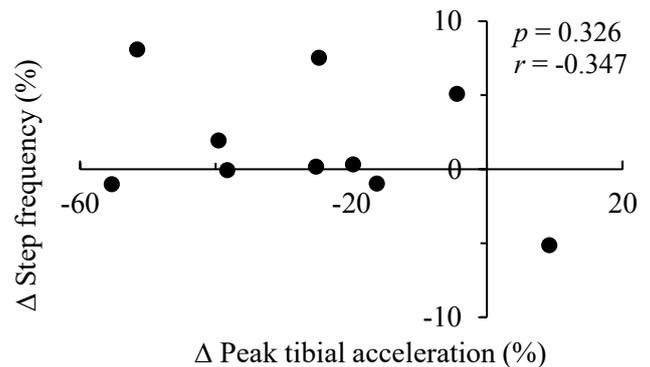

### Methods

Ten high impact runners (5M-5F, age:  $32.1\pm 7.8$  year, body height:  $1.74\pm 0.11$  m, mass:  $71.5\pm 18.3$  kg, running volume:  $27\pm 10$  km/week, APTA:  $10.9\pm 2.8$  g) completed a 3-week gait retraining program in an athletics facility. Six sessions of running at ~2.9 m/s were completed on an athletic track with real-time biofeedback aimed at reducing APTA by 30%. The wearable biofeedback system provided tempo-synchronized music that was superimposed with pink noise coupled to the momentary APTA. As main outcome of the gait retraining protocol, APTA was evaluated before the start and upon completion of the running program. An additional pre-post evaluation took place in a biomechanics laboratory. In this post-session, we asked the participants to replicate the running form in the absence of biofeedback. Step frequency was derived from the timing of consecutive APTAs. Changes were normalized to the absolute values obtained before the start of

the experiment [3]. Paired t-tests evaluated the changes in APTA. The Pearson correlation coefficient was calculated between the change in APTA and the change in step frequency for each of the test settings.

### Results and Discussion

The APTA was substantially reduced in the athletic facility ( $\Delta\bar{x} = -25.5\%$ ,  $p = 0.008$ , Cohen's  $d = 1.08$ ). This decrease was not significantly different ( $p = 0.798$ ,  $d = -0.08$ ) from the relative decrease observed in the laboratory ( $\Delta\bar{x} = -26.9\%$ ). Thus, following the retraining protocol, the group reproduced a form of lower impact running upon request in the absence of biofeedback in another setting. We observed substantial between-subjects variability in APTA reduction, but significant correlations between the changes in APTA and step frequency were absent both in the athletic facility (Figure 1) and in the laboratory ( $p = 0.606$ ,  $r = -0.186$ ). However, step frequency may still have influenced APTA on the individual level. A 3D gait analysis may improve insight into the mechanisms of APTA reduction during over-ground running.

**Figure 1:** Relationship between individual mean changes ( $\Delta$ ) in APTA and step frequency during running on the athletic track.

### Conclusions

The group of high impact runners successfully completed a biofeedback-driven retraining program outside the lab and could reproduce a form of lower impact running in another setting without the biofeedback. Altering step frequency was not the prominent strategy to reduce APTA in this cohort.

# THE EFFECT OF CADENCES ON LOWER EXTREMITY BIOMECHANICS DURING STAIR ASCENT AND DESCENT

Qi Li, Ruixia Zhang, Shengnian Zhang

School of Kinesiology, Shanghai University of Sport, Shanghai, China

\*corresponding author: E-mail: [zhangsnx@163.com](mailto:zhangsnx@163.com)

## INTRODUCTION

The U.S. Centers for Disease Control and Prevention (2007) states that more than half of all fall injuries are attributable to slope and stair walking [1]. The study found that the incidence of falls when stair ascent(77%) is more than three times that of stair descent(23%) [2]. However, the biomechanical mechanism of stair ascent(SA) and stair descent(SD) has not been clearly explained, and even joint moments at the lower extremity during SA and SD are still controversial.

## METHODS

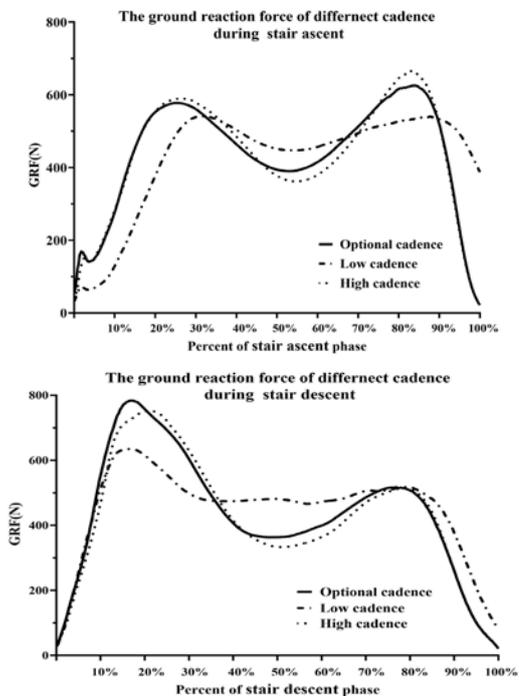

Thirteen healthy women were selected without lower limb injury (age:24±1.7 yrs, height:162.3±5.8m, body mass: 55.0±7.3kg), using an 8-camera VICON system (200 Hz) with 3 Kistler force plates (1000Hz) to synchronously collect the dynamics and kinematics data of the subjects ascending and descending stairs.

The staircase consists of five steps, each 17cm high. Three Kistler force plates are placed on the ground and the third and fourth steps. The subjects were asked to walk up and down stairs three times with low(70beats/min), optional(The normal cadence of each subject and is between high and low), and high(110beats/min) cadence, which is controlled by a metronome.

A Two-way ANOVA was used for statistical analysis of the experimental data, and the significance level  $\alpha$  was set at 0.05 (21.0, SPSS Inc., USA).

## RESULTS AND DISCUSSION

In both SA and SD, no significant differences were found in peak joint moments at the lower extremity during three cadences, the peak ankle moment is greater than that of the hip and knee at the low cadence, the peak knee moment is greater than that of the ankle and hip at the optional and high cadence. In SD, the ground reaction force at both high and optional cadence is greater than that at low cadence, and the difference is significant( $p<0.05$ ).

**Figure 1:** The ground reaction force of different cadence during stair ascent and descent phase

## CONCLUSION

It is clear that SD is a process that more at risk of falling, the ground reaction force of SD under the three cadences is greater than that of SA. And a higher cadence may lead to a greater likelihood of falling. Future studies are needed to confirm the relationship between muscle co-activation and dynamics of SA and SD.

## ACKNOWLEDGEMENTS

None.

# ANALYSIS OF FLAT SERVICE IN TENNIS

**P.RAJINIKUMAR<sup>1</sup>**

<sup>1</sup>Dept. of Exercise Physiology and Biomechanics, Tamil Nadu Physical Education and Sports University, Chennai, India. Email: rajinipkp88@gmail.com

## Summary

The purpose of the study was to predict flat serve performance (speed and accuracy) based on the selected anthropometric, skill related fitness and biomechanical variables among elite tennis players. Thirty (N=30) male elite tennis players were selected at random and they were tested on their flat service performance (speed and accuracy) and the selected independent variables such as height, weight, arm length, leg length, grip strength, dynamic balance, co-ordination, arm power, leg power racket lowest point, and relative height of contact. Multiple regression statistical technique was used to predict the influence of selected independent variables on flat service performance Height, co-ordination, racket lowest point and relative height of contact were the predictors of flat serve performance in tennis.

## Introduction

The serve has been the most important skill in professional players<sup>1</sup>. The serve determines the success of a player, deciding the outcome of the match. The professional player's ability to produce high ball velocity to be the key elements of successful play, because it puts the opponent under stress and may hinder its return. In tennis, the serve is a sequence of motion referred to as a kinetic chain that begins with the lower limb action and followed by rotations of the trunk and the upper limb<sup>2</sup>. In tennis, serve is one of the most important basic technique keys to success<sup>3</sup>. Tennis serve is the only closed skill a player has a full control on the trajectory path of the ball. But at the same time, it is difficult to master it involves the complex co-ordination of the lower and upper body segments. The purpose of the study was to predict flat serve performance (speed and accuracy) based on the selected anthropometric, skill related fitness and biomechanical variables among elite tennis players.

## Methods

Thirty (N=30) male elite tennis players who had represented state and interuniversity competitions were selected from Chennai as the subjects of the study. They were selected at random from various tennis clubs, academies, colleges and universities from Chennai from a population of 70 male players. All the selected players were right hand players for the purpose of homogeneity. The age of the subjects ranged from 18 to 25 years. The independent variables such as

anthropometric variables namely height, weight, arm length and leg length and the skill related fitness variables namely, grip strength, dynamic balance, co-ordination, arm power and leg power were measured using standardized tests. The biomechanical variables such as ball release height, ball toss peak height, racket lowest point and relative height of contact were measured using max TRAQ 2D analysis software. Multiple regression statistical technique was used to predict the influence of selected independent variables on flat service performance. The Statistical Package for Social Sciences was used to analyze the data and alpha level of 0.05 was fixed to determine statistical significance.

## Results and Discussion

Results showed that the multiple correlation co-efficient R=.983, which indicated that there was a high level of multiple correlation with flat service performance and nearly good predictor of dependent variable.

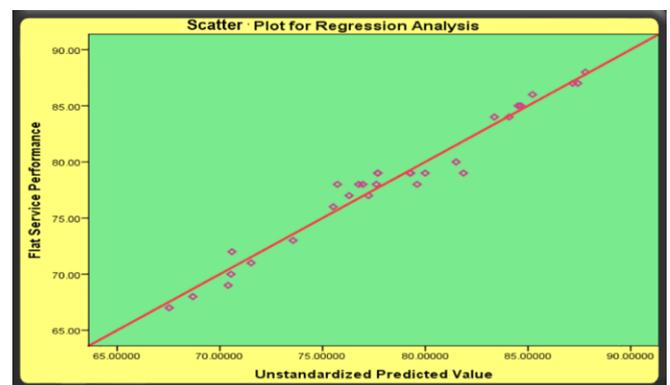

Figure 1: Scatterplot predicting flat service in tennis .

## Conclusions

It was concluded that height (anthropometric variable), co-ordination (skill related fitness variables) and racket lowest point and relative height of contact (biomechanical variables) were the predictors of flat service performance (speed and accuracy) among elite men tennis players.

## Kinematics Analysis of a Malaysian Female Elite Tenpin Bowler - A Case Study

Victoria Chin Quan Weoi<sup>2</sup>, Yallini Selva<sup>1</sup>, Viswanath Sundar<sup>1</sup>

<sup>1</sup> Sports Biomechanics Centre, National Sports Institute of Malaysia, Kuala Lumpur, Malaysia

<sup>2</sup> Centre for Sport and Exercise Sciences, University Malaya, Kuala Lumpur, Malaysia

Email: viswabiomech@gmail.com

### Summary

Tenpin bowling is a highly competitive sport that is popular in Malaysia. This study focuses on analysing the influence of lane oiling pattern on the kinematics of an individual bowler. Qualisys Track Manager and Visual 3D were used to identify and extract joint angles and angular velocities of the shoulder, elbow, wrist, hip, knee and ankle of three key variables (PH, FS & R). All investigated variables were analysed using the point biserial correlation. Several kinematic variables were identified to have a significant difference between bowling on short oil and long oil.

### Introduction

Tenpin bowling is a popular sport with an estimation of more than 100 million players worldwide [1]. The technical skills of a tenpin bowling player are crucial in the delivery of a good throw. Previously, only two studies used 3D Motion Capture to analyse the kinematics of a bowler [2, 3]. However, none has investigated the influence of the oiling pattern on bowling lanes. The objective of this study is to investigate the influence of lane oiling pattern on the kinematics of a tenpin bowler.

### Methods

One right-handed elite female Malaysian tenpin bowling athlete was recruited for this study (age 22, mass 55.15 kg, height 1.67m), the participant was briefed with the procedure and informed consent was obtained from all participants. A standard bowling ball (15lb) was used by the athlete. All data were collected in a sanctioned tenpin bowling alley. Eleven Oqus 7+ series infrared cameras (Qualisys AB 411 05, Goteborg, Sweden) at a frequency of 200Hz are used. Seventy-one, 12.5 mm reflective markers were attached to key body landmarks to create a 15-segment representation in Visual 3D v2020 (C-Motion Inc., Germantown, USA). Ten shots each from a total of 30 shots of short and long oil was chosen for further analysis. A 15-segment model in Visual

3D was used to calculate descriptive kinematic parameters. Key variables were calculated at three key instants; peak height (PH) (highest point of the backswing), foot slide (FS) (initial contact point of the foot to the lane during the last step), and release (R) (the point at which the bowling ball leaves the bowler's hand). Joint angles and angular velocities of the shoulder, elbow, wrist, hip, knee and ankle were identified. A point-Biserial correlation was conducted to analyse any relationship between oiling pattern and (kinematic) variables of the subject.

### Results and Discussion

Point Biserial correlations results are displayed in (Table 1). Higher and lower shoulder abduction was found in short oil during peak height and release respectively. Higher right hip and knee angle during peak height was found in long oil patterns. During the foot slide, a higher left hip angle was found in short oil while a higher right wrist angle and velocity was found in a long oil pattern. Higher left dorsiflexion was also found in long oil during this phase.

### Conclusions

This study has increased the understanding of kinematics between long and short oil patterns by highlighting the differences. Through this method, individualized technique identification could be provided to coaches for further improvisation.

### Acknowledgments

This work was supported by the National Sports Institute of Malaysia.

## Analysis of pacing strategy adopted by long-distance cross-country skiers

Xianshuang Yuan<sup>1</sup>, Hui Liu<sup>2</sup>

<sup>1</sup>Biomechanics Lab, School of Sport Science, Beijing Sport University, Beijing, China

<sup>2</sup>China Institute of Sport and Health Science, Beijing Sport University, Beijing, China

Email: y\_x\_s7508@163.com

### Summary

This study analyzed the section speed and the velocity coefficients for 141 skiers in the 10-km (female, n=57) and 15-km (male, n=84) Chinese cross-country skiing races with the classic technique. Data were collected at 120Hz using six cameras. Every two cameras as a group placed at flat, uphill, and curve terrain were used for three-dimensional shooting. A two-way (distance and 3 levels of performance) repeated-measures ANOVA was conducted. Optimal pacing strategy during the race differs for males compared with females.

### Introduction

Cross-country (XC) skiing is a complex endurance sport, in which an optimal pacing strategy is essential for desirable performance [1]. Studies on the pacing strategy of XC skiers are limited, especially for the Chinese skiers. The purpose of this study was to investigate the pacing strategy differences during long-distance XC skiing races in China related to the categories of performance level.

### Methods

A total of 141 (57 females and 84 males) athletes finished the Chinese 10/15 km XC skiing races using the classic technique. The athletes were divided into 3 performance groups named L1, L2, and L3, in which L1 is the fastest, based on rankings. The time in each section of the race was measured using 6 synchronized 120Hz video cameras (FDR-AX700, Sony Inc., Tokyo, Japan). Every two cameras placed at flat, uphill, and curve terrain were used to capture the speeds for each athlete in each section. The main optical axis for the two cameras was about 90°. Velocity coefficient (%) was calculated as follows: velocity coefficient = 100% × (section velocity - mean velocity of the whole distance) / mean velocity of the whole distance. Two-way analysis of variance with repeated measures was used to examine the effects of performance level and distance (2\*2) on the speed and velocity coefficient.

### Results and Discussion

All the skiers adopted a positive pacing strategy, only the males in L1 used a reverse J-shaped pacing (Figure 1). This profile characteristics of males consisted with Bilodeau's report [2]. Significant effects of performance (p<0.001) and distance (p<0.001) on speed were observed for females. A moderate performance × distance interaction on speed was

observed, with speed difference between L1 and L3 ranging from 1.561 m/s (13850- 14458m) to 0.65 m/s (0 - 700m) and faster developing less decrease in speed during the whole course for males ( $\eta^2 = 0.112, p = 0.023$ ). A large performance × distance interaction on the velocity variation of the whole course, with L1 presenting the smallest changes and the 0-700m section gained with the greatest variability, was shown for females ( $\eta^2 = 0.383, p < 0.001$ ) and males ( $\eta^2 = 0.154, p = 0.004$ ). This demonstrated that faster skiers had a more even pacing [3].

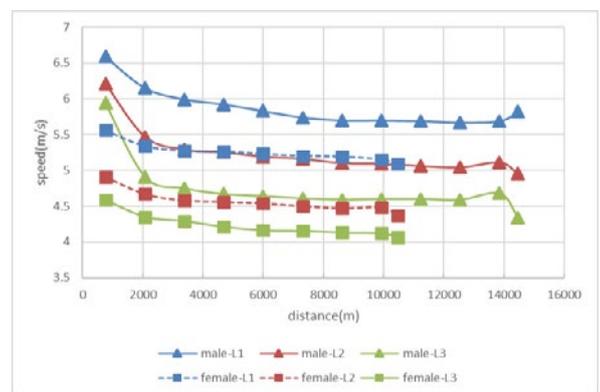

Figure 1: Speed profile of skiers across the race.

### Conclusions

Faster skiers utilized a more even pacing. Furthermore, increasing speed in the final section was favorable for males. To optimize performance, it could be beneficial to increase their aerobic capacity through training.

### Summary

The recent developments in sports biomechanics have enabled the use of various motion capture systems to study the biomechanics of cricket. Fast bowling is known to be deceitful towards the batsman to reduce his delivery response time and effectiveness. Kinematics factors such as run-up speed, pre-delivery stride length, delivery stride length, lean back angle, and angular velocities of arm have been studied over the last two decades to correlate with ball release speed. The aim of this study is to correlate kinematic factors with ball release speed using an Inertial Measurement Unit (IMU) sensor-based motion capture system.

### Introduction

Cricket has been the epicenter of sports for several decades now. The increasing global audience has attracted researchers to study and improve bowling techniques. One of the most crucial variables involved in fast bowling is the speed at which the ball is delivered [1]. Numerous human body kinematic factors have been studied to improve ball delivery. These include stride lengths, run-up speed, flexion angles, and angular velocity of each segment of body arm during delivery stride. Motion capture systems using marker-based optical systems have been implemented to study the significance of these factors, but no deterministic result has been concluded yet as to which kinematic factor contributes more to the ball delivery speed. These systems are commonly used in indoor environments but have limitations to use in outdoor environments. The sensor-based systems have the potential to be used in outdoor and even in-game situations.

### Methods

Two male fast bowlers (semi-professional cricketers) volunteered for this study. Subject 1, aged 24 was a right-hand front-on fast bowler with an average ball speed of  $65.3 \pm 2.3$  mph. Subject 2, aged 28 years old was a left-handed side-on fast bowler with an average ball speed of  $64.47 \pm 2.6$  mph. The human body kinematic was measured by sensors-based motion capture systems using 17 IMUs developed by XSENS. This system is capable of measuring position, velocity, and acceleration (both translational and rotational) of 23 body segments. The ball release speed was measured using *K-Band*

*Handheld Doppler Speed Radar* with an accuracy of  $\pm 1$  mph. 30 delivery trials were recorded for each subject. Three kinematic parameters (run-up speed, pre-delivery stride length, delivery stride length) were calculated from the sensor data. These factors were calculated for both subjects and related with ball release speed to find correlation coefficient (*R*).

### Results and Discussion

The mean values of kinematic parameters and the r-value of these parameters with ball release speed for both subjects are presented in Table 1. The correlation between run-up speed and ball release speed for both subjects is shown in Figure 1. Ball released speed showed significant dependency on the run-up speed, whereas, pre-delivery stride lengths showed negligible dependency for both subjects and delivery stride length yielded a slightly negative correlation coefficient.

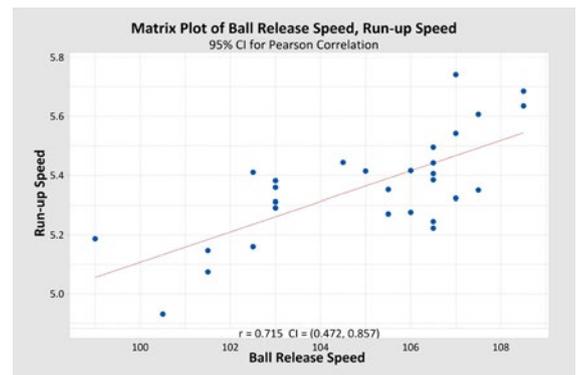

Figure 1: Correlation of run-up speed and ball delivery speed

### Conclusions

This is a comprehensive biomechanics study of fast bowling using wearable sensors. The effects of kinematic parameters on ball release speed were investigated and it was found run-up speed is directly related to ball release speed, this is in accordance with previously published results using optical systems of motion capture. This study will help to investigate the biomechanics of bowling in outdoor environments.

## Combinations of release parameters for accurate baseball pitching

Ayane Kusafuka<sup>1</sup>, Kazutoshi Kudo<sup>1</sup>, Kimitaka Nkazawa<sup>1</sup>

<sup>1</sup> Department of Life Science, Graduate School of Arts and Sciences, The University of Tokyo, Tokyo, Japan

Email: [ayane422@g.ecc.u-tokyo.ac.jp](mailto:ayane422@g.ecc.u-tokyo.ac.jp)

### Summary

This study revealed that combinations of release parameters which determine the pitch location of baseball pitching. We focused on two strategies to improve the accuracy of the pitch locations, thereby increasing the reproducibility of individual parameters and coordinating covariation among parameters. To examine whether coordinated covariation is used by skilled pitchers, for hypothetical combinations of release parameters, in which the coordinated covariation was eliminated, the variability of the pitch location was simulated and compared to the measured pitch location. The results showed that there was little coordinated covariation for all release parameters and that the variability of the pitch locations was decreased by improving the reproducibility of the release angle.

### Introduction

In various motor skills in sports, such as throwing, kicking, and hitting, accurately controlling a ball to a target position is one of the most important skills. The flight trajectory and final arrival position of the ball are physically determined by its state at the time of release or impact approximately. In baseball pitching, pitch location is determined by the combination of nine release parameters. If the state at the time of release is always the same, the ball will always arrive at the same position. However, it is known that there is always variability in each release parameter, even for skilled players. Therefore, the purpose of this study was to investigate the combinations of release parameters in pitching of skilled player to quantify the relationship between parameters which has an effect to improve accuracy of pitch location i.e., coordinated covariation.

### Methods

The release parameters were obtained using TrackMan Baseball while eight skilled baseball pitchers pitched to a target. Using a model to predict the pitch location from the release parameters [1] and the data randomization method [2,3], we simulated the variability of the vertical and horizontal pitch location when changing the relationship between the parameter i.e., one parameter varied individually. If the variability of the simulated pitch locations was larger than that of the measured ones, this was interpreted as an effect of a reduction in the variability of the pitch location the release parameters had (coordinated covariation). In the case where there was no or little coordinated covariation, increasing the reproducibility of individual release parameters was interpreted as effective. We defined the ratio of the variability of simulated pitch locations to the actual

ones as the index of covariation (IC) and a one-sample t-test was used to determine if the IC was greater than 1.

### Results and Discussion

Significantly large ICs were not observed for all release parameters of all pitchers in either the vertical or horizontal pitch location ( $M = 1.06$ , 95% CI [0.97, 1.15],  $t(7) = 1.50$ ,  $p = 0.18$  in vertical;  $M = 1.03$ , 95% CI [0.91, 1.14],  $t(7) = 0.66$ ,  $p = 0.53$  in horizontal; Fig. 1 shows the result in vertical). This suggests that varying the relationships between release parameters does not significantly affect the variability in the pitch location (i.e., there is little coordinated covariation).

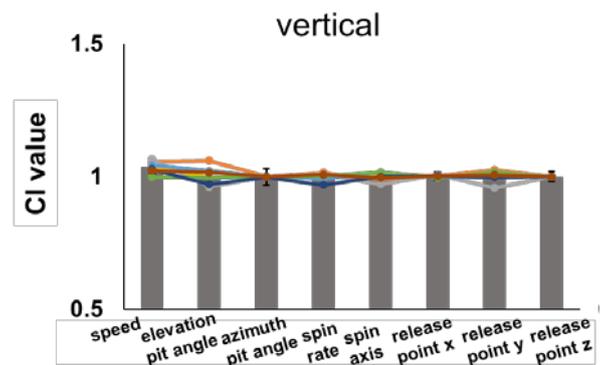

Figure 1: ICs for each release parameter in vertical pitch location.

The reason can be inferred by considering the effect of the variability of each release parameter on the pitch location. A previous study [3] found that the elevation pitching angle and the azimuth pitching angle have much larger effects on the vertical pitch location and horizontal pitch location, respectively, than other release parameters. In such a case, it is expected that compensating for the variability of the release angle by other parameters is difficult.

### Conclusions

There was little coordinated covariation among all the release parameters of all pitchers in both the vertical and horizontal pitch locations. The variability of the pitch location can be decreased by improving the reproducibility of the release angle, rather than using a coordinated covariation relationship with other release parameters.

Email: jiixiang0016@163.com

## Summary

The purpose of this study was to evaluate the effect of two different kayaking ergometers (wind resistance, KWR; electronic resistance, KER) on training. Six elite male kayakers executed three trainings of 200m, 500m and 1000m on-water (TW) and two kayak ergometers. The significance testing was used to analyze the difference between KWR and KER on TW, the coefficient of variation (CV) was used to analyze the working stability of the two ergometers. The results showed that no significant difference was found between the TW and the two ergometers performance on 200m. In 500m and 1000m, the two kayak ergometers showed poorer sport performance than the TW. In addition, the results also show that both kayak ergometers have good stability. Therefore, KWR and KER can be used by athletes as a training device. But an athlete's TW performance could not be predicted by KWR and KER.

## Introduction

Most kayakers rely on ergometers for training, especially in winter seasons [1,2]. The KWR calculate power via a mathematical relationship with the angular velocity of the flywheel. About KER, on the other hand, does not use the same approach [3]. Therefore, the purpose of this study was to analyze of kayaking ergometer with different drag resistance in kayak training.

## Methods

Six elite male kayakers volunteered to participate in the study (age: 17±1 years; Height: 182±4.45cm; Weight: 75.5±5.47kg; Training years: 4.67±0.47 years).

The test was conducted on six separate days, it was performed on TW and two kayak ergometers respectively, in randomised order. Three different distances of 200m, 500m and 1000m were tested. Before the each test, the athletes had a 15-minute warm-up followed by a 2-minute rest. Participants were asked to perform at the highest level throughout the test on TW and on two ergometers.

The participants' performance on TW was collected by the testers, and the measured data on the display of the ergometers was downloaded. Shapiro-Wilk's Test was used to test the normal distribution of the data. Since the data were normally distributed, the independent samples T-test was used to test the significance of the TW and two ergometers performance. CV was used to analyze the stability of KWR and KER in test. Data were analyzed using SPSS 19.0 statistical software, and the significance level was set at  $P < 0.05$ .

## Results and Discussion

In the 200m race, the difference between the two kayak ergometers and the TW performance was not found ( $P > 0.05$ ) (Table 1). In 500m and 1000m sports, the two kayak ergometers showed slower athletic performance than TW ( $P < 0.05$ ). Kayakers increase thoracolumbar extension and wider lateral bending range of motion during on water kayaking [4], over a long period of kayaking, these differences are magnified. The CV has good consistency when less than 10% [5]. Two kayak ergometers possess a stable CV (2.77 - 9.8 %) (Table 2).

## Conclusions

These findings show that both kinds of kayak ergometers have good stability in operation. They can be used by athletes as a kind of land training device. But, an athlete's TW performance could not be predicted by KWR and KER.

# GAIT VELOCITY INFLUENCE DYNAMIC GAIT STABILITY IN A DUAL-TASK PARADIGM

Jingwen Wang<sup>1</sup>, Li Li<sup>2</sup>, Wei Sun<sup>1</sup>, Qipeng Song<sup>1</sup>

<sup>1</sup>College of Sports and Health, Shandong Sport University, Jinan, China

<sup>2</sup>Department of Health Sciences and Kinesiology, Georgia Southern University, Statesboro, 30460, USA

Corresponding author: Dr. Qipeng Song, songqipeng@sdpei.edu.cn

## Summary

The effects of a concurrent cognitive or manual dual-task paradigm and gait velocity on dynamic gait stability (DGS) remain unclear. A total of 16 healthy young females descended a staircase under three different walking conditions: descend stairs only (single task), descend stairs while performing subtraction (cognitive dual-task), and descend stairs while carrying a glass of water (manual dual-task). An eight-camera Vicon motion analysis system and a Kistler force plate embedded into the third step of the staircase were used synchronously to collect kinematic and kinetic data. Gait velocity decreased and DGS increased with both cognitive and manual dual-task conditions. The center of mass–center of pressure inclination angle (IA) increased with gait velocity but decreased with the manual dual-task condition.

## Introduction

Stair descent imposes significant challenges to dynamic gait stability (DGS) in people of all ages [1]. A dual-task involves performing a physical task while performing a concurrent cognitive (CT) or manual (MT) task. Previous studies revealed different dual-task effects on DGS. A possible explanation for the inconsistent results is the different variables used to measure DGS, including center of mass (COM) displacement, center of pressure (COP) displacement, COM–COP separation. IA formed by the vertical line and the projection of the vector onto the sagittal and frontal planes, was proposed to provide a more comprehensive assessment than the examination of COM or COP [2]. The greater the IA, the further the COM diverges from the COP, a fall can occur [3]. Changes in gait velocity caused by a dual-task paradigm may be another reason for DGS differences. The purpose of this study was to examine the relationship between velocity and a dual-task performance on DGS during stair descent. And address the importance of gait velocity in assessing the effects of a dual-task. We hypothesized that velocity would decrease under dual-task conditions. A concurrent dual-task condition would adversely affect DGS during stair descent, DGS would decrease with increasing gait velocity under a dual-task.

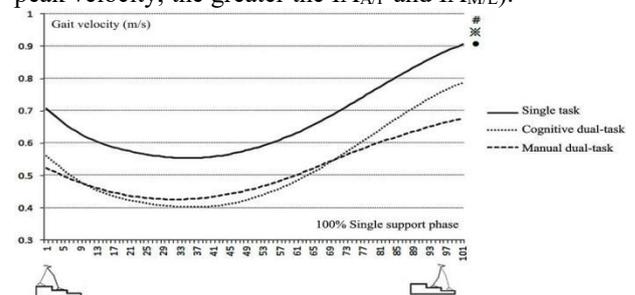

## Methods

A total of 16 healthy young females participated in this study. All kinetic and kinematic data were obtained from a right foot single-support phase. The participants were instructed to descend the staircase step-over-step under three conditions: 1) single task; 2) cognitive dual-task; and 3) manual dual-task. Gait velocity and IA normality were tested using the Shapiro–Wilk test. One-way repeated-measures ANOVAs were employed to examine the first and second hypotheses. Multiple regression analysis was

used to predict the independent variables of IA (y) based on the dependent variable of velocity (x) during ST, CT, and MT conditions.

## Results and Discussion

First, peak gait velocity decreased under CT or MT conditions and Peak velocity was also lower in MT than in CT. (CT velocity =  $0.79 \pm 0.09$ ; MT velocity =  $0.68 \pm 0.08$ ; ST velocity =  $0.91 \pm 0.11$  m/s; Figure 1); Second, the peak IA<sub>AP</sub> was less under the CT and MT dual-task conditions (CT<sub>AP</sub> =  $8.29 \pm 0.82^\circ$ ,  $p = 0.019$ ; MT<sub>AP</sub> =  $7.16 \pm 0.89^\circ$ ,  $p < 0.001$ ) than under the ST (ST<sub>AP</sub> =  $9.05 \pm 0.79^\circ$ ) and the peak IA<sub>ML</sub> during MT (MT<sub>ML</sub> =  $5.95 \pm 1.02^\circ$ ,  $p = 0.020$ ) was less than that during ST (ST<sub>ML</sub> =  $6.49 \pm 0.53^\circ$ ), our results failed to support our second hypothesis in both the anterior/posterior and medial/lateral directions, the decreased IA indicates improved DGS under CT or MT conditions during stair descent; Third, IA was positively related to gait velocity and negatively related to a concurrent MT (By regression equation  $y = 4.976 + 4.365x - 0.768B$  and  $y = 4.115 + 2.712x$  indicates the faster the peak velocity, the greater the IA<sub>AP</sub> and IA<sub>ML</sub>).

**Figure 1:** Descending velocity (y) of the single-support phase (x) during single-task and cognitive and manual dual-task conditions.

## Conclusions

Gait velocity decreased under CT and MT. DGS decreased with increasing gait velocity during stair descent. Finally, the influence of gait velocity should be considered when assessing the effects of dual-tasks.

# THE EFFECT OF DIFFERENT ILLUMINATION LEVELS AND TAI CHI EXERCISE ON THE POSTURAL STABILITY OF THE ELDERLY DURING STAIR ASCENT

Qi Wang<sup>1</sup>, Cui Zhang<sup>2</sup>, Li Li<sup>3</sup>, Qipeng song<sup>1</sup>

<sup>1</sup>College of Sports and Health, Shandong Sport University, Jinan, China

<sup>2</sup>Lab of Biomechanics, Shandong Institute of Sport Science, Jinan, 250102, China

<sup>3</sup>Department of Health Sciences and Kinesiology, Georgia Southern University, Statesboro, 30460, USA

Corresponding author: Dr. Qipeng Song, songqipeng@sdpei.edu.cn

## Summary

The effects of long-term Tai Chi exercise on postural stability of the elderly during stair ascent under high and low illumination were investigated. Forty-five healthy elderly women were divided into Tai Chi exercise (TC), brisk walking (BW) and no-exercise control (CON) groups. We use force platforms and a motion capture system to collect data. Under the high illumination, TC exhibited a greater loading rate and anteroposterior center of pressure (COP<sub>ap</sub>) displacement and a lower braking impulse than CON. Under the low illumination, TC demonstrated greater COP<sub>ap</sub> and mediolateral center of pressure (COP<sub>ml</sub>) displacements and lower braking and lateral impulses compared with CON. The center of mass (COM<sub>ml</sub>) sway in TC and CON were greater than BW. Therefore, low light increases the risk of falling, and Tai Chi practice can improve stability under this condition.

## Introduction

The stability of the elderly is challenged during stair descent and ascent. Tai Chi is believed to improve the postural stability of the elderly. However, the veracity of whether low illumination could adversely affect the postural stability of the elderly remains unclear. If it does, then we should recommend what exercise to reduce the risk of it. Therefore, this study was performed to investigate the effects of Tai Chi exercise on postural stability of the elderly during stair ascent under high and low illumination. We hypothesize that Tai Chi practitioners can increase the postural stability of the elderly during stair ascent under low illumination.

## Methods

Forty-five healthy elderly women were divided into Tai Chi exercise (TC), brisk walking (BW) and no-exercise control (CON) groups. We built a six-stage staircase and embedded force platforms in the third and fourth steps to collect ground reaction forces. The lux meter was placed 15-cm above the ground. In each session, the participant was asked to ascend the simulated staircase under high (300-lux) and low (3 lux) illumination levels [1]. The participants walk for 400-m at a self-selected pace as a level walking test before the stair ascent test, and took a one-minute rest between each test. In the experiment, we also used an eight-camera motion analysis system and 39 spherical markers. Descriptive analysis was conducted using the mean and standard deviations for both kinematic and kinetic variables.

Group and condition differences were examined using a mixed model two-factor ANOVA. Significance level set at 0.05.

## Results and Discussion

Under the high illumination, the loading rate of BW and the COP<sub>ml</sub> of TC were greater than those of CON (walking group,  $W_{high}=4.92\text{BW/s}$ , no-exercise group,  $N_{high}=3.96\text{BW/s}$ , 95%CI of the mean difference [CI<sub>95%</sub>]:0.17/1.75; Tai Chi group,  $T_{high}=0.032\text{m}$ ,  $N_{high}=0.024\text{m}$ , CI<sub>95%</sub>:0.001/0.015). Under low illumination, TC demonstrated higher foot clearance, COP<sub>ap</sub> and COP<sub>ml</sub> displacements ( $T_{low}=0.051\text{m}$ ,  $N_{low}=0.040\text{m}$ , CI<sub>95%</sub>:0.003/0.018;  $T_{low}=0.139\text{m}$ ,  $N_{low}=0.117\text{m}$ , CI<sub>95%</sub>:0.002/0.044;  $T_{low}=0.033\text{m}$ ,  $N_{low}=0.024\text{m}$ , CI<sub>95%</sub>:0.001/0.016) and lower braking and lateral impulses than the CON ( $T_{low}=10.88\text{BW/s}$ ,  $N_{low}=14.56\text{BW/s}$ , CI<sub>95%</sub>:-6.63/-0.71;  $T_{low}=2.32\text{BW/s}$ ,  $N_{low}=3.76\text{BW/s}$ , CI<sub>95%</sub>:-2.87/-0.01). The lateral impulse in CON was greater under low illumination than under high illumination ( $N_{high}=2.56\text{BW/s}$ ,  $N_{low}=3.76\text{BW/s}$ , CI<sub>95%</sub>:-2.28/-0.22). Compared with the low illumination, the COP<sub>ap</sub>, foot clearance, and head inclination angle of TC under the high illumination were lower ( $T_{high}=0.121\text{m}$ ,  $T_{low}=0.139\text{m}$ , CI<sub>95%</sub>:-0.029/-0.008;  $T_{high}=0.043\text{m}$ ,  $T_{low}=0.051\text{m}$ , CI<sub>95%</sub>:-0.014/0.002;  $T_{high}=10.54^\circ$ ,  $T_{low}=16.26^\circ$ , CI<sub>95%</sub>:-9.41/-2.04), and the trunk inclination angle and COM<sub>ml</sub> of BW and CON under the high illumination were lower ( $W_{high}=14.35^\circ$ ,  $W_{low}=17.07^\circ$ , CI<sub>95%</sub>:-5.12/-0.30;  $N_{high}=14.96^\circ$ ,  $N_{low}=18.03^\circ$ , CI<sub>95%</sub>:-4.26/-0.33).

## Conclusions

Low illumination increases the risk of falling. Tai Chi practitioners adopted appropriate strategies to maintain postural stability during stair ascent under low illumination.

# Optimization of the whole-body motion to minimize the muscle-tendon length of biceps femoris long head during the late swing phase of high-speed running

Terumitsu Miyazaki<sup>1</sup>, Norihisa Fujii<sup>2</sup>

<sup>1</sup>Doctoral Program in Physical Education, Health and Sport Sciences, University of Tsukuba, Tsukuba, Japan

<sup>2</sup>Faculty of Health and Sport Sciences, University of Tsukuba, Tsukuba, Japan

Email: s1930497@s.tsukuba.ac.jp

## Summary

Strain injuries in the biceps femoris long head (BFH) frequently occur during high-speed running. Stretching the muscle-tendon complex while generating muscle force is considered as one of the factors for strain injuries. To establish the optimal running motion that controls muscle-tendon dynamics, we aimed to optimize the whole-body motion by minimizing the muscle-tendon length of BFH using an angle-driven simulation during high-speed running. The results showed that the hip and knee flexion/extension angles were more sensitive joint angles than the other lower limb joint angles for minimizing the BFH length. The hip abduction/adduction and pelvic axial rotation angles also affected the BFH length. That optimization results were implicated an optimal running motion that reducing the risk of strain injuries in BFH.

## Introduction

Strain injuries in BFH often occur during the late swing phase of high-speed running [1]. The late swing phase is defined from the timing of maximum knee flexion to the foot strike. BFH generates greater force while lengthening in this phase [2]. We aimed to optimize the whole-body motion using an angle-driven simulation that minimizes the BFH length during the late swing phase of high-speed running.

## Methods

Fourteen male soccer players (mean age 20.2 years, body weight 67.4± kg, and height 173.6± cm) participated in this study. The participants completed the 50-m sprinting trials with their maximum effort in an outdoor track. The three-dimensional trajectories of markers that were attached to the whole-body were obtained using a motion-analysis system with three force platforms. An inverse kinematics algorithm was conducted after a filtering process to the trajectories [3].

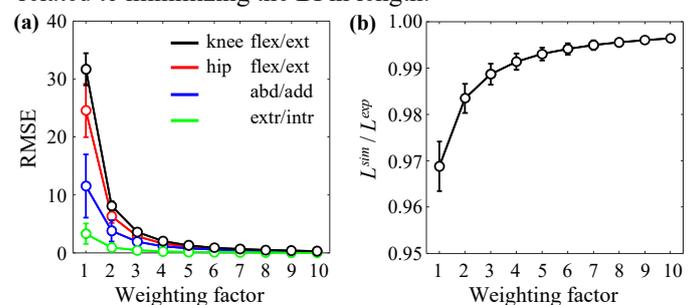

To optimize the whole-body motion, an angle-driven simulation at each time step was conducted by minimizing the objective functions ( $J(q)$ ) during the late swing phase. Residual forces and moments, which represent inconsistencies between the model's dynamics and experimental ground reaction forces, were not removed in this optimization. The objective function was the sum of two components: (1) the weighted ( $w$ ) squared error between the experimental ( $q^{exp}$ ) and simulated ( $q^{sim}$ ) joint angles for each DoF ( $n_q$ ) of the model. (2) the squared muscle-tendon length ratio of simulated ( $L^{sim}$ ) to the experimental ( $L^{exp}$ ) lengths.

$$J(q) = w \cdot \sum_{i=1}^{n_q} (q_i^{exp} - q_i^{sim})^2 + \{L_{bfh}^{sim}(q^{sim})/L_{bfh}^{exp}\}^2$$

The weighting factor ( $w$ ) was perturbed from 1 to 10, to clarify the influences of the weighting factor on the results. The root means square errors (RMSE) for each joint and segment angle at each weighting factor were calculated before and after the optimizations.

## Results and Discussion

As the weighting factor increased, the mean of RMSE values for the knee and hip joint angles tended to decrease, and the mean values of the ratio of simulated to experimental length ( $L^{sim}/L^{exp}$ ) tended to increase (Fig. 1). When the weighting factor was 1, the mean and one standard deviation of RMSEs for the knee flexion/extension, hip flexion/extension, abduction/adduction, and external/internal rotation angles were  $31.7 \pm 2.8$  [deg],  $24.6 \pm 4.6$  [deg],  $11.6 \pm 5.5$  [deg], and  $3.3 \pm 1.8$  [deg], respectively (Fig. 1). The RMSEs for pelvic tilt, obliquity, and axial rotation angles were  $0.3 \pm 0.2$  [deg],  $1.2 \pm 0.7$  [deg],  $23.6 \pm 9.1$  [deg], respectively. The results showed that the hip and knee flexion/extension angles were more sensitive factors for minimizing the BFH length than the other lower limb joint angles. The hip abduction/adduction and pelvic axial rotation angles also affected the BFH length. These results suggested that not only the hip and knee flexion/extension angles but also the hip abduction/adduction and pelvic axial rotation angles related to minimizing the BFH length.

**Figure 1:** (a) The RMSEs for the hip and knee joint angles, and (b) the length ratio ( $L^{sim}/L^{exp}$ ) at each weighting factor.

## Conclusions

This study clarified the optimal running motions that minimize the BFH length during high-speed running. The results showed that the hip and knee flexion/extension, the hip abduction/adduction, and pelvic axial rotation angles affected minimizing the BFH length.

Email: [irenehwl@163.com](mailto:irenehwl@163.com)

### Summary

CKE exhibited high stability coefficients in short, medium and long distances. The operation of the training equipment conformed to the actual application standards and can be used as a CK training equipment. With the increase of the test distance, CKE on-land specific physical training equipment runs better, and it can be used as a better choice for evaluating or testing the long-distance sports performance or aerobic capacity of kayak athletes.

### Introduction

The real modern-style Canoe & kayak (CK) ergometer with wind resistance (CKR) appeared in 1988 after one-decade revolution [1]. Nowadays, ergometer has been an essential part of strength training facilities and specific stimulation equipment for CK training, aiming to improve the power output of athletes [2].

However, both of them are 'non-isokinetic' ergometers that is the biggest difference compared with water training. This design limitations of the CK ergometer at present likely limit the deep understanding on CK's characteristics. CK ergometer with electromechanical drag resistance (CKE) realizes isokinetic pattern based on the control from microcomputer. As so far no relevant study confirm effect of this ergometer; in order to test its effect on the training, we operated test on this device.

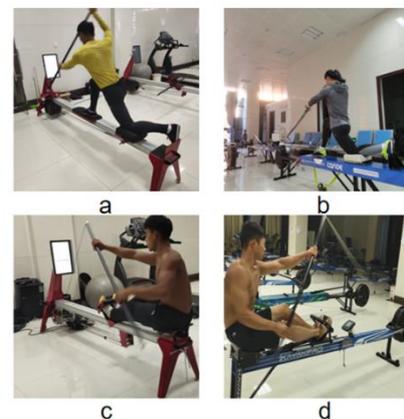

### Methods

33 mixed-sexual canoe & kayak national team athletes participated this test (Figure 1). All participants had been fully informed about the whole test procedure. Before test, 5-10 mins were given athletes for warm-up and device preparation. After athletes had to finish 200m, 500m and 1000m training on the all ergometers. There was a 20-min break between the tests on two different ergometers in order to operate comparable experiment.

Data were collected by the electronic display station. Parameters including time (T), 500 split (500 S), stroke rate (SR), velocity (V), power (P) and calories (C) were used for analysis. Coefficient of variation (CV) and intraclass correlation coefficient (ICC), Pearson correlation test and T-test were used to analyze canoe-kayak equipment performance on the training.

### Results and Discussion

Both CKE had a good running performance in longer distance (CV<0.15); CKE of kayak had a poorly correlated relationship with water performance. CKE of canoe had a poor performance at short distance training but had a good performance at long training distance (CV<0.15). CKE of canoe in 1000m had a highly correlated relationship with water performance ( $r=0.73$ ). The significant differences of CKE were found in T and P.

**Figure 1:** The test equipment in this experiment (a: CKE ergometer of canoe, b: CKR ergometer of canoe, c: CKE ergometer of kayak, d: CKR ergometer of kayak)

### Conclusions

CKE had a good performance with the increase of training distance, which indicated that CKE would be used as a good equipment in longer distance training and test. However, short-distance event like 200m event was a difficult point of canoe-kayak technology research and development.

### Acknowledgments

The authors would like to thank all rowers who took part in this study and for their efforts. And there is no conflict between authors.

# THE BIOMECHANICAL CHARACTERISTICS AND RULES COULD IMPROVE INJURY RISKS DURING RACE WALKING

Xiaohui Duan<sup>1</sup>, Li Li<sup>2</sup>, Qipeng Song<sup>1</sup>

<sup>1</sup>Shandong Sport University, Jinan, 250102, China

<sup>2</sup>Department of Health Sciences and Kinesiology, Georgia Southern University, Statesboro, 30460, USA

Corresponding author: Dr. Qipeng Song, songqipeng@sdpei.edu.cn

## Summary

The purpose of this study is to describe the biomechanical characteristics during race walking and identify whether the race walking rules could cause potential injury risks. Fourteen elite race walkers participated in this study. Rs-scan plantar pressure plate and three digital cameras were used to collect data during race walking and normal walking. Paired t-tests were used to detect differences. The results showed that during race walking, the peak pressure of lateral heel (HI) and medial heel (HM), The displacements of center of pressure (COP), ankle dorsiflexion, plantarflexion, knee extension, hip adduction, foot eversion, ankle angular velocity and average horizontal velocity were significantly larger than those during normal walking. The greater heel peak pressure and more ankle eversion may be the injury risks caused by the race walking rules.

## Introduction

In recent years, race walking has grown in popularity, and the events of 5 and 10 km are becoming increasingly popular for casual athletes [1]. Few researches have examined peak pressure, COP and temporal parameters, such as total contact time and time to peak pressure, for race walkers, compared with the large numbers of researcher investigating the normal kinematics and kinetics of normal human walking and running [2]. As such, there is limited understanding of the kinematic and kinetic aspects of race walking.

## Methods

Subjects: Fourteen elite race walkers (9 male, 5 female; age, 20.4±3.3 years [Mean (SD)]; height, 173.1±7.8 cm; body mass 59.8±9.6 kg) were recruited. Subjects had no history of lower limb pathology at the time of the study or in the preceding six months. All of them have given informed consent. Setting: The plantar pressure plate (Rs-scan International, 2m×0.4m×0.02m,) was used to collect plantar data. Two rubcor tracks (5m×0.4m×0.02m) were connected

the two sides of the plantar pressure plate to prevent the subjects from adjusting their walking style by aiming for the plate. Three 50 Hz digital cameras (Sony 9800, Japan) were placed approximately 5m away from the right, left front and right front of pressure plate edge, they were used to record the movement of the lower limb. Protocol: Race walkers walked on the plate with their training race walking speed and normal walking pattern respectively. In the current study, only the right foot plantar data was collected (Goble et al, 2003) and minimum of 5 valid trials were recorded and analyzed. Before testing, the subjects completed consent forms and were given sufficient time to warm up.

## Results and Discussion

Our research regarded the high peak pressure of the heel areas as a potential risk factors of tibial foot injuries that is caused by the extended knee part of the race walking rule. and we believe eversion is another risk factor for injuries.

Table 1 shows the comparison of lower leg kinematic parameters between race walking and normal walking. The ankle dorsiflexion (P=0.003), ankle plantarflexion (P=0.002), ankle angular velocity (P=0.000), knee extension (P=0.000), hip adduction (P=0.038), foot eversion (P=0.013) and average horizontal velocity (P=0.000) during race walking were significantly greater than those in normal walking.

## Conclusions

During race walking, The greater heel peak pressure and more ankle eversion may be the injury risks caused by the race walking rules.

# LONG-TERM TAI CHI PRACTITIONERS WERE LESS INFLUENCED BY THE DUAL-TASK PARADIGM DURING STAIR DESCENDING

Xiaoli Ma<sup>1</sup>, LiLi<sup>2</sup>, Wei Sun<sup>1</sup>, Qipeng Song<sup>1</sup>

<sup>1</sup>Shandong Sport University, Jinan 250102, China;

<sup>2</sup>Department of Health Sciences and Kinesiology, Georgia Southern University, Statesboro, 30460, USA

Corresponding author: Dr. Qipeng Song, [songqipeng@sdpei.edu.cn](mailto:songqipeng@sdpei.edu.cn)

## Summary

Taking the stairs is common in daily life among the elderly under dual-task (DT) conditions; stair descending contributes to a high risk of falls among the elderly under dual-task (DT) conditions. The purpose of this study was to determine whether the practitioners of Tai Chi (TC) have lower fall risks under DT conditions during stair descending, compared with their no-exercise (NE) counterparts. Fifteen TC practitioners with at least 10 years of experience in TC and fifteen NE participants were recruited in this study. They were asked to descend a six-step staircase under single-task (ST) and DT conditions. An eight-camera motion analysis system and two force plates were used for data collection. Results showed the TC practitioners were less influenced by the DT paradigm than their NE counterparts. Our observations indicated that TC practitioners have lower fall risks under DT conditions during stair descending.

## Introduction

The continuously increasing number of the stair-related injuries [1] has made stairs one of the most hazardous locations for fall accidents and the leading cause of accidental death for the elderly. Compared with level walking, stair descending demands a greater lower limb joint range of motion [2] and muscle strength [3], which imposes a significant challenge to postural control in the elderly. In a dual-task (DT) paradigm, the introduction of a concurrent task (mostly a cognitive task) during a primary task (mostly a physical task) leads to an increase in the risk of falls. Exercise has been proven effective in preventing falls and decreasing the risk of falls, and one of its most popular forms is TC. However, TC's potential as a mind-body exercise to reduce fall risks under DT conditions has not received considerable attention. Therefore, our study aims to investigate the effects of TC under the DT condition. We hypothesized that TC practitioners have lower fall risks under DT conditions during stair descending than their NE counterparts.

## Methods

We recruited 25 participants, 13 in the TC group, with TC experience of 19.7±6.4 years, and 12 in the no-exercise (NE) group. A staircase with six steps was constructed for data collection. Two force platforms were embedded in the third and fourth steps of the staircase to collect ground reaction force data at a sample rate of 1,000 Hz. The participants were asked to ascend the staircase in a step-over-step manner under two conditions (ST and DT). All variables were collected by a Vicon system (kinematic sampling rate at 100 Hz) and then exported to Microsoft

Excel 2016 for further calculation. The group and condition effects were examined using a mixed model two-way ANOVA with a significance level set at 0.05.

## Results and Discussion

Fig 1 presents the outcomes of the kinematic variables during stair descending. Our outcomes indicated that the lower fall risks under the TC group's DT condition might be related to some of their unique gait strategies, such as decreased walking velocity. Both groups took a more cautious gait strategy under the DT condition than under the ST condition, as represented by the increased foot clearance. Compared with the NE group, the TC group had higher foot clearance under both conditions during stair descending. TC group had lower head and trunk tilt angles than the NE group. TC exercise movements may be applied to stair descending when the TC group held their heads and kept their trunks erect under both conditions.

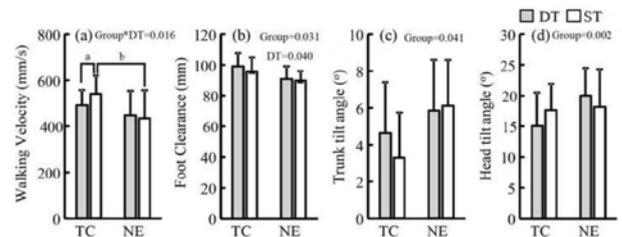

Figure 1: Kinematic variables during stair descent.

## Conclusions

The TC group were less influenced by the DT paradigm than their NE counterparts. Our observations indicated that TC practitioners have lower fall risks under DT conditions during stair descending.

## Summary

This study investigates the effects of backpack weight on posture and gait patterns for children with obesity. A total of 16 obese ( $75.26 \pm 15.99$  kg) and 21 the control group ( $48.13 \pm 9.52$  kg) schoolboys were recruited. Two video cameras were used. Multivariate analysis of variance with repeated measures was employed. Obese children showed increased trunk and head forward inclination angle, gait cycle duration, stance phase, and decreased swing phase compared with the control group. The changes were observed even with an empty backpack in comparison with the control group and a 15% increase in backpack weight led to further instability and damage on their already strained bodies.

## Introduction

Carrying a backpack is an activity in daily life for students. Many studies reported that excessive backpack weight results in back pain and muscle fatigue [1]. Our literature review did not show any study on the effects of backpack weight on posture, gait patterns of children with obesity. Obesity leads to a significant disadvantage in movement and discomfort in simple daily activities such as stair-climbing [2]. Large proportions of their body weight do not contribute to their movement performance. This study aimed to determine the effects of backpack weight on posture, gait pattern of male obese children in stair descent.

## Methods

Each participant was asked to complete one testing session per day for a total of four testing sessions. The mean bodyweight was  $75.26 \pm 15.99$  kg for children with obesity, and  $48.13 \pm 9.52$  kg for control. The participant

was asked to carry a two strap backpack with both shoulders in a given backpack weight (0, 10, 15, or 20% of body weight) in each session. Two high-speed video cameras were placed 12 m from the walking track with an angle of 90° to record level walking and stair descent movements at a 100 Hz sampling rate. A two-way MANOVA with mixed design was performed to determine the effects of backpack weight and obesity condition. Significant level set at 0.05.

## Results and Discussion

Compared to the control group, children with obesity showed increased trunk and head forward inclination angles ( $p = 0.003$ ,  $p = 0.001$ ), single and double support phase durations ( $p = 0.030$ ,  $p = 0.000$ ), and decreased swing phase duration ( $p = 0.001$ ). See Table 1 for more details.

## Conclusions

1. Children with obesity increased their trunk forward inclination angle, head forward inclination angle, and gait cycle durations in comparison to control when carrying a backpack weight between 0 to 20% of their body weight during stairs descent.
2. A backpack weight of more than 15% of body weight led to further instability and damage on the already strained bodies of children with obesity.

<sup>3</sup> University of Human Arts and Sciences, Saitama, 339-8555, Japan

\*Email: kanemura-naohiko@spu.ac.jp

## Summary

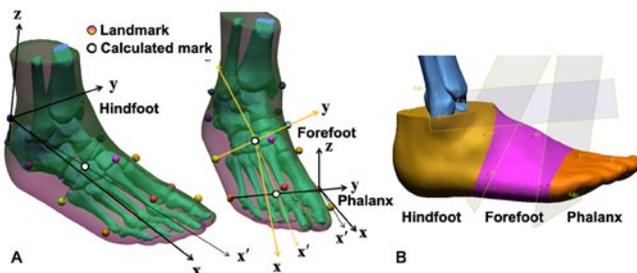

This study aimed to evaluate potential sex differences in foot mechanics during drop-jump by an inverse dynamic analysis using a newly-proposed multi-segment foot model. Thirty healthy adults (15 males, 15 females) performed drop-jumps. Inter-subject variabilities in joint angle and moment profiles during drop-jump were small. However, statistically significant sex differences were observed in metatarsophalangeal joint angle and moments during drop-jump. Biomechanical analysis based on the proposed multi-segment foot model may be useful to investigate pathogenetic mechanisms of foot injuries and disorders.

## Introduction

It is generally accepted that the prevalence of foot injuries is greater in females than in males possibly because of higher joint laxity in females [1]. However, detailed kinematics and kinetics of the human foot during dynamic movements have not been sufficiently investigated mainly due to the lack of detailed foot model available to estimate internal forces and moments in the foot segment. The present study aimed to evaluate potential sex differences in foot kinematics and kinetics during drop-jump by an inverse dynamic analysis using our newly-proposed multi-segment foot model.

## Methods

The proposed foot model had three segments: phalanx, forefoot, and hindfoot (Figure 1). Mass, center of mass, and moment of inertia of each segment were calculated based on the CT data of the foot from one healthy male subject (42 years old, 72 kg, 172 cm) using CAD software. The model was scaled by the cube root of the segment mass to create a subject-specific foot model.

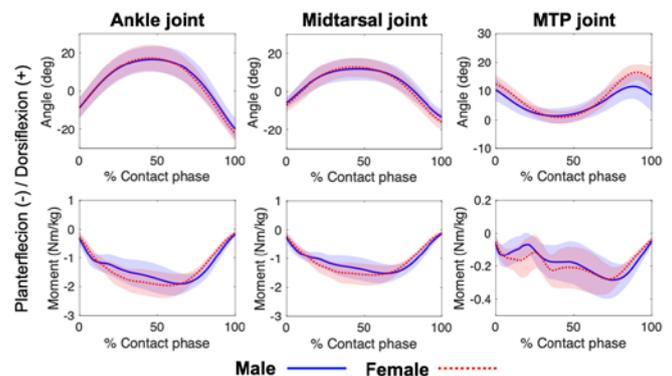

**Figure 1:** (A) The foot model definition; (B) The segmented foot based on the CT data

Thirty healthy adults (15 males, 15 females) performed drop-jumps. The participants were asked to land on the front and rear force-plates by their fore- and hindfoot, respectively. Trajectories of surface markers were collected using the Vicon Nexus 2.10.2, a three-dimensional motion analysis system (Vicon, Oxford, UK) with 20 infrared cameras at 100

Hz. The 3D rotation angles of the joints (ankle joint, midtarsal joint, and metatarsophalangeal joint: MTP joint) were described by y-x-z Euler angles. The joint moments were calculated by inverse dynamics analysis based on the Newton-Euler method. Sex differences were examined using the Wilcoxon rank-sum test, with a significance level of 5%.

## Results and Discussion

The measured time-series of the joint angles were generally in good agreement with those reported in our previous study [2]. The joint angle and moment profiles (Figure 2) were found to be quite similar among the participants. Although there was no sex difference in the foot joint angles during quiet standing, dorsiflexion of the MTP joint was significantly larger in female than in male ( $p < 0.01$ ). The timing of the peak plantarflexion moments was also significantly earlier in female than in male ( $p < 0.01$ ).

**Figure 2:** The joint angles and moments on the sagittal plane

Females may have taken a force-exertion strategy to compensate for higher joint laxity of the foot, since there were no sex differences in the kinematics of the ankle and midtarsal joints. The proposed model successfully extracted the differences in 3D motions and moments within the foot segment during drop-jumps between males and females.

## Conclusions

The findings obtained from the proposed foot model possibly enhance our understanding of sex differences in dynamics of the foot during drop-jumps. The proposed multi-segment foot model may be useful to investigate pathogenetic mechanisms of foot injuries and disorders.

### Summary

Aim of this study was to confirm effect of tDCS on rowing endurance performance by testing performance on the ergo of ten professional rowers. The result showed that rower after intervention of tDCS used minimum time to finish 5km compared with intervention of sham and baseline although no significant difference was found in performance parameters at statistics.

### Introduction

As a new neuro-doping ergogenic technique transcranial direct current stimulation (tDCS) has been testified the positive influence on athlete performance [1]. A lots number of researches have suggested that tDCS not only improve the endurance performance of single joint exercise but also enhance the endurance performance of whole-body exercise [2]. And most of these studies have used cycling and running to test effect of tDCS on endurance performance as well as confirm that cycling is benefit from this way.

Both of cycling and rowing belong to the period sports event; however, there is only one research compared different stimulated intensity on rowing performance [3], and no research to confirm whether tDCS has the same effect on rowing endurance performance like cycling.

Taking research in this area may be provide some useful strategies on rowing performance, therefore, the aim of this study was to confirm this effect on rowing endurance performance. Based on previous studies, we hypothesed that tDCS would have a better performance compared with sham and none.

### Methods

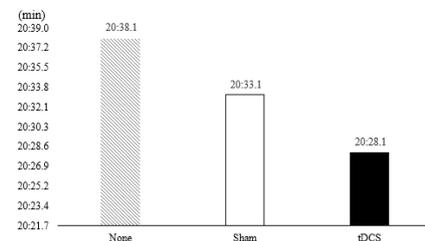

Ten professional female rowers voluntarily participated to this research and got the informed consent before test. Rowers had 5-15min to warm up and were asked to complete 5km on the ergometer at 20sr/min after 20min randomly stimulating by tDCS or sham and baseline respectively. When the 5km was finished, 10min-15min was give to cool down by ergo cycling. Each test was separated by for 48h at least.

Four halo sports (San Francisco, CA, United States) were used to complete 20min, 2mA tDCS and sham stimulation (ramp-down 30s). Three foam electrodes (4cmx6cm) were place over the Cz (anodal polarity), C5 and C6 (cathode polarity). 5km time (5kT), 500m/split (500-S),

power (P) and energy consumption (EC) was used to reflect endurance performance using one-way ANOVA by SPSS (version 26, SPSS, Chicago, IL, USA)

### Results and Discussion

No significance was found in 5kT, 500-S, P and EC between intergroup during 5km endurance straining after three stimulated interventions (Table 1). However, compared with baseline(20:38.1±00:31.4), rower could fast complete 5km after intervention of tDCS (20:28.1±00:32.1) and sham (20:33.1±00:32.6) , and the tDCS was also better than sham (Figure 1).

**Figure 1:** 5km endurance performance after different stimulated interventions

### Conclusions

Although no significant difference in performance parameters was showed at statistics. Rower after stimulating by tDCS could use the less time to finish 5Km; tDCS might be as an effective way to improve rowing endurance performance

### Acknowledgments

The authors would like to thank all rowers who took part in this study and for their efforts. This study was supported by grant from national natural science foundation of China (11932013) and MOE Foundation of Humanities and Social Sciences (19YJCZH115).

### Summary

Knee osteoarthritis (KOA) is a common disease that causes pain and limits functionality in the elderly during daily activities, especially during stair descent. Proprioceptive neuromuscular facilitation (PNF) practices promote multiple-plane joint movements, which relieve pain and increase joint range of motion (ROM). We randomized 36 elderly with KOA who met the inclusive criteria into two groups: the twelve-week PNF intervention group and the control group. The aim of this study was to examine the effects of a 12-week PNF intervention on pain relief, ROM, and frontal plane knee moments in the elderly with KOA during stair descent. Compared to the control group, the PNF group showed a decreased pain score, increased passive hip, knee, ankle ROM, a decreased minimum knee flexion angle, and increased hip adduction moment (HAM) during stair descent.

### Introduction

The prevalence of knee osteoarthritis (KOA) is associated with aging; over 40% of adults 65 and older are symptomatic [1]. Increased joint pain and decreased joint range of motion (ROM) are the most common complaints associated with KOA and confirmed by physical examinations. Stair walking requires greater functional ability than level walking for people with lower extremity disorders [2] and is influenced by knee pain [3]. In comparison with stair ascent, stair descent exhibits faster gait velocity [2] and knee angular velocity [4] in patients with KOA. Proprioceptive neuromuscular facilitation (PNF) practices promote movement at the joints in sagittal, frontal, and horizontal planes to achieve diagonal movements, which can relieve pain [5] and increase ROM [6].

### Methods

PNF group included 36 participants who experienced 12-week PNF stretching. Participants (N=16) in the control group watched television or read magazines at the same time. The overall pain score (0-10) from the affected leg was self-assessed at the end of weeks 0, 6, and 12 by completing the Western Ontario and McMaster Universities Arthritis Index. Lower extremity passive flexion-extension joint ROMs from the affected leg were measured using standard goniometric procedures. One force platform (Kistler, 9287BAs), embedded in the 4th step from the bottom of the staircase, was used to collect ground reaction force data at a sampling rate of 1000 Hz.

The stair descent test was recorded by an eight-camera motion analysis system (Vicon, Oxford Metrics, Ltd.) at 100 Hz. Vicon Plug-In Gait model used to analyze data via a 13-segment whole-body model. Sagittal plane joint angle (representing the active ROM) and frontal plane joint moment were estimated using commercially available software (Visual 3d, C-motion). The normality of all

outcome variables was tested using the Shapiro-Wilk test. The mean and standard deviations for the kinematic and kinetic variables were subjected to descriptive analysis. A mixed model two-way analysis of variance was used to determine the PNF intervention effects and group differences on each of the outcome variables. A Bonferroni-adjusted post hoc analysis was conducted when time-group interaction was detected. Partial eta squared ( $\eta^2_p$ ) was used to represent the effect size of main effect and interaction of two-way analysis of variance.

### Results and Discussion

Significant time by group interactions were detected in pain scores, which significantly decreased from week 0 to weeks 6, then to week 12, in the PNF group, and were significantly lower in the PNF group compared with that in the control group at week 6. Significant time by group interactions was detected in ROM, which significantly increased from week 0 to weeks 6 and 12 in the PNF group. The ROMs were significantly greater in the PNF group than those in the control group at weeks 6 and 12.

This study confirmed that a 12-week PNF intervention could relieve pain without increasing KAM, enhance passive ROM, increase active knee flexion ROM, and increase HAM in the elderly with KOA during stair descent. These findings support that PNF practice is an effective intervention to relieve the symptoms and slow down the progression of KOA.

### Conclusions

This study confirmed that a 12-week PNF intervention could relieve pain without increasing KAM, enhance passive ROM, increase active knee flexion ROM, and increase HAM in the elderly with KOA during stair descent.

### Summary

Visual assistance is important for persons with intellectual disabilities to understand something. In this study, we have developed a squat-exercise support system for persons with intellectual disabilities. In the system, the human joint positions during the squat-exercise of the subject was detected by a Kinect sensor and the subject guided to correct movement by the animation. 16 persons with intellectual disabilities used this system and they were able to exercise more correctly than instruction by lecture movie.

### Introduction

Persons with intellectual disabilities are lack exercise and they have a high risk of locomotor disorders. To prevent the deterioration of their mental and physical functions, physical measurements and exercise programs have been carried out at the welfare facility of the disabled. In the exercise program, the instructor shows the correct movement using the lecture movie and verbally conveys the part of the body that should be careful. They do not fully understand the meaning of the verbal explanation and cannot move correctly. The purpose of this study is to construct a training system that enables the person with intellectual disabilities to exercise correctly and effectively with visual support.

### Methods

In this system, the joint positions of a whole-body during squats-exercise were detected by the Kinect for Windows v2 (Microsoft Japan Co., Ltd.), and the subject was instructed in the correct movement using the animation function. There were two types of squats: normal squats with both feet shoulder-width and wide squats with both feet wider than shoulder-width. The joint positions of the shoulders, hips, knees, and ankles were measured by the Kinect sensor and the knee joint angle was calculated from the joint positions of the ankle, knee, and hip. A correct squat-exercise was judged when the knee joint angle is maintained in the range of 70 to 120 degrees for 1.5 seconds. A figure of the user and the joint positions measured by the Kinect sensor was displayed on a large monitor in front of them. If the knee joint angle was less than 70 degrees, an animation of a downward arrow displayed and the user had to bend the knee further. If the knee joint angle was more than 120 degrees, an animation of an upward arrow displayed and the user had to extend the knee. When the knee joint angle was kept from 70 degrees to 120 degrees, a flame animation that means correct squat-exercise displayed on the thigh. A red circle gauge displayed above the user's head at the same time as the

flame animation, and after 1.5 seconds it turned light blue and counts as the correct squat. In wide squats, the system displayed a warning message if the width of both feet of the user was narrower than the width of the shoulders.

16 persons with intellectual disabilities (6 females and 10 males) aged 20 to 49 years (averaged:  $31.6 \pm 9.02$  years) such as autism and Down's syndrome participated in the evaluation experiment of this system. The Kinect sensor and 50-inch monitor were installed at a height of 80 cm above the ground and the subjects lined up at 3.0 to 3.5 m from the Kinect sensor. Subjects performed normal-stance and wide-stance squat-exercise with both the lecture movie and the proposed system. In the lecture movie, subjects performed squat-exercise watching the correct behavior movie by the trainer. In the proposed system, the subjects performed squat-exercise while watching their body movement and the support animation on the monitor. In each condition, subjects performed the squat-exercise 10 times.

### Results and Discussion

The percentage of correct squat-exercise was shown in Table 1. Data from two subjects who refused the experiment on the way were excluded from the results. In both normal and wide squat-exercises, the use of a proposed system significantly increased the correct percentage. In the cognitive ability test of an autistic person, it is reported that the visual information ability is higher than the auditory information processing ability [1]. Therefore, it is expected that the proposed system having a visual support function was effective.

**Table 1:** Correct percentage of squat-exercises (n=14)

Squat-exercise	Lecture method	Correct percentage (%)	t-test
Normal stance	Movie	62.1 ± 34.7	p<0.05
	Proposed system	88.6 ± 24.2	
Wide stance	Movie	44.4 ± 39.9	p<0.01
	Proposed system	87.1 ± 25.8	

### Conclusions

In this study, the squat-exercise support system was developed using Kinect sensor and the animation function. The effectiveness of this system was recognized in the squat-exercise of persons with intellectual disabilities.

## Directional Dependence of Uniaxial Response Characteristics of the Porcine Thoracic Aorta

Manoj Myneni<sup>1</sup>, Raghuvver L. Sridhar<sup>1</sup>, K.R. Rajagopal<sup>1</sup>, Chandler C. Benjamin<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Texas A&M University, College Station, TX, USA

Email: manojmyneni@tamu.edu

### Summary

We studied the response of the porcine thoracic aorta under uniaxial extension using dumbbell shaped specimens oriented at 0°, 30°, 45°, 60°, 90° with the circumferential direction. The stress-strain curve shows a characteristic J-shape for all the specimens. Specimens oriented at 30° show an increasingly negative shear strain, while specimens at 45° and 60° depict a non-monotonic shear strain with increasing nominal stretch.

### Introduction

Aorta is generally regarded to have an orthotropic material symmetry with respect to the circumferential-axial-radial planes[1]. Negligible twist undergone by animal aortas in their unloaded tubular forms during inflation-extension experiments led to this observation[2]. Most of the recent studies, however, are conducted on square or dumbbell shaped specimens obtained after cutting open the aorta along its length and flattening it[3]. All these studies restrict their testing to the specimens oriented along circumferential and axial directions. Material symmetry depends on the choice of the reference configuration, and it is possible that the material symmetry with respect to the tubular form of the aorta may be different from the material symmetry in the flattened form obtained after a longitudinal cut. The data presented here can be used to evaluate if the existing constitutive models of the thoracic aorta, which were proposed based on the assumption of orthotropic material symmetry, can be used to study the deformations from the flattened state. (Note: Arteries are not elastic solids. They are a mixture of solids and fluids. Refer to [4] for a review on problems with existing constitutive models almost all of which assume artery as an elastic solid, and the limitations of current experiments, many of which presume that the arterial wall is an elastic solid.)

### Methods

Fresh porcine aortas (n=10) were harvested from a slaughterhouse on the Texas A&M University campus. Loose connective tissue was carefully removed, and the segment of the aorta between the end of the aortic arch and the third branching arteries was stored in 0.01M Phosphate Buffer Saline (PBS) solution at -20°C. After thawing overnight, the aorta was cut open along its length and dumbbell shaped specimens (Total length ~30mm, gauge length ~10mm, gauge width ~3mm, width of the wider portion of the specimen ~6mm) were punched out using an in-house machined punch. Images of the specimens were taken to measure the width and the thickness of the specimens. After clamping the specimen, Rust Oleum<sup>®</sup> spray paint and primer was used to create a speckle pattern on the intimal surface. A preload of <0.05N was applied to straighten the specimen. One of the clamps was displaced (by applying appropriate force) to produce a constant nominal stretch rate of 2%/s until a nominal stretch of 1.5. Seven preconditioning cycles were applied. The data was collected from the loading part of the next cycle. Images were captured for a Digital Image Correlation(DIC) analysis using Ncorr [4]. The Green strain ( $\mathbf{E}$ ) obtained from Ncorr is

averaged over a 1.5 mm x 1.5mm region around the center of the specimen.

### Results and Discussion

The mean curves for the specimens obtained from all the aortas are given in Figure 1. The nominal stress shows an inclined J-shaped dependence on the nominal stretch for the specimens oriented in all directions. The X-component (direction of the uniaxial displacement) of the Green strain increases with nominal stretch with a change of slope occurring at a nominal stretch between 1.3-1.4. This can be attributed to the straightening of the collagen fibers as they deform during loading.  $E_{yy}$  decreases with  $E_{xx}$  demonstrating a slope change occurring due to increased collagen fiber engagement. Circumferential (0°) and axial (90°) specimens show nearly zero shear strain ( $E_{xy}$ ). The remaining specimens undergo shear during uniaxial extension with 45°, 60° specimens showing a non-monotonic  $E_{xy}$  with increasing  $E_{xx}$ .

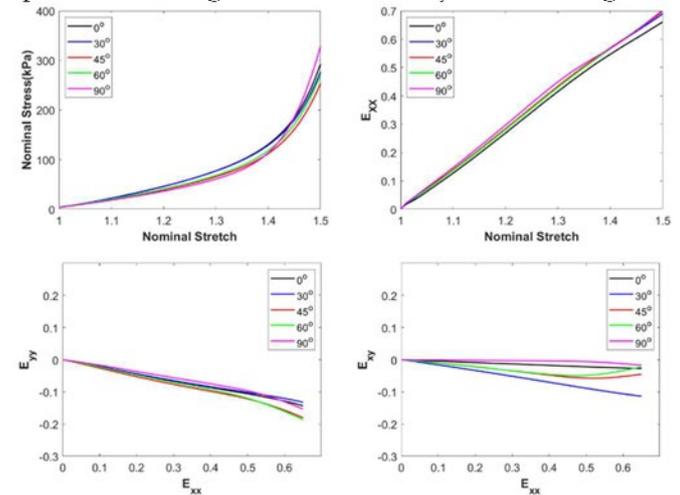

Figure 1: (a) Nominal Stress vs. nominal stretch (b)  $E_{xx}$  vs. nominal stretch (c)  $E_{yy}$  vs.  $E_{xx}$  (d)  $E_{xy}$  vs  $E_{xx}$

### Conclusions

Our study demonstrates the variation of the uniaxial stress-strain behavior with the direction in which the specimens are obtained after a longitudinal cut of the aorta. Specimens from all the directions depict a nearly overlapping stress-stretch relation,  $E_{xx}$  vs. stretch, and  $E_{yy}$  vs.  $E_{xx}$ . Strong anisotropy can, however, be observed in the  $E_{xy}$ - $E_{xx}$  curve of 30°, 45° and 60° specimens, indicating the importance of testing specimens oriented along non- circumferential and non-axial directions.

### Acknowledgments

## Ventricle of terrestrial Anura is stiffer than that of aquatic Anura due to differences in collagen density

Megumi Ito<sup>1</sup>, Shukei Sugita<sup>1</sup>, Masanori Nakamura<sup>1</sup>, and Yoshihiro Ujihara<sup>1</sup>  
<sup>1</sup>Biomechanics Lab, Nagoya Institute of Technology, Nagoya, Japan  
 Email: megumi1123ito@gmail.com

### Summary

During the evolution of vertebrates, the hearts have undergone marked anatomical changes to adapt to different environments and lifestyles. The transition from aquatic to terrestrial life may have required the acquisition of the ability to circulate blood against the force of gravity. Here, we investigated the passive mechanical properties and histology of the ventricles of two species of Anura (frogs and toads) with different habitats, *X. laevis* (aquatic) and *B. j. formosus* (terrestrial). Pressure-loading tests demonstrated that the ventricle of *B. j. formosus* was significantly stiffer than that of *X. laevis*. Histological analysis revealed the collagen density of *B. j. formosus* was significantly higher than that of *X. laevis*. These results suggest that the ventricles become stiff in the process of terrestrialization by increasing ventricular collagen fibers.

### Introduction

Vertebrate hearts have undergone marked morphological and structural changes to adapt to different environments and lifestyles in the course of evolution. However, it remained unclear how structural changes is related to evolutionary changes in mechanical properties. Amphibians are the first vertebrates that come to land. The transition from aquatic to terrestrial life requires the acquisition of the ability to support the body and to perform locomotion against gravity. It is therefore possible that mechanical properties of the ventricles that affect the pumping functions of the heart have changed in association with terrestrialization. Here, we evaluated the passive mechanical properties of the ventricles of two species of Anura (frogs and toads) with different habitats, *X. laevis* (aquatic) and *B. j. formosus* (terrestrial). Differences in the passive mechanical properties of the ventricles were discussed in light of the collagen density and the cardiomyocyte stiffness.

### Methods

To analyze the passive mechanical properties of the ventricles, we obtained the relationship between the ventricular pressure and the ventricular volume by introducing cardioplegic solution into diastolic-arrested ventricle. To compare different-sized hearts, the ventricular volume was normalized with its weight. The second-harmonic generation (SHG) light from the collagen fibers of sliced ventricles was imaged under a multiphoton microscope (FV1200MPE, Olympus) [1]. The collagen density was quantitatively assessed by dividing the total intensity of SHG light by the area using ImageJ 1.53c. Sarcomere length of isolated ventricular cardiomyocytes [2] was determined by SarcOptiM [3], a plug-in for the ImageJ.

### Results and Discussion

Typical examples of the pressure-normalized ventricular volume curves of *X. laevis* and *B. j. formosus* (Fig. 1). Larger pressures are required to expand the ventricles of *B. j.*

*formosus* than *X. laevis*, demonstrating that the ventricle of *B. j. formosus* was stiffer than that of *X. laevis*. The SHG light of the collagen fibers was observed in the myocardium, but it was more apparent in the outermost layer of ventricles in both animals. In both the outermost collagen layer of the ventricle and the myocardium, the collagen density of *B. j. formosus* was significantly higher than that of *X. laevis* (Fig. 2). Since collagen is a primary component to provide mechanical strength of tissues [4], *B. j. formosus* may have enriched collagen fibers and stiffened its ventricles to adapt to life on land. The sarcomere length of isolated cardiomyocytes of *X. laevis* and *B. j. formosus* was almost the same. Because sarcomere length determines the stiffness of cardiomyocytes [2], the stiffness of the cardiomyocytes of *X. laevis* and *B. j. formosus* was considered to be similar. These results suggest that the stiff ventricles of *B. j. formosus* compared to *X. laevis* is attributed to differences in collagen density, not in the stiffness of the cardiomyocytes.

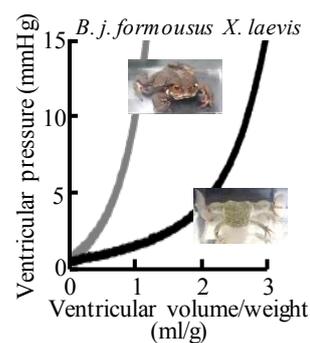

Fig. 1 Pressure-volume/weight curves

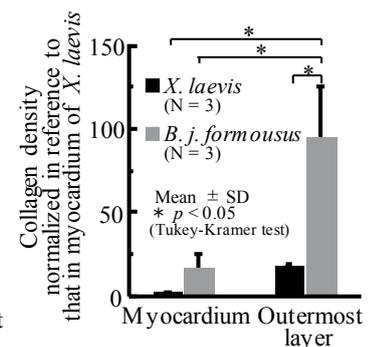

Fig. 2 Collagen density

### Conclusions

In the present study, the passive mechanical properties and histology of the ventricles of aquatic *X. laevis* and terrestrial *B. j. formosus*. These results suggest that the ventricles of Anura become stiff in the process of terrestrialization by increasing collagen fibers of the ventricles.

## The importance of inertial measurement unit placement in assessing upper limb motion

Fredrik Öhberg, Gustav Höglund, Helena Grip

Dept. Biomedical Engineering, University Hospital of Umeå, Umeå, Sweden

Email: [Fredrik.Ohberg@regionvasterbotten.se](mailto:Fredrik.Ohberg@regionvasterbotten.se)

### Summary

Motion analysis using inertial measurement units (IMU) has emerged as an alternative to optical motion capture but still the validity and reliability of upper limb measurements varies between studies. The objective was to determine how sensor placement affects joint angle measurements during motion of the arm, shoulder, and scapula. Results show that sensor placement considerably affects the measured joint angle.

### Introduction

Motion analysis provides an objective and detailed way to assess upper limb motion. Optical marker systems are the gold standard method, but they require remittance of patients to a clinical movement laboratory [1]. IMUs, consisting of gyroscopes, accelerometers, and magnetometers [2], are an alternative that can be used in ordinary clinics, since they require only wearable IMU-sensors, and a computer where data are registered and analysed. Still, clinical use of IMUs is limited, due to the lack of standardized and validated kinematic protocols [3] and because the validity and reliability for measuring upper limb motion has not been concluded [4]. One cause is that the sensors output is affected by skin and muscle movements. Such errors must be minimized by standardization of measurement protocols regarding biomechanical models, calibration procedures, and sensor placements.

To evaluate the treatment outcome, different measurement protocols are used, e.g., Modified Mallet scale [5]. Today, no study has investigated the impact of IMU sensor placement on joint angle measurements during upper limb motion measurements.

The objective was to evaluate the effect on joint angle measurements from distal and proximal sensor placements on arms, and from lateral and medial placements on the scapula, in a group of healthy individuals, while performing standardized arm movements included in the modified Mallet scale [5].

### Methods

Five female and six male healthy participants with a mean age of  $28 \pm 6.5$  years was recruited. Motion was assessed by a portable movement-analysis system, including seven IMU sensors (MoLab™, AnyMo AB, Umeå, Sweden). Two sensors were placed distally/laterally and proximally/medially on each body segment (forearm, upper arm, and scapula) except on thorax. The test procedure was standardized and consisted of nine arm-movement tasks based on the Modified Mallet Scale [5]. All tasks were repeated five times, where each task began with the right arm hanging vertically. The

joint angle (elevation/rotation for upper arm and scapula; Euler for elbow) where computed for both sensor positions. The linear relationship between angular data from the proximal/medial and distal/lateral sensor for each task and segment were analysed by a linear regression.

### Results and Discussion

Scatter plots, together with the results of the linear regression and  $R^2$ -values for the shoulder flexion/extension and forearm pronation/supination are illustrated in Fig 1 together with a description of the analysed planes. The results show that sensor placement has a considerable effect on motion measurement, which could explain the inconclusive validity and reliability reported in previous studies [4].

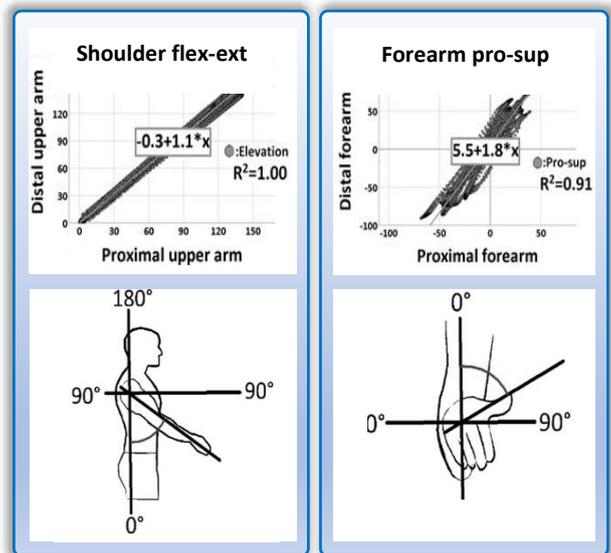

Figure 1: Top: Linear model. Bottom: Analyzed planes.

### Conclusions

Sensor placement affects the obtained kinematic output differently, depending on the analyzed joint and plane of rotation.

## Comparing Surface and Intramuscular Electromyography Patterns of the Brachialis Muscle during the Dynamic Elbow Movement.

Shota Date<sup>1</sup>, Hiroshi Kurumadani<sup>1</sup>, Yuko Nakashima<sup>2</sup>, Akio Ueda<sup>1</sup>, Toru Sunagawa<sup>1</sup>

<sup>1</sup>Biomedical & Health Sciences, Hiroshima University, Hiroshima, Japan

<sup>2</sup>Hiroshima University Hospital, Hiroshima, Japan

Email: sdate@hiroshima-u.ac.jp

### Summary

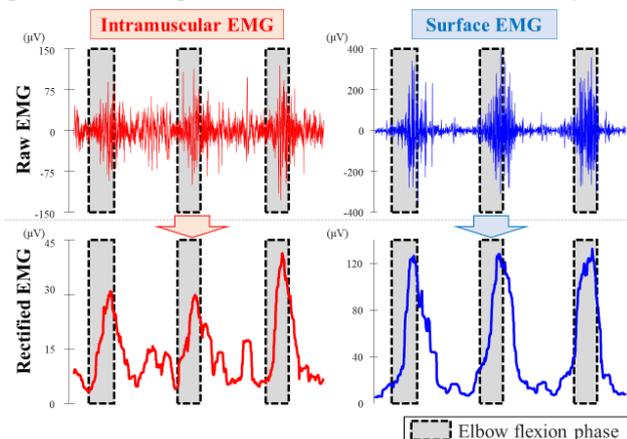

This study aimed to compare the muscle activity of the brachialis (BR) between surface and intramuscular electromyography (EMG) in dynamic elbow movement. Six healthy subjects performed the active elbow flexion. The EMG signal was recorded from the BR. The coefficient of determination ( $R^2$ ) of the muscle activity pattern between the surface and intramuscular EMG was assessed. The result showed that the mean  $R^2$  was higher than 0.8, indicating the muscle activity patterns of surface and intramuscular EMG were statistically similar. Thus, it is suggested that the muscle activity of the BR can be assessed using surface EMG in dynamic elbow movement.

### Introduction

The muscle activity of the BR has mainly been measured using intramuscular EMG [1], and there are a few studies using surface EMG [2]. Moreover, these studies using surface EMG have measured the muscle activity in a static condition (isometric contraction) [1, 2]. Therefore, it remains unclear whether the muscle activity of the BR can be assessed using surface EMG in a dynamic motion.

### Methods

Six healthy right-handed volunteers participated in this study. They performed an active elbow flexion task with the non-dominant upper limb. The forearm positions during the task were supination, pronation, and neutral. Surface and intramuscular EMG were recorded from the BR using surface and fine-wire electrodes. Each electrode was set on the lateral sides of the distal upper arm where the muscle belly was superficial. The placement of the BR muscle belly was

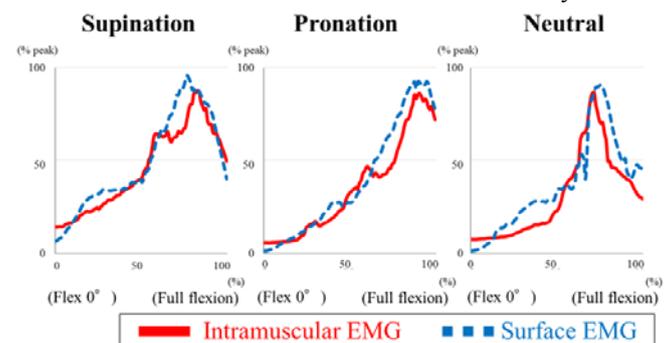

**Figure 1.** Intramuscular and surface EMG signals during the elbow flexion.

confirmed by ultrasonography. The EMG data were filtered, rectified, and then normalized by the peak values during the task (**Figure 1**). To compare the muscle activity patterns between the surface and intramuscular EMG, the coefficient of determination ( $R^2$ ) of the patterns were assessed using regression analysis.

### Results

As shown in **Figure 2**, the muscle activity of the BR tends to increase in the second half during elbow flexion. For comparing muscle activity patterns between the surface and intramuscular EMG, the  $R^2$  of all subjects were higher than 0.8 in all forearm positions (Supination:  $R^2 = 0.85 \pm 0.16$ ; Pronation:  $R^2 = 0.92 \pm 0.08$ ; Neutral:  $R^2 = 0.83 \pm 0.16$ ) (all  $p < 0.05$ ). This result indicated that the muscle activity patterns of surface and intramuscular EMG were statistically similar.

**Figure 2.** The muscle activity patterns of intramuscular and surface EMG.

### Discussion

The BR has two heads: a superficial and a deep head. The superficial head is larger and places on anterolaterally [3]. Thus, in this study, it is considered that the surface and intramuscular EMG could be recorded from the surficial head of the BR.

### Conclusions

It is suggested that the muscle activity of the BR can be assessed using surface EMG in the dynamic elbow flexion.

## System identification to characterise shoulder stiffness in a functional posture at various levels of muscle contraction

Email: [yyah724@aucklanduni.ac.nz](mailto:yyah724@aucklanduni.ac.nz)

### Summary

In this study, we present a method to quantify the function of the shoulder joint. This method is based on using system identification techniques to characterise shoulder joint stiffness in two degrees of freedom, internal/external rotation and horizontal abduction/adduction, at various levels of muscle voluntary contraction. Experiments have been conducted on six healthy participants. It has been verified that this method can successfully estimate shoulder stiffness and, therefore, it has potential to be used as a diagnostic tool for patients with shoulder disorders.

### Introduction

The glenohumeral and scapulothoracic joints rely upon muscle for stability and normal function. Characterising muscles' influence on joint stiffness remains a challenge, but is important for understanding normal and pathological function. System identification can be used to characterise the mechanical stiffness,  $K$ , inertia,  $I$ , and viscous,  $B$ , parameters of human joints [1]. However, previous studies that have used system identification to investigate shoulder function did not evaluate the joint in functional postures [1,2].

The objective of this study was to use system identification to characterise the intrinsic mechanical properties of the shoulder joint during in/external rotation and horizontal ab/adduction at various levels of muscle activation. Shoulder stiffness, inertia and viscous properties were evaluated with the arm in an abducted, throwing posture.

### Methods

Six male participants (age: 31 years  $\pm$  5 years, body mass: 77 kg  $\pm$  9 kg, and height: 1.77 m  $\pm$  0.09 m), with no history of shoulder injury or neuromuscular disease, participated in this study.

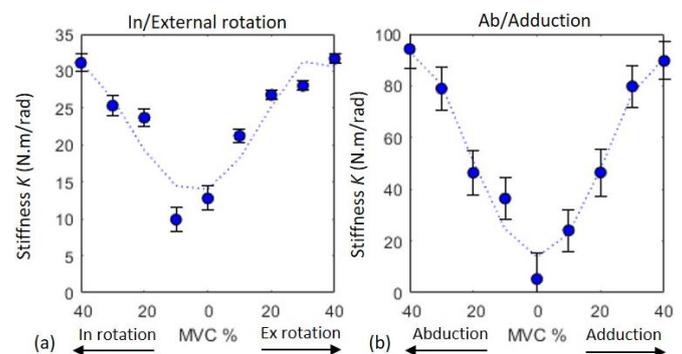

A shoulder perturbation robot was developed to provide perturbations to the humerus in multiple degrees of freedom (DOF) [3]. Shoulder perturbations were performed in in/external rotation and horizontal ab/adduction, with the upper arm abducted to horizontal, elbow flexed to 90° and the palm of the hand facing forward. Maximum voluntary contractions (MVCs) in each DOF were performed. Then torque and angles were measured during stochastic binary sequence waveforms filtered by a low pass filter of 10 Hz cutoff frequency, while the participant was asked to maintain 0%, 10%, 20%, 30% and 40% of their MVC.

A parametric system identification approach was used to evaluate the stiffness, inertia and viscous properties from

angle and torque measurements [2] at each level of contraction.

### Results and Discussion

As expected, across all participants, muscle activity resulted in changes to the stiffness and viscous parameters of the shoulder. The stiffness parameter,  $K$ , increased with the level of muscle contraction in internal rotation, external rotation, abduction and adduction. The viscous parameter,  $B$ , tended not to change with contraction.

**Figure 1.** Stiffness parameters,  $K$ , and their 95% confidence intervals, for a typical participant, at various levels of contraction, (a) in/external rotation and (b) ab/adduction (right shoulder).

Previous studies [1,2] showed that the stiffness parameter,  $K$ , increased with contraction, and this is similar to what we found. Measuring shoulder stiffness in such a posture, where the shoulder is vulnerable to injury, is clinically important.

### Conclusions

To conclude, shoulder joint stiffness was quantified in relevant posture and degrees of freedom. In the future, we will use this method to investigate shoulder pathology.

## Assessing Upper Extremity Function by Applying a Sensor-Embedded Device

Charlie Chen Ma<sup>1</sup>, Hsiao-Feng Chieh<sup>1</sup>, Chien-Ju Lin<sup>1,2</sup>, Fong-Chin Su<sup>1,2</sup>

<sup>1</sup>Department of Biomedical Engineering, <sup>2</sup>Medical Device Innovation Center, National Cheng Kung University, Taiwan  
Email: P88061041@gs.ncku.edu.tw

### Summary

Upper extremity dysfunction could be occurred due to several disorders, diseases, or aging. It is crucial for clinicians to understand patients' upper extremity function (UEF) before offering treatments. However, current assessments of UEF are not digitized nor might be subjective by testers. This study offered a novel sensor-embedded holding device (SEHD) to digitized UEF evaluation, the results showed promising data to evaluate movement smoothness and grip strength which could offer objective clinical references for clinicians to understand each patient's UEF at site or remotely.

### Introduction

Upper extremity dysfunctions could occur due to several diseases or systematic disorders, such as stroke, acute trauma, arthritis, aging, etc. Upper extremity dysfunctions are highly correlated to compromise quality of life. Therefore, to evaluate UEF is important to identify the problem and further customize rehabilitation programs for each individual.

There are many assessments for evaluating UEF which could be classified into groups: clinical tools, questionnaires, and functional test. However, most of the tests might not be able to be digitized or might be subjective that different testers might have different results from the same subject.

Therefore, this study focuses on designing a novel holding device to offer digitized upper extremity movement data and functional evaluation data for clinical references.

### Methods

The SEHD includes one 6-axis IMU sensor, 14 force sensors and connects to MCU for further processing. The cylindrical outlook design of SEHD is due to the common shape for hand holding movements in the daily living.

13 young healthy individuals (male: female = 10:3, age = 25 ± 3) were recruited with signed consent form as subjects to perform tasks related to upper extremity movements.

Two movements were designed: (a) 2-step lifting, (b) maximum grip strength. The subjects were asked to practice once with each task and perform 3 trials for each task. The data were recorded and were processed by MATLAB.

Movement smoothness and force are the main parameters for this study. To calculate movement smoothness, based on Balasubramanian, S.'s study [1], log dimensionless jerk (LDLJ) would be most similar as what this study needs.

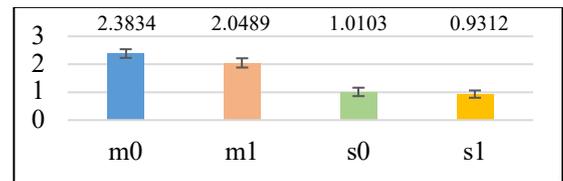

$$DLJ \triangleq \frac{-(t_2-t_1)^5}{v_{peak}^2} \int_{t_1}^{t_2} \left| \frac{d^2v(t)}{dt^2} \right|^2 dt$$

$$LDLJ \triangleq -\ln|DLJ|$$

The combined force of maximum grip of SEHD were recorded to understand the difference between SEHD and traditional grip test.

### Results and Discussion

The movement of 2-step lifting could be divided into 4 phases, m0, m1 represents dynamic movement phases, s0, s1 represents static movement phases. The higher LDLJ number represent more jerk movements. The result (Figure 1.) showed during dynamic movement phases (m0 and m1) were not smooth as static movement phases (s0 and s1). The result could offer possible development of identify phases during movements, which could further apply in robotic designs.

**Figure 1:** Movement smoothness (LDLJ) of 2-step lifting task, m0 represent first lifting dynamic movement, s0 represent holding phase after m0, m1 represent second lifting phase, and s1 represent holding after m1.

When comparing the SEHD maximum grip strength data with Jamar dynamometer, the result showed closely related (Table 1.) but not significant ( $t = 0.091$ , ns.). It could be due to the verbal instruction of the task that the researcher only ask subjects to grip SEHD as hard as they could, and the subjects did not place the fingers precisely on top of the sensors. However, the results were promising that the next version of the SEHD could offer force related data as clinical references.

**Table 1:** Grip strength comparison between Jamar dynamometer and SEHD

	Mean	N	Std. Deviation
Jamar	35.50000	13	9.067103
SEHD	39.47300	13	10.295808

### Conclusions

This study focused on develop a novel sensor-embedded device for upper extremity functional evaluation. The main purpose of the device is to digitize evaluation data and offer proper clinical reference for clinicians to monitor the user's improvements and further to offer customized rehabilitation program for users.

## Quantify hand tremor of Parkinson's disease based on Channel State Information

Hui-Hsin Chen<sup>1</sup>, Chi-Lun Lin<sup>2</sup>

<sup>1,2</sup> Department of Mechanical Engineering, National Cheng Kung University, Tainan, Taiwan  
Email: n16090023@gs.ncku.edu.tw

### Summary

To provide physicians an objective way to consistently assess the severity of Parkinson's disease (PD), this study developed an approach to quantify the motor symptom via Wi-Fi channel state information (CSI). Our computer algorithm computed the frequency and duration of simulated hand tremors from the CSI data with an average accuracy of 90.94% and standard deviation of 3.53%.

### Introduction

PD is a long-term neurodegenerative disease that mainly affects the motor functions of peripheral structures. Clinically, neurologists use Unified Parkinson's Disease Rating Scale to measure the progression of PD. However, different diagnoses may be made owing to the subjective judgment of professionals.

In this paper, we propose an innovative approach to quantify the hand rest tremor, which is a subtle motion and challenging to detect. This approach requires no intervention to the subject, captures no personally identifiable information, and allows long-term monitoring in the subject's natural state.

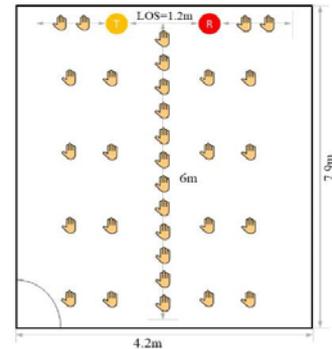

### Methods

The proposed method captured the CSI of wireless communication links and recorded the multi-path fading effect in the environment. The contactless sensing was built by observing the corresponding relation between CSI variation and human activities.

We conducted experiments using the Linux 802.11n CSI Tool [1] with a TP-link Archer C60 commercial router (transmitter) and a Dell E6440 laptop (receiver). The network interface controller worked at a 5 GHz frequency band with a transmission rate of 1000 Hz. The experimental environment (Figure 1) is an enclosed classroom with existing desks and chairs.

A healthy participant, the only person in the room, imitated the hand tremor. The test was performed at 12 locations on the line perpendicular to line of sight (LOS) with equal distance of 50 cm and other 20 locations that uniformly spread in the room. The test at each location was repeated ten times with a frequency of shaking around 3-6 Hz [2] and a range of displacement fluctuation about 10-15 cm.

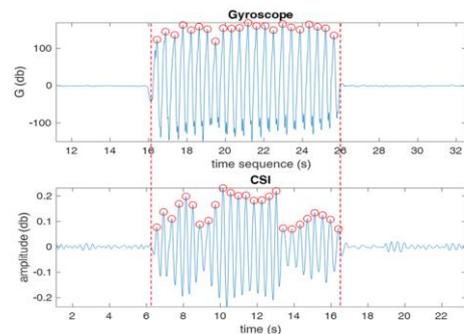

We applied the band-pass filter and principal component analysis to remove the noise from the CSI raw data and used energy-threshold segmentation to extract the target motion data. The frequency and duration of the motion were calculated. The participant also wore a MetaMotionR gyroscope (MBIENTLAB Inc., USA) on the wrist during the test with a sampling rate of 200 Hz to capture the reference data for evaluating the accuracy of our method.

**Figure 1:** The experimental setup for the hand tremor detection. The 'T' denotes the transmitter, and the 'R' is the receiver.

### Results and Discussion

Our algorithm was able to distinguish the active and rest states in the room. The influence of hand tremor induced wave crests in the received signals, as the center region framed by red dashed lines shown in Figure 2. We obtained the frequency and duration of hand tremor by computing the number of wave crests and their occurrence intervals. The results revealed that the accuracy of our approach was ranged from 85 to 95% (AVG. 90.94%, STD. 3.53%) by comparing with the gyroscope data. We also found that the measurement accuracy reduced as the motion location moved away from the LOS. Overall, the results showed that accurate motion detection could be achieved in the whole room.

**Figure 2:** The results of the hand tremor detection using the gyroscope (top) and our approach (bottom).

### Conclusions

We achieved non-contact PD symptom qualification with high accuracy by using the Wi-Fi CSI and robust signal processing methods. We overcame the restriction of the past research that subtle motion could only be sensed at designated positions and succeeded in detecting them in a whole room.

# Positioning effects of GPS Sensors during running

Clint Hansen<sup>1</sup>, Alina Schneider<sup>2</sup>, Carl Schwenke<sup>2</sup>, FalkPetzold<sup>2</sup>, Stefan Kratzenstein<sup>2</sup>

<sup>1</sup>Neurogeriatrics, University Hospital Kiel, Kiel, Germany

<sup>2</sup>CAU Motion Lab, Kiel University, Kiel, Germany

Email: c.hansen@neurologie.uni-kiel.de

## Summary

GPS sensors are widely used in strength and conditioning (S&C) settings around the world. Preliminary results of eight sensors show little inter and intra sensor variability. In summary the sensors are suitable for S&C applications such as track and field or large pitch games.

## Introduction

Measuring human movement during sports applications has a long standing tradition in biomechanics and especially in strength and conditioning (S&C). The systems vary and with the technological development training load estimations are more and more performed using GPS. The GPS sensors however often suffer from connectivity glitches introducing errors to the analysis. This becomes especially pertinent if training load parameters are assessed with multiple sensors e.g. to evaluate training load of a whole team. Previous work has reported that GPS sensors suffer from low acquisition frequencies or occlusion problems [1]. Applying signal processing techniques (e.g. filtering) could help to overcome some of those issues. In this work we test the intra and inter reliability of eight GPS sensors of the same brand to understand the overall bias introduced by the sensors positioning during a running task.

## Methods

A distance of 200m was set at track and field stadium at the University Kiel. The test was performed by young healthy participants. In contrast to the manufacturer recommendation participants were equipped with eight GPS sensors attached to the back. 200m running trials were performed at 8 & 10km/h (2.22 & 2.78m/s). Data were collected and analyzed using the Titan Team Stats data processing tool.

## Results and Discussion

A total of ten runs was performed. Here, we show the visualization from one sensor throughout the ten runs as a heatmap (Figure 1). The resulting distances are shown in Table 1.

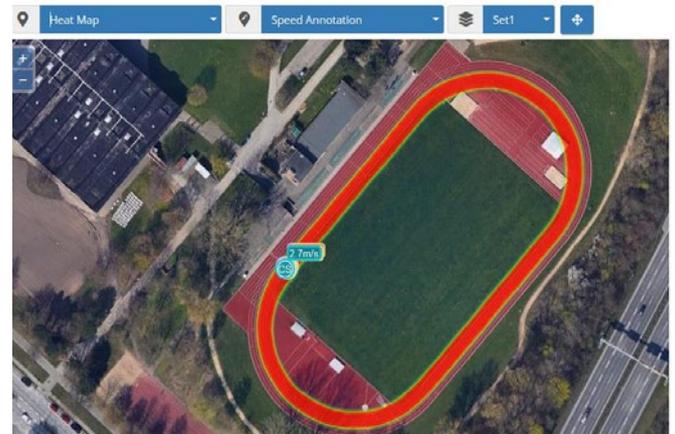

Figure 1: Heatmap showing the GPS units during the running trials on the track and field stadium .

## Conclusions

The aim of this work was to present the potential errors introduced by positioning GPS sensors on various locations of the back of an athlete. The positioning introduced errors however on average the errors remain lower than eight percent. In addition to the positioning, the manual data analysis may have also introduced a bias resulting in those relative large absolute errors of 9.2m for the 10km/h and 8.7m for the 15km/h runs. Even though we need to account error in positioning the sensors on the back in a practice session, current GPS systems are a promising technology for tracking motions on the field.

# Evaluating The Validity Of An Inertial Measurement Unit For Determining Knee And Trunk Kinematics During Athletic Landing And Cutting Movements

Chia L.<sup>1</sup>, Andersen J.<sup>1</sup>, McKay M.<sup>1</sup>, Sullivan J.<sup>1</sup>, Megalaa T.<sup>1</sup>, Pappas E.<sup>1,2</sup>

<sup>1</sup>Sydney School of Health Sciences, Faculty of Medicine and Health, The University of Sydney, Sydney, NSW, Australia

<sup>2</sup>University of Wollongong, Wollongong, NSW, Australia

Email: [lclionelchia@gmail.com](mailto:lclionelchia@gmail.com)

## Summary

Inertial Measurement Units (IMUs) are a promising alternative to laboratory-based motion-capture methods for the biomechanical assessment of athletic movements. The aim of this study was to investigate the validity of an IMU system for determining knee and trunk kinematics during landing and cutting tasks in sporting populations. Twenty-seven participants performed five cutting and landing tasks while their motion was simultaneously recorded using an optoelectronic motion capture system and an IMU system. Based on good-to-excellent correlation, reasonable accuracy (RMSE<5°), bias within 2°, and limits of agreements within 10°, we recommend the use of this IMU system for knee sagittal-plane range-of-motion (ROM) estimations during cutting, trunk sagittal-plane peak angle estimation during double-leg landing, trunk sagittal-plane ROM estimation for almost cutting and double- and single-leg landing tasks. Due to poor comparisons with the optoelectronic system, we currently do not recommend this IMU system for knee frontal-plane estimations.

## Introduction

Knee injuries account for up to a third of severe injuries in sports involving high pivoting and landing demands such as basketball and soccer [1]. To reduce injury risk, a greater understanding of injury biomechanics is required. IMUs are convenient, cost- and time-effective devices that are promising alternatives to ‘gold-standard’ laboratory-based motion capture methods. However, current IMU algorithms are activity-specific, and their validity in sporting contexts remains limited. The aim of this study was to investigate the validity of an IMU system for determining knee and trunk kinematics during landing and cutting tasks for clinical and research applications in sporting populations.

## Methods

Twenty-seven participants (14 males and 13 females, 28.7 ± 5.6 years, 1.7 ± 7.5m, 70.3 ± 15.2kg) performed five cutting

and landing tasks – anticipated 45° jump-stop cutting task to the right (CUTR) and left (CUTL) double-leg drop landing (DLL), and single-leg drop landing on the right (SLLR) and left leg (SLLL)– while their motion was recorded using a gold-standard optoelectronic motion capture system and an IMU system (Figure 1). Intra-class coefficients (ICC 2,1), Pearson’s *r*, root-mean-square error (RMSE), bias, and Bland-Altman limits of agreements between the motion capture and IMU systems were quantified for knee and trunk sagittal- and frontal-plane range-of-motion (ROM) and peak angles.

## Results and Discussion

IMU validity was task-, joint-, and plane-dependent (QR Code links to full results). Based on good-to-excellent (ICC) correlation, reasonable accuracy (RMSE<5°), bias within 2°, and limits of agreements within 10°, our findings support the use of this IMU system for sagittal-plane estimations, especially for the knee and trunk during cutting, and the trunk during double-leg landing movements. Increasing trunk and knee flexion during landing and cutting movements is a common objective of knee injury prevention programs [2]. Due to poor comparisons with the optoelectronic system, we currently do not recommend this IMU system for knee frontal-plane kinematic estimations.

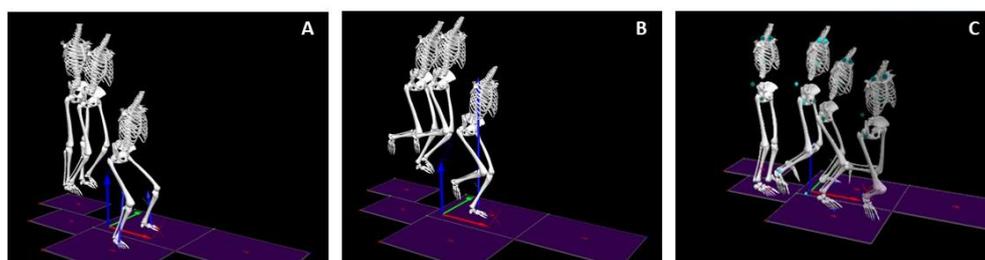

## Conclusions

The IMU estimated sagittal-plane movements better than frontal-plane movements. IMU validity was task-, joint-, and plane-dependent. Fast athletic movements, such as those assessed in this study, present challenges for IMUs and further evaluation of algorithms, biomechanical models, sensor fixation and placement methods in sport-specific contexts should be performed before widespread usage.

<sup>4</sup>Ningbo University School of Medicine, Ningbo University, Ningbo, China

Email: guyaodong@hotmail.com

### Summary

The purpose of this study was to investigate if the standing long jump specific-shoe (SS) can really help Chinese students achieve greater performance during the standing long jump test compared to normal sports shoe (NS). Eight participants (4 male and 4 female) performed six standing long jumps with jump distance and kinetic parameters collected utilizing long jump mat and Kistler force platform simultaneously. Both male and female participants tended to achieve greater jump distance in the SS condition, however, more research with larger sample size are warranted for further verification.

### Introduction

The performance of standing long jump is often used as one of the best fitness tests to examine explosive power of the school students, especially in China [1]. Thus, many sports products companies introduced the standing long jump specific-shoe (SS), and claimed that SS can effectively enhance performance. The performance of standing long jump is highly associated with various factors based on previous studies [1,2]. Two questions arise, however. Firstly, few studies have attempted to explore the effect of different kinds of shoes on the quality of standing long jump. Moreover, the internal mechanisms contributed to this effect are consequently not so clear. Therefore, this study aimed to investigate if the SS can really help Chinese students achieve greater standing long jump performance.

### Methods

A total of 8 university students (4 male and 4 female) were recruited. Participants reported no professional long jump experiences before. The study was approved by the Ethics Committee of Ningbo University and written informed consent forms were obtained. Conventional sports shoe and standing long jump specific-shoe with the same ethylene-vinyl acetate (EVA) midsole were used in this study (EU size 41-43, Figure 1). Participants were asked to perform 6 successful standing long jumps in each shoe. The jump distance was measured by a long jump mat and the kinetic data including vertical peak force (Fz), horizontal peak force (Fy) were collected by Kistler force platform (Kistler, Switzerland)

and then normalized to the participants' body weight (N). The traction coefficient (TC) was further calculated from the ratio of horizontal and vertical force [3]. A dependent-sample T-test was used to analysis the statistical differences of the jump distances and kinetic data. All data are presented as mean  $\pm$  SD and *P* was set at 0.05.

Figure 1: Experimental shoes (Left: SS; Right: NS)

### Results and Discussion

The present study has found that both male and female participants tended to achieve greater jump distances when they jumped wearing SS (Table 1). The reason for the lack of significance may be the limited sample size. Further research with larger sample size must be done to verify the result.

The greater the TC is, the more one can lean forward [3]. It was found that the TC at take-off was significantly larger when jumped using SS (Table 1). Thus, it is deduced that the greater TC increases the horizontal length of the body's center of gravity, contributes to more horizontal force (which is also found in this study) and propulsive impulse, and further enhances performance [3].

### Conclusions

It was found that SS may increase the jump distance partly due to the increased traction coefficient and horizontal force at take-off. However, more studies are warranted before it can be further verified.

## Development of snowboard force measurement system

Yun Chen<sup>1</sup>, Ming Li<sup>1</sup>, Wei Zhuang<sup>1</sup>, YiWu Xiong<sup>1</sup>, Yu Liu<sup>1</sup>

<sup>1</sup>School of Kinesiology, Shanghai University of Sport, Shanghai 200438

Email: [15617165575@163.com](mailto:15617165575@163.com)

### Summary

With the approach of 2022 Beijing Winter Olympic Games, how to improve the performance of winter athletes quickly and efficiently has become the core issue of coaches and sports workers. In order to promote the scientific and effective training of skiers and promote the biomechanical research of skiing, based on the existing structure of snowboard, a three-dimensional force sensor and a high-precision data acquisition box are installed between the skis and the fixator components, and a snowboard force measurement system with high-precision XYZ triaxial force acquisition is designed, which provides technical support for improving the performance of skiers.

### Introduction

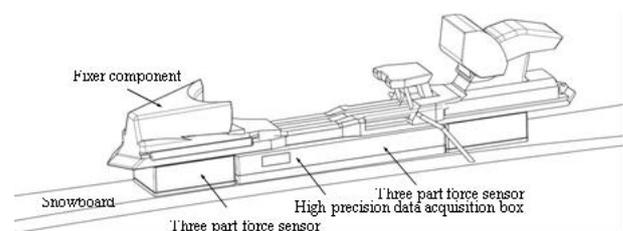

Skiing in the Winter Olympic Games is an outdoor speed racing and skilful sport with the characteristics of wide range of motion. Due to its fast displacement speed and relatively complex movement technology, it is difficult for the existing laboratory to collect its dynamic data indoors [1]. The measurement of force is a necessary condition for the research and analysis of skiing biomechanics. Timely acquisition of the ground reaction force can help coaches and related researchers to analyze and diagnose the athletes' pedaling force. However, reviewing the existing findings, there is not enough accurate force measuring equipment to conduct a complete mechanical analysis of skiers' performance [2]. Therefore, in order to promote the scientific and effective training of skiers and promote the biomechanical research of skiing, it is necessary to develop relevant force measuring equipment to detect the stress state and performance of skiers in skiing. Based on this, the research team designed a snowboard force measurement system for skiers according to the characteristics of skiing and biomechanical technology.

### Methods

**The overall design :** This product is a snowboard force measuring system, which is installed in the whole snowboard assembly, including two three-component force sensors, a set of high-precision data acquisition system, a SD

card, a power supply, etc. Based on the existing structure of the ski, a three-component force sensor and a high-precision data acquisition box are installed between the snowboard and the fixator component (Figure 1). Power supply interface, SD card slot interface and power switch are designed on the side, and the interface is covered by the corresponding cover plate to facilitate the training.

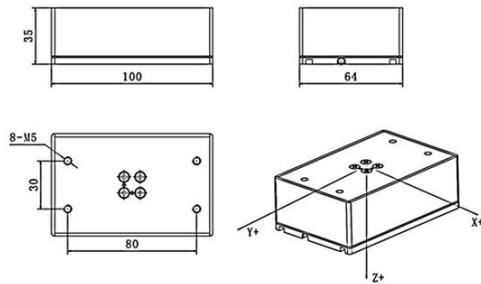

The three-component force sensor (including the transfer plate) is connected with the skis and the fixator components, and is divided into two front and back, which is used to measure the load changes in the training process of athletes. The high-precision data acquisition box is installed in the middle area of the two three-component force sensors, which can convert the analog signals of the two three-component force sensors into digital signals that are convenient for calculation and transmission. The three-component force sensor is made of aluminum alloy, while the high-precision data acquisition box is made of nylon and other plastic materials, which greatly reduces the quality of the whole system, while ensuring the strength and stiffness of the structure to meet the actual use requirements.

**Figure 1:** Schematic diagram of snowboard force measurement system

### Key components : Three-component force sensor :

Three-component force sensor design, on the basis of the principle of strain electrical measuring temperature of output signal, high sensitivity, can effectively meet the training test requirements of skis force measurement and control system, and to prevent it in the process of skiing, snow because of the intense exercise into the force measurement and control system, both the closed and block processing (figure 2), to ensure that the skis force measurement and control system can meet the requirements of snow training.

**Figure 2:** Three component force sensor contour diagram

**High precision data acquisition system :** The high-precision data acquisition system on the snowboard force measuring system includes signal conditioning circuit, A/D conversion circuit, data calculation, data transmission and storage modules. The analog signals of the two three-component force sensors can be converted into digital signals that are convenient for calculation and transmission, and the precision and speed of the output data can reach a higher level with the help of high-speed acquisition and machine learning algorithms and other technologies. The data of the high-precision data acquisition system is stored in the SD card in real time, and can be transmitted to the computer in real time, so that the customer can read and use it later.

## Locomotor changes in knee osteoarthritis patients during a 6-minute walk test

Stuart C. Millar<sup>1</sup>, Kieran Bennett<sup>1</sup>, Mark Rickman<sup>2</sup> and Dominic Thewlis<sup>1</sup>

<sup>1</sup>Centre for Orthopaedic and Trauma Research, University of Adelaide, Adelaide, Australia

<sup>2</sup>Department of Orthopaedics and Trauma, Royal Adelaide Hospital, Adelaide, Australia

Email: stuart.millar@adelaide.edu.au

### Summary

Several means have been proposed to assess the presence, severity and impairment associated with knee osteoarthritis (OA). Recent studies have suggested the use of physical performance tests to assess joint function for those with knee OA. This study investigated lower limb kinematics over the course of a 6-minute walk test (6MWT). Hip, knee and ankle joint angles were computed for the first and last minute of the 6MWT. Results indicated there to be no locomotor breakdown over the 6-minute period highlighting the 6MWT as a strong measure to quantify functional changes in people with knee OA.

### Introduction

Knee osteoarthritis (OA) is a chronic condition affecting the entire joint and surrounding tissues, resulting in pain, stiffness and impaired movement [1]. While end-stage disease is most frequently treated with total knee replacement surgery, there is no definitive treatment option for people with mild-moderate knee OA – yet this is a significant target for pharmaceutical companies around the world. Recent regulatory approval processes now require, or at least strongly suggest, that joint function should form part of the assessment of efficacy of new treatments for knee OA. The 6-minute walk test (6MWT) has been consistently identified as a strong candidate tool for assessing function in people with knee OA [2]. The aim of this study was to investigate the stability of lower limb biomechanics during a 6MWT in people with moderate-severe knee OA.

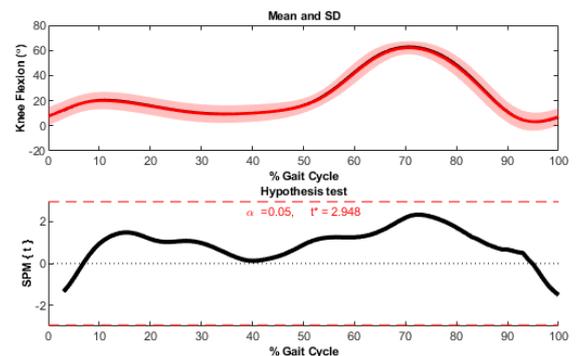

### Methods

Nineteen participants with knee OA were recruited for this study (Table 1). Gait data were collected in a single testing session during which participants were required to complete a 6MWT. Participants walked barefoot around a 20 m course with walking gait captured using a 10-camera Vicon Vantage system and two AMTI force platforms. Kinematic reconstruction of the data was undertaken in Visual 3D (V6, C-Motion Inc.). Gait speed and joint angles for the hip, knee and ankle were calculated during the first and last minute of the 6MWT. A paired samples t-test was performed to determine if there were changes in temporospatial or kinematic parameters between the first and last minute of the 6MWT. Additionally, a one-dimensional paired t-test was

performed in SPM1D [3] to determine if there was a difference in knee kinematics across a complete gait cycle.

### Results and Discussion

Patient demographics and temporospatial measures from the 6MWT are presented in Table 1. There were no statistically significant differences in joint angles (Figure 1) or gait speed measured between data from the first and last minute of the test.

**Figure 1:** Mean and standard deviation for knee flexion during first (red) and last minute (black). The paired t-test shows no significant difference between the two groups across the entire gait cycle.

### Conclusions

The data indicate there to be no breakdown of locomotor control across the course of the 6-minute period for knee OA sufferers. These data serve to support the notion that the 6MWT can be considered an appropriate performance test to quantify gait changes in people with knee OA when assessing the efficacy of treatments or interventions to reduce pain or improve function.

### Acknowledgments

This study received funding from XALUD Therapeutics and the NHMRC (CDF ID: 1126229).

# A Study on The Hip Joint Mechanism of The Exoskeletal Robot to Improve The Assistance Performance

Mingoo Jeong<sup>1</sup>, Taeyeon Kim<sup>2</sup>, Kyongchul Kong<sup>\*</sup>

<sup>1,2,\*</sup> Department of Mechanical Engineering, Korea Advanced Institutes of Science and Technology, Daejeon, South Korea  
Email: mg.jeong@kaist.ac.kr

## Summary

This paper proposes a new hip joint mechanism for an exoskeletal robot that can deliver the assisting torque without limiting the wearer's hip movement. The proposed mechanism allows all hip joint movements of the wearer and solves the rotation axis mismatch problem between the wearer and the robot.

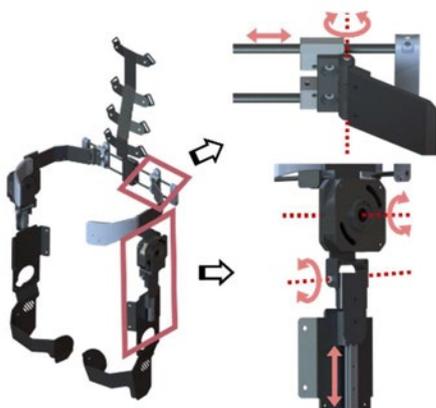

## Introduction

The human hip joint is one of the joints that play a significant role in daily human movements. As such, the hip joint impact on daily life is immense, so many researchers are developing exoskeletal robots to assist the hip joint [1, 2]. However, since the hip joint has the shape of a spherical joint, allowing all the hip joint movements with an exoskeletal robot is a challenging problem. Furthermore, if the rotation axis of the human and the exoskeletal robot are mismatched, the wearer must feel uncomfortable during motion. In this paper, a new mechanism of an exoskeletal robot for hip joint assistance is proposed to solve these difficulties.

## Methods

Figure 1 shows the hip joint mechanism that was designed to solve the problem of rotation axis mismatch between the wearer and the robot and allow movement about all three rotation axes. In the proposed mechanism, a hinge joint and a prismatic joint are arranged in series on the back part, allowing the hip joint's internal and external rotation. There is also one hinge joint and a prismatic joint on the thigh side, so adduction and abduction motion can be allowed without any restrictions. In the case of flexion and extension, like other exoskeletal robots, one actuator is installed on each side to assist the movement. Furthermore, the robot is equipped with a backplate, so that the torque output from the actuator can be effectively transmitted to the trunk.

The experiment compares the difference in motion before and after wearing the robot to verify the proposed mechanism does not interfere with or limit the wearer's

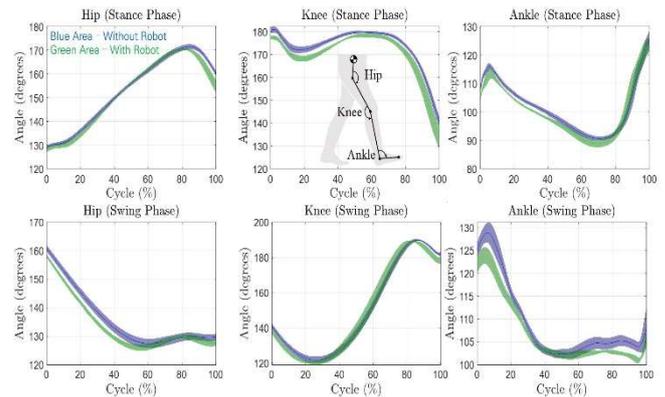

**Figure 1** : The proposed hip joint mechanism

movement. Since the robot was customized for one person, the test subject consists of one person. The comparison motion was set as a walking motion, and a 3D motion capture system was used to measure the movement for each condition. The subject walked a 5m walking rail and performed a total of 10 walks for each situation. Besides, the subject performed the walking speed and the step length according to the subject's preference.

## Results and Discussion

Figure 2 shows the motion of each joint in the sagittal plane. As can be seen through this, there is no significant difference in walking motion before and after wearing the robot. In addition, the walking speed with and without the robot was 1.393 m/s and 1.391 m/s, respectively, and the stride length was 1.386 m and 1.382 m, respectively. Therefore, through the above experimental results, it can be concluded that the proposed robot does not interfere with or limit the movement of the wearer.

**Figure 2** : Difference in motion in the sagittal plane

## Conclusions

The mechanism proposed in this paper was devised to solve the mismatch of the rotation axis with the wearer while allowing all the wearer's hip joint motion. The effectiveness of this mechanism was verified by comparing the differences in gait motion. However, additional experiments are required to analyze the burden acting on the wearer more clearly.

## The 3D CoM kinematic estimation using a simple machine learning for portable gait monitoring

Myunghyun Lee<sup>1</sup>, Kyoungchul Kong<sup>1</sup>, Sukyung Park<sup>1</sup>  
<sup>1</sup>Dept. Mechanical Engineering, KAIST, Daejeon, Republic of Korea  
 Email: sukyungp@kaist.ac.kr

### Summary

The center of mass (CoM) can be used as a major factor for gait monitoring. Therefore, many studies have tried to estimate the CoM kinematics using an inertial measurement unit (IMU) attached to the sacrum, but the estimation accuracy of velocity and acceleration was not high enough. In this study, we estimated the 3-axis CoM kinematics by first estimating CoM velocity using a machine learning. The change in velocity was estimated from the sacral IMU data using an artificial neural network (ANN), and the position and acceleration were derived by integrating and differentiating the velocity. We estimated the CoM kinematics with high accuracy, which reduced an error of up to 4 times compared to the sacral kinematics. With help of this accurate estimation method, it is expected that the CoM-based gait monitoring with a single IMU would be improved.

### Introduction

The CoM is used as an indicator for gait monitoring. Since the CoM is not fixed to a specific part of the body, many gait analysis have used an IMU attached to the sacrum, which is most similar to the CoM[1]. However, the range and phase of motion of sacrum differ from that of the CoM[2]. In order to narrow the difference, many studies have tried to estimate the CoM kinematics using the sacral kinematics, but only focused on estimating the position[3]. However, a large error could occur by differentiating the estimated position to calculate the velocity and acceleration. To prevent a large error resulting from differentiating the position, highly accurate estimation method is required to estimate the CoM kinematic such as the velocity or the acceleration. In this study, the CoM velocity were estimated using machine learning, and the position and acceleration were estimated based on the estimated velocity.

### Methods

To estimate the 3-axis CoM kinematics, the CoM velocity was estimated from the IMU data, and then the position and acceleration were calculated using the estimated velocity (Fig. 1). The sacral kinematics from an IMU were used to estimate the CoM velocity using an ANN. The walking speed was estimated from IMU data[1] and the velocity and position were derived by integrating the acceleration. The output was set as 3-axis CoM velocity with the average walking speed in the anteroposterior (AP) direction removed. The 3-axis acceleration and position were calculated using the estimated velocity added the estimated walking speed by IMU.

To verify the proposed method, 17 healthy subjects walked on the treadmill at four speeds (0.7, 1.0, 1.3 and 1.6 m/s) after signing the consent form approved by the KAIST IRB. The sacral kinematics were measured by a motion capture system and a sacral IMU. The CoM kinematics were calculated using the ground reaction forces measured by the force plates under

the treadmill. The estimation accuracy was verified by the normalized root-mean-square error (NRMSE) and RMSE between the measured and estimated CoM kinematics.

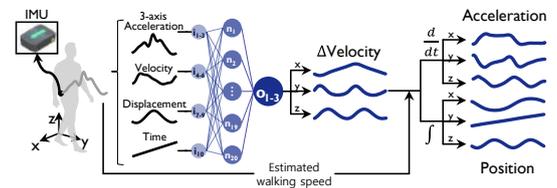

Figure 1: The CoM estimation method using machine learning

### Results and Discussion

By estimating the change in velocity instead of absolute velocity, CoM velocity was estimated using machine learning from IMU data. The change in velocity could be estimated within 15% of the average NRMSE and within the average RMSE of 0.05m/s. With the estimated velocity change, the 3-axis position, velocity, and acceleration of CoM could be estimated (Fig. 2) within 17% of the average NRMSE except AP velocity. The average of RMSE were 5-57 mm for position, 0.029-0.102 m/s for velocity and 0.4-0.9m/s<sup>2</sup> for acceleration. Compared with the sacral kinematics from IMU, the estimation error was reduced by at least one-time (AP position) and up to four times (mediolateral (ML) acceleration).

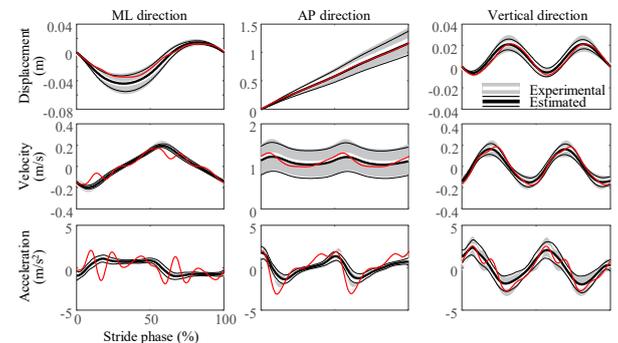

Figure 2: The CoM kinematics (red: sacral kinematics)

### Conclusions

By first estimating the CoM velocity using machine learning, the CoM kinematic estimation from the sacral IMU could be improved. The CoM kinematic estimation method using a single IMU can be used for CoM-based gait monitoring.

## Design and Verification of Bio-mimetic Knee Joint Mechanism for Exoskeletal robots

Taeyeon Kim<sup>1</sup>, Mingoo Jeong<sup>2</sup> and Kyoungchul Kong\*

<sup>1,2,\*</sup> Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea  
Email: ty.kim@kaist.ac.kr

### Summary

A novel knee joint mechanism that mimics knee anatomy has been proposed to reduce misalignment. It consists of curved guide rails and bearings. The curve is designed based on human motion data. In this paper, the single pin joint and the proposed biomimetic joint are compared through experiments using pressure sensors. Pressure data between the human body and the frame was measured. The results showed that the bio-mimetic knee joint could improve the wearability by reducing misalignment.

### Introduction

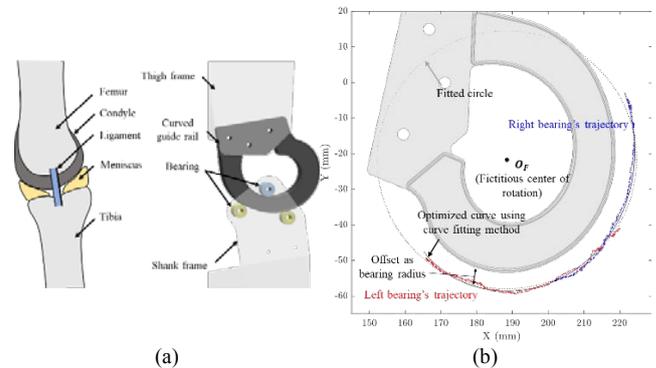

Knee is the most complex joint in the human body. While the knee bends, sliding and rolling occur in the sagittal plane. Thus, the instantaneous center of rotation of shank moves significantly with the flexion angle. However, many of well-developed exoskeleton robots have fixed pin knee joint structure[1]. If the robot frame and shank have different rotation axis, the exoskeleton will deviate from the human movement. This misalignment acts as the main factor of the unintentional repulsive force between the wearer and the robot system. Therefore, it is essential to decide the joints' structure so that it can smoothly follow the movements.

### Methods

As shown in Figure 1(a), The curved guide rail acts like femur condyle. Three bearings that are fixed at the shank frame keep contact with this rail, maintain 1DOF movement. Two of them (yellow) support the weight like meniscus, and the top one (blue) prevents deviation like a ligament.

The shape of guide rail is designed using motion data of the shank with respect to the thigh. However, two bearings fixed at the shank will create two different trajectories as knee bent if the locations are arbitrary selected. For make continuous and simultaneous contact of two bearings, the trajectories need to be overlapped. Thus, it is necessary to optimize the bearings location. Figure 1(b) shows the optimized bearing trajectories and generated rail's shape. Using curve-fitting method, the result curve is derived which has minimum error. Bottom curve of the rail is generated by offset the result curve with bearing radius.

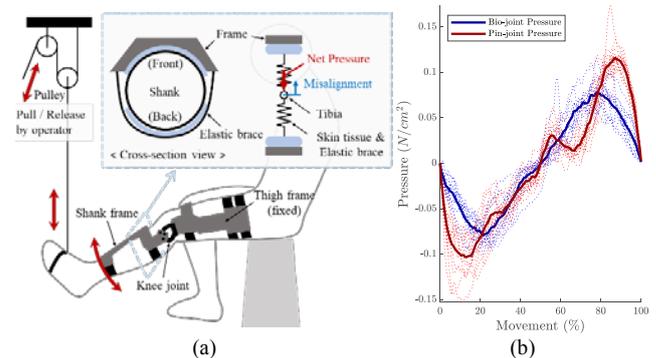

Evaluation and comparison the wearability by wearing the robot in real environment is necessary. The overall experimental process is shown in Figure 2(a). Air bladder made with silicon tube with pressure sensor [2] is chosen for measuring the repulsive pressure between human skin and robot's braces. Pressure sensor is attached to the both side of the shank. Assume that the human skin and the braces are elastic, then the measured pressure is proportional to the misalignment via Hook's law. For minimize the muscle activation effect, the wearer was seated in a chair and his shank were moved by a pulley.

**Figure 1:** (a) Design method of the bio-mimetic joint. (b) Optimization result for curved guide rail

### Results and Discussion

Pressure difference between front and rear side of the shank is plotted in Figure 2(b). As can be seen in the figure, the maximum pressure value and the sum of the absolute value of pressure are reduced about 70% when using bio-mimetic joint. Therefore, through this experiment, it was verified that the bio-mimetic joint greatly improved wearability.

**Figure 2:** (a) Experimental procedure diagram. (b) Pressure data of bio-mimetic joint and pin joint.

### Conclusions

Misalignment reduction using bio-mimetic knee joint is verified. A new direction for developing more comfortable exoskeletal device was established to compare the wearability according to the structural characteristics.

## The repeated bout effect in the human medial gastrocnemius muscle: the influence of fascicle stretch elicited during different muscle contractions

### Summary

The aim of this study was to determine the influence of muscle fascicle stretch elicited during eccentric (ECC) and isometric (ISO) contractions on the magnitude of exercise-induced muscle damage (EIMD) and the repeated bout effect (RBE). In 14 participants, we measured medial gastrocnemius' (MG) twitch torques and soreness scores before and after repeated bouts of ECC and ISO performed in contralateral legs. The results show that both contraction types elicited EIMD (i.e. reduction in torque) and a RBE (i.e. less soreness after the second exercise bout). However, the ISO condition caused less damage and less protection against muscle soreness two days after the repeated bout. Overall, our results suggest that the action of stretching an actively contracting muscle rather than sustained contractions at long lengths is more important for causing EIMD and a RBE in the MG.

### Introduction

Controversy remains about whether EIMD and the RBE are caused by the process of stretching an actively contracting muscle (ECC), or whether damage arises due to the production of high force at long muscle lengths (ISO). This is particularly true for the MG, where fascicle stretch (and thus damage) is buffered by the Achilles tendon and the muscle's aponeurosis [1]. If high forces at long muscle lengths are important to elicit EIMD in the MG, at matched exercise volumes (i.e. time under tension), a bout of ISO should cause a larger, or similar, reduction in torque (i.e. contractile failure) and larger, or similar, increase in muscle soreness than a bout of ECC. If this is true, a bout of ISO may be more effective than a bout of ECC in protecting the muscle towards subsequent muscle damage from repeated bouts. As such, this study sought to compare the effect of ISO and ECC on MG markers of EIMD and the RBE.

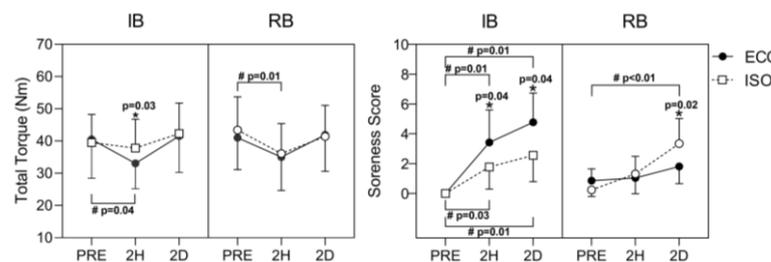

### Methods

Fourteen participants (11 male, age  $26 \pm 4$  yrs, mass  $74.6 \pm 11$  kg, height  $178 \pm 6$  cm; 3 female, age  $28 \pm 8$  yrs, mass  $70.4 \pm 6$  kg, height  $171 \pm 7$  cm) performed an initial bout of ISO with one leg at a long muscle length. Subsequently, the contralateral leg performed a bout of ECC as heel drop exercise. Seven days later, both legs performed the ECC condition. Time under tension (600 s) was matched between the ECC and ISO conditions. Twitch torque elicited by supramaximal peripheral nerve stimulation (i.e. the average peak torque of stimuli elicited at seven angles across the ankle

range of motion) and muscle soreness scores (participant's self-reported muscle soreness after a palpation test, reported using a 10-point analogue scale) were used to examine MG muscle damage before (PRE), two hours (2H) and two days (2D) after the bouts of exercise.

### Results and Discussion

Both ECC and ISO conditions elicited EIMD and a RBE (Figure 1). However, ISO caused less damage 2H after the initial bout (14% less drop in twitch torque) and less protection 2H after the repeated bout (56% higher soreness) compared to ECC.

**Figure 1:** Markers of muscle damage. \*Significant difference when comparing between the ECC and ISO contraction types. #Significant difference when comparing between timepoints (PRE, 2H, 2D) of the same contraction type. IB, initial bout; RB, repeated bout.

These results show that in the MG muscle, ECC elicits higher levels of muscle damage compared to ISO at a long muscle length, when time under tension is matched between the two conditions. Yet, the level of damage is considered to be low to moderate and is expressed mainly as an increase in soreness rather than changes in muscle force producing capacity. Both ECC and ISO are able to produce a RBE. Nevertheless, the protection conferred by the latter is less. This suggests that ISO do not produce enough muscle damage during the IB, and/or that significant muscle damage cannot be elicited in vivo in MG due to its capacity to buffer fascicle stretch via its elastic properties [1].

### Conclusions

The process of stretching an actively contracting MG seems to provide a distinct stimulus for damage, more so than isometric contraction of MG at long lengths.

## Relationship between A2 Pulley Venting and resultant Flexor Tendon Superficialis Slack

Tyler Shipley, William Adcock, Karl Bilderback, Tara Saxena, Jennifer Walt, Shane Barton, and Giovanni Solitro  
Louisiana State University Health Shreveport, Shreveport, Louisiana  
Email: gsolit@lsuhsc.edu

### Summary

Discrepancies in documented outcomes of A2 pulley venting in flexor tendon repair indicate a need for further study of the biomechanical sequelae of venting. The purpose of this study is establishing whether difference exists in flexor slack that develops between fingers and if there is a threshold of venting at which point a significant increase in slack develops.

### Introduction

It is understood that the A2 pulley along with the A4 pulley is crucial in prevention of flexor tendon bowstringing. However, occasionally during repair of flexor tendon lacerations the pulley must be released. Compared to partial excision of the A2 pulley, increased gliding resistance has been documented with intact A2 pulley in flexor tendon repair. Ruptures and inadequate flexion have also been documented as complications of flexor tendon repair with an intact A2 pulley. The purpose of this study is to assess the effect of incremental A2 pulley release on flexor tendon slack. Reduction of such surgical complications will lead to proper finger kinematics and more rapid return to activities of daily living. Our hypothesis is that full release of the A2 pulley leads to significant increase in tendon slack and there is difference among fingers on the exhibited slacks.

### Methods

After receiving IRB exemption, 18 fingers (79±10yo) were isolated from fresh frozen cadavers. Transverse metacarpal pins were used to fix the hand to a custom apparatus (see Figure 1), which allowed control of tendon excursion while monitoring the loading. With a running lock stitch, the flexor digitorum superficialis (FDS) and extensor digitorum were tied to the apparatus which tested fingers by imposing an alternate displacement with loads ranging from 30±1 N to 2 N on the FDS in flexion. Each A2 pulley configuration was cycled 100 times into a force plate to 90 degrees of proximal interphalangeal joint flexion. The A2 pulley was sequentially incised in 20% increments until full release. Paired T-tests for means were performed between index and middle fingers and between ring and middle fingers to identify at which extent of pulley venting the fingers would show different slacks at a level of significance of 0.05.

### Results and Discussion

The index fingers showed average of 0 mm slack at intact A2 pulley, 1.78 mm slack at 20 percent release, 3.03 mm slack at 40 percent release, 4.18 mm slack at 60 percent release, 5.01 at 80 percent release, and 7.05 mm at full release (see Figure 1). The middle fingers showed average of 0 mm slack with intact A2 pulley, 0.93 mm at 20% release, 1.7 at 40 % release,

2.35 mm at 60% release, 2.86 mm at 80% release, and 4.43 at full release. Ring fingers had average of no slack at intact A2 pulley, 2.06 mm at 20%, 3.2 at 40 %, 4.3 at 60%, 5.43 at 80%, and 6.36 at full release.

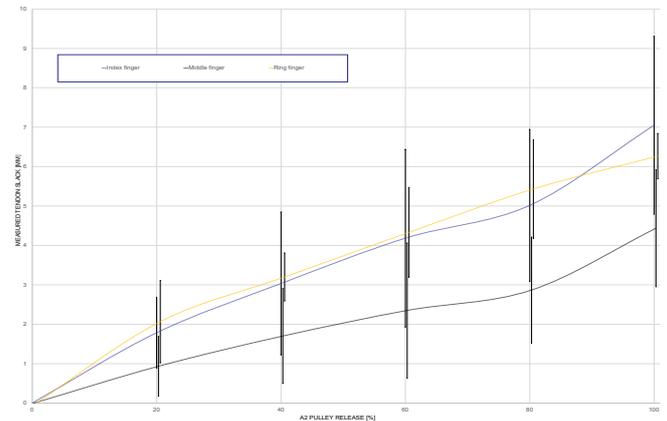

Figure 1: Pulley slack in relation to incremental A2 pulley release.

In a previous study, losses in joint flexion was documented with venting, however a direct relationship between venting and slack underlying this mechanism was not proposed (Tomaino et. al, 1998). The present study that indicate incongruence of slack development in the fingers, in which the index and ring fingers are more prone to slack than is the middle finger. Further research is needed to fully understand the sliding mechanism of the flexor tendon in presence of surgical repair and consequential adhesions. We did not associate the resultant slack to what could be potentially recovered through physical therapy and further research is needed for this specific purpose.

### Conclusions

At the time of surgery it must be considered that there is direct proportionality between the A2 venting used in flexor repair and slack. The differences in slack between fingers demonstrates that each finger needs to be treated differently.

### Acknowledgments

We would like to thank Mr. Alan Ogden for his assistance in performing the experiments.

### Summary

This work assesses the feasibility of wearable magneto-inertial measurement units (MIMUs) for the segmentation of the archery shooting technique in athletes with and without disability. MIMU-based segmentation was validated against stereophotogrammetry, showing good reliability.

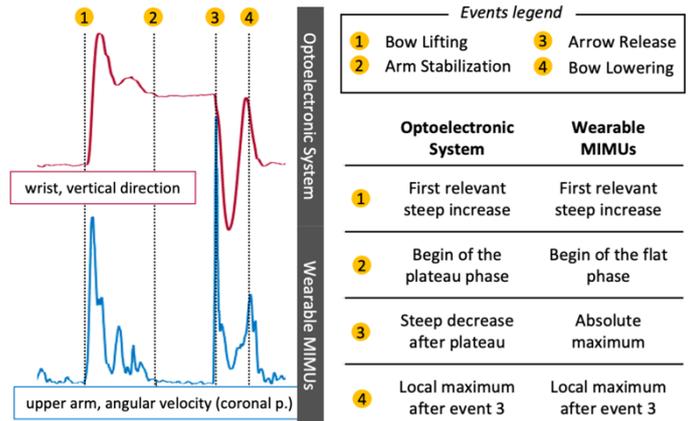

### Introduction

Archery is a sport accessible to a wide range of people and can be practiced by both athletes with and without disability on a level playing field. Archery shooting technique consists in a sequence of movements which is consistently repeated. The main phases of the shot cycle – draw, aim, follow through – are defined by specific upper limb movements [1]. To date, the segmentation of the whole cycle has been mainly obtained through manual video analysis [1]. Wearable solutions, such as electromyography (EMG) or MIMUs, were devised only for the identification of the arrow release instant [2,3]. However, athletes with disability were never included in any of these investigations. For this reason, this preliminary work aims at proposing a wearable setup for the identification of the main events of the shot cycle, assessing its validity in both athletes with and without disability.

### Methods

The experimental setup includes four MIMUs (Xsens, Netherlands, sampling rate 100 Hz) synchronized with an optoelectronic system (Vicon, UK, sampling rate 200 Hz). MIMUs were bilaterally positioned on forearm and upper arm, while markers were attached on both acromion processes, elbows and wrists. One non-disabled elite archer and one Paralympic athlete affected by spastic tetraparesis participated in the study. Participants shot 3 ends of 6 arrows at a target positioned at 10 meters from the shooting line. The time instants of four events within the shot cycle - bow lifting, arm stabilization, arrow release, bow lowering - were first identified from the optoelectronic data and then from MIMUs signals. Visual detection of the events was performed using bow-wrist marker trajectory in the vertical direction and it was considered as gold standard. The proposed event detection from MIMUs signals was performed using the angular velocity in the coronal plane of the bow-upper arm. The criteria considered for the identification of the events for the two measurement systems were the same for both the athletes,

and are provided in Figure 1. Non-parametric Bland-Altman analysis was performed to compare the agreement of the two techniques, with acceptable limits of  $\pm 200$  ms considering the sampling rate and the sport gesture characteristics ( $\sim 6\%$  of total shooting time).

**Figure 2:** Events detected for the task segmentation. For the sake of readability, signals from the Paralympic athlete only were reported.

### Results and Discussion

Bland-Altman analysis revealed an overall good agreement between the two measurement systems (Table 1). In particular, a strong agreement was found for the arrow release and bow lifting events in both athletes. The arm stabilization and bow lowering events showed wider limits of agreement between the two measurement systems, with a slightly lower accuracy found in the athlete with disability.

### Conclusions

The proposed wearable setup based on MIMUs proved to be an overall reliable solution for the archery technical gesture segmentation in athletes with and without disability. Further studies will focus on validating this result on a larger cohort of athletes and on identifying phase-specific key performance indicators to support athletes and coaches during training.

## Summary

Joint replacement represents the gold-standard surgical treatment to preserve joint motion in end-stage osteoarthritis. One of the main biomechanical causes for aseptic late failure of orthopedic implants is the stress shielding. This is normally due to the larger stiffness of the implant with respect to that of the adjacent bone, causing periprosthetic bone resorption due to reduced loading at the peri-implant bone. The aim of the study is to present a method for the in-vitro evaluation of strain distribution between bovine bone specimens and Cobalt-Chromium-Molybdenum (CoCrMo) scaffolds with different porosity in compression. Full-density samples appeared to rigidly transfer the compression force to the bone which was subjected to large deformations ( $2.2 \pm 0.3\%$  at 15 kN). The scaffolds made of 1000  $\mu\text{m}$  pores cubic-cells allowed for a smoother load transfer to the bone and thus may decrease the stress-shielding of orthopedic implants.

## Introduction

One of the main biomechanical causes for aseptic failure of orthopaedic implants is the stress shielding [1]. This is caused by uneven load distribution across the bone due to a stiff metal prosthesis component, leading to periprosthetic bone resorption and eventually to implant loosening and failure. To reduce the stress shielding and to improve osseointegration, biocompatible porous structures suitable for orthopaedic applications were developed [2, 3]. Aim of this study was to propose a novel in-vitro model of the interaction between metal lattice structures and bovine cortical bone in compression.

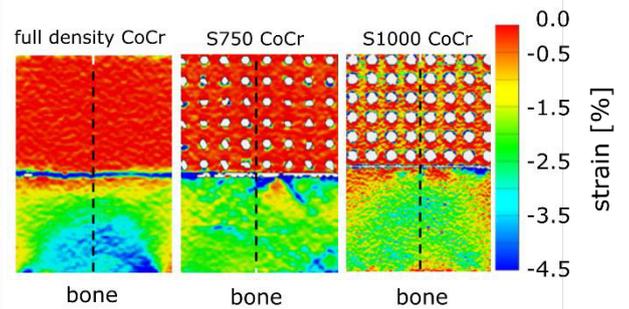

## Methods

Full density and lattice structures with a nominal porosity of 43.5% (S750) and 63.2% (S1000) obtained by the repetition of 1.5 mm edge cubic elements were manufactured via Laser Powder Bed Fusion (SISMA MYSINT100, Vicenza, Italy) of CoCrMo powder, and characterized for mechanical properties using standard compressive testing. Local deformation and strains of metal samples coupled with fresh bovine cortical bone samples were evaluated using Digital Image Correlation (DIC) analysis via GOM Correlate (vers. 2.0.1) up to failure in compression. Visualization and quantification of the local strain gradient across the metal-bone interface was used to assess

differences in mechanical behaviour between structures which could be associated to stress-shielding in compression.

## Results and Discussion

Stiffness and local mechanical properties of lattice and bone were consistent across samples (Table 1). Full-density metal samples appeared to rigidly transfer the compression force to the bone which was subjected to large deformations ( $2.2 \pm 0.3\%$  at 15 kN). Larger porosity lattice was associated to lower stiffness and elastic modulus, and to a smoother load transfer to the bone (Fig 1).

**Figure 1:** DIC-based analysis showing color map of local strains in three CoCrMo-bone sandwiches at 14-15 kN compressive load.

## Conclusions

While tested on a limited sample size, the proposed in-vitro model appears robust and repeatable to assess the local mechanical interaction of metal samples suitable for orthopaedic applications with the bone tissue. According to the present results, CoCrMo scaffolds made of 1000  $\mu\text{m}$  pores cubic cells may allow for a smoother load transfer to the bone when used as constitutive material of orthopaedic implants, which could result in lower stress-shielding with respect to a full-density metal implant.

## A gait pattern comparison between healthy adults and neurological patients at different walking speeds

Elke Warmerdam<sup>1</sup>, Felix von der Recke<sup>1</sup>, Clint Hansen<sup>1</sup>, Walter Maetzler<sup>1</sup>

<sup>1</sup>Department of Neurology, Kiel University, Kiel, Germany

Email: e.warmerdam@neurologie.uni-kiel.de

### Summary

Aging and neurological diseases are known to influence the gait pattern. This study compares the gait patterns of healthy young adults, healthy older adults, Parkinson patients and stroke patients with each other during different walking speeds. For all groups, the increase in speed showed a decrease in step time and an increase in step length, but no change in step width. There were significant differences in the gait parameters between the young adults and the other groups, no significant changes were found between older adults and neurological patients. These results suggest an increased risk of gait disorders in healthy older adults.

### Introduction

Gait disorders are common in their occurrence and can be caused by pathological processes, but also by the physiological aging process. The consequences of these gait disorders are an increased rate of hospitalisation and death. [1] This study focusses on a better understanding of gait deficits in the aging population and neurological patients walking at different speeds.

### Methods

Forty-nine participants consisting of four different groups took part in this study (Table 1). The participants completed five meters of steady state walking at slow, preferred and fast speed. Participants were measured with a 3D optical motion capture system. Gait velocity, step time, step length and step width were calculated. The changes in gait parameters with speed were analysed with a repeated measures ANOVA, the differences between the groups were analysed with a one-way ANOVA.

Table 1: Number and age of the participants

	Young adults	Older adults	Parkinson patients	Stroke patients
N (female)	17 (4)	10 (2)	14 (4)	8 (2)
Age, yrs ± SD	32 ± 9	73 ± 6	64 ± 10	64 ± 12

### Results and Discussion

All participants modified their velocity, step time and step length between the different speed conditions. The step width did not significantly change between the three trials. Between preferred and fast speed, both the neurological patients and older adults (OA) groups showed no significant changes of their step length. The young adults (YA) showed a significantly higher velocity and longer step length than the other groups. No significant changes were found between the gait parameters of the older adults and the gait parameters of the neurological patients (Figure 1).

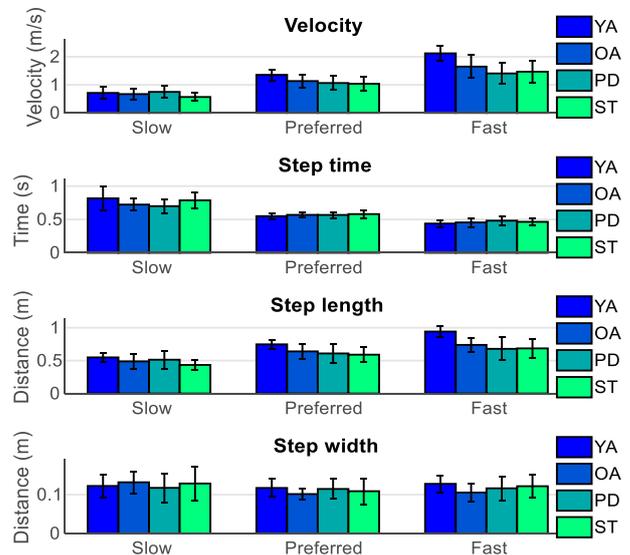

Figure 1: Alteration of gait parameters during different walking speeds

The similarities between the gait pattern of OA and neurological patients suggest that the neurological disorder is not the only cause of changes in the gait pattern and that supposedly healthy OA also have an increased risk of gait disorders and the associated consequences.

### Conclusions

We demonstrate that OA and neurological patients have lower gait velocities and smaller step lengths than YA. No differences were found between the OA and neurological patients. This highlights the risk of age-related gait disorders and suggests that only a part of the gait disorders seen in neurological patients are caused by the disease.

### Summary

The purpose of this pilot study was to determine whether muscle fatigue generated by a golf specific fatiguing protocol would have an effect on proprioception and kinematic parameters of both left and right hip knee and ankle joints during the six phases of the golf swing. Five healthy, right handed male subjects participated in this pilot study respectively. The participants were asked to perform 125 golf swings using various clubs whilst being recorded with a 3D Motion capture System. A subset of swings were calculated as Pre-Fatigue and Post Fatigue for evaluation purposes. All data was then analysed and the results compared using both descriptive and inferential statistics.

### Introduction

The golf swing is a complex movement of the whole body that encompasses the Sagittal, Frontal and Transverse planes. Several golf related studies have been carried out to improve performance in this field with regards to physical conditioning, mood, injury prevention and swing mechanics. According to studies [1] and [2] hip and knee mechanics can be substantially altered whilst fatigued. However, [3] points out that both “golf specific fatigue did not relate to the initial lower body sagittal plane angles at address nor was simulated golf specific fatigue related to peak transverse plane pelvis and trunk rotational velocities (or their timings) in a manner that indicates a relationship to resultant club head velocity and shot consistency”.

### Methods

Five healthy, right handed male subjects participated in this pilot study (Height 176.8 + 27cm, Weight 71.48 + 33.8 kg) respectively. Participants were asked to perform 125 golf swings using various clubs (5 x 5 iron, 60 x 7 iron, 5 x 9 iron, 55 x Driver). Kinematic angle data of both left and right hip, knee and ankle joints in the Frontal (X), Sagittal (Y), and Transverse (Z) planes were recorded using a Vicon Nexus Bonita (Oxford Metrics Ltd) Motion Capture system operating at 250Hz. A Vicon plug in gait Lower Body Model was selected with 16 retro-reflective markers placed on the correct anatomical positions of the lower limbs and four on the shaft of the golf club. This allowed for correct identification of the six golf phases. The first five swings of the Driver and 7 Iron were extracted and used as “Pre-Fatigue” with the last 5 swings of the study stored as “Post-Fatigue” for evaluation and comparison purposes. All joint angle data was stored in Degrees (<sup>o</sup>).

A paired t-test was used to compare the differences between the Pre-Fatigue and Post-Fatigue swings with respect to their corresponding joint angles. Significance was set to P = 0.05.

**Table 1:** t-test Pre-Fatigue v Post-Fatigue

### Results and Discussion

There were significant differences (P>0.05) observed throughout the study with the exception of the Y and Z axes of the Right Knee Angle during all phases with both Driver and 7 Iron and also the 7 Iron at the Top of the Backswing for all joint angles. However, the scattering pattern of data displayed as significant differences does highlight similarities for both the Driver and shorter 7 Iron club particularly at the phases of the swing with higher Club Head Speed (CHS) (Acceleration, Impact and Early Follow Through).

### Conclusions

The results of this study show that there were no significant differences displayed for the Y and Z axes of the Right Knee Angle during all phases with both clubs. The variability in the p values with respect to the joint angle and golf swing phases highlight the changes between the Pre-Fatigue and Post-Fatigue swings.

### Summary

The aim of this work is to propose and validate a semi-automatic procedure, including bone segmentation and ICP-based bone registration, for the reconstruction of bone kinematics in the foot and ankle through Weight-Bearing CT. The semi-automatic segmentation is compared to manual one and the overall accuracy of the procedure is addressed.

### Introduction

Several methods are available to measure the human bone absolute and relative motion from in-vitro and in-vivo experiments [1]. When the structures under investigation become complex and the number of bones to be tracked grows, motion is often reconstructed from a series of static 3D scans [2]. In this case, the challenge is to define a fast yet accurate procedure for the elaboration of the dataset. Typically, this involves segmentation and registration: assessing the accuracy and the computational time of these operations is crucial. The aim of this study is to propose a procedure consisting in a semi-automatic segmentation, evaluated in terms of processing time and DICE score with respect to a manual segmentation, and an automatic ICP-based registration process. Also, a method for the accuracy quantification of the reconstructed bone motion is proposed.

### Methods

The full procedure for bone kinematics reconstruction is based on two steps: 1) segmentation of all scans, 2) registration of each bone of a reference scan to the corresponding bone model in each scan.

Semiautomatic segmentation is tested on three feet, scanned in a Cone Beam CT. Firstly, each foot is divided into two parts by cropping the CT scan in Slicer 4.10, to reduce the amount of data to be processed at once. The segmentation is carried out in MITK software: firstly, bones are identified by a single bound threshold (fig. 1.1), whose lower bound is manually varied between 280 and 400 Hounsfield Units to minimize the overlap among bones. If necessary, bones are further manually separated (fig. 1.2). Then, each bone segmentation is completed by morphological operation: closing (structuring element: ball; radius:18 mm) and filling (fig. 1.3). A smoothed stl model is then created. To assess the

quality of segmentations, DICE score [3] was used, comparing manually and semiautomatically segmented talus, intermediate cuneiform and first metatarsus, for all the feet.

Anatomical reference systems for each bone are defined at the neutral scan. Bone registration is performed by an ICP-based automatic algorithm defined in Matlab (fig 1.4) from the neutral to the specific scan, to define bone kinematics. To assess the accuracy of the overall procedure, bone motion is simulated with a set of 5 synthetic scans obtained by applying 5 rigid rototranslations to the DICOM files of the neutral position through Slicer and by resampling them. The transformations are chosen randomly within the foot range of motion. These scans are processed with the procedure and the computed kinematics is compared with the imposed motion. For the sake of simplicity, analysis is limited to 2 feet and to talus, intermediate cuneiform and first metatarsus.

### Results and Discussion

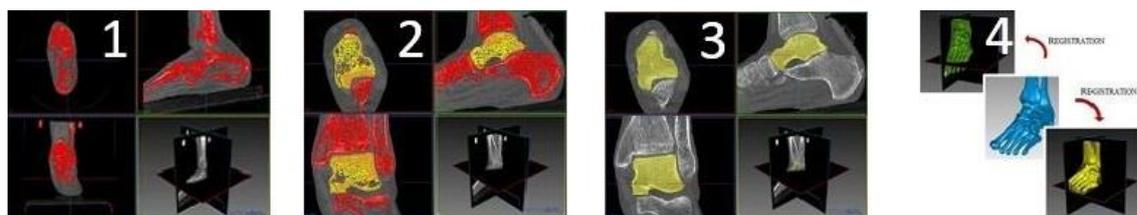

DICE score has a minimum value of 94.5% for the intermediate cuneiform and a maximum value of 98% for the talus. The average value is  $96.4\% \pm 1.0$ , higher than what found in the literature for fully automated segmentation algorithms [3]. The process time is about 2 hours to segment a foot scan (14 bones excluding toes). The operator time is mainly devoted to the separation of the cuneiforms. In comparison, manual segmentation requires 12 hours. The overall registration accuracy is  $0.37^\circ \pm 0.30^\circ$  and  $0.09 \pm 0.08$  mm. The worst accuracy is in the reconstruction of the intermediate cuneiform ( $0.53^\circ \pm 0.23^\circ$  and  $0.09 \pm 0.08$  mm). The lowest values are found for talus  $0.13^\circ \pm 0.06^\circ$  and  $0.09 \pm 0.09$  mm.

### Conclusions

A fast and accurate semiautomatic procedure for computing the bone kinematics of the foot-ankle complex is presented. The need of an operator to guide the segmentation is balanced by the high accuracy achievable. This procedure has been successfully employed for the investigation of 3 feet.

# The project RefLabPerform - Development of a reference laboratory for the evaluation of playing- and performance-related dysfunctions of performing artists to derive individual prevention and rehabilitation strategies

Dirk Möller, Florian Avermann, Christoff Zalpour

Department of Movement and Rehabilitation Science, University of Applied Sciences, Osnabrück, Germany  
Email: d.moeller@hs-osnabrueck.de

## Summary

Performing artists are a socially relevant group through numerous forms such as dance, music or singing. In contrast to competitive athletes, however, medical and therapeutic care tends to be inadequate, which is seen as a contributing factor to the high prevalence of musculoskeletal complaints in this group. The project RefLabPerform is developing a reference laboratory for the assessment of neuromusculoskeletal disorders with the support of physiotherapeutic diagnostic methods in combination with biomechanical motion analyses. This also includes the automatized merging of physiotherapeutic assessment results with biomechanical analysis results to an individual treatment recommendation with decentralized health care suggestions for a home-based therapy on evidence-based prevention and rehabilitation strategies.

## Introduction

Performing artists are exposed to high levels of strain, e.g. from rehearsals or performances. This is comparable to the strains of athletes, but performing artists additionally strive for the perfect dance performance or the perfect sound in a concert. Competitive athletes receive optimal medical care in their sport clubs, olympic or state sports centers. In contrast to this, there is no nationwide supply of performing artists, only on their own initiative they get a better medical care. A consequence of this inadequate supply is the high prevalence of neuromusculoskeletal complaints.

The aim of RefLabPerform is to develop a reference laboratory for the assessment of neuromusculoskeletal disorders using manual physiotherapeutic assessment methods in combination with biomechanical motion analysis.

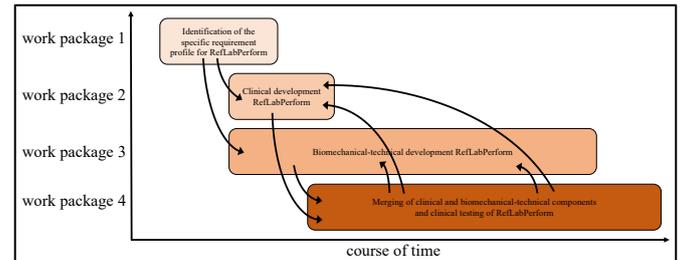

## Methods

Several work packages are carried out systematically (fig. 1):

1. Identification of the specific requirement profiles for the different performing artist groups.
2. Development of the individual physiotherapeutic protocols, prevention and rehabilitation strategies as well as the biomechanical setup and the technical routines of the laboratory.
3. At the same time, various biomechanical analysis protocols will be developed and at the end of this work package these protocols will be merged with the physiotherapeutic protocols.
4. Overlapping with the previous work packages, the reference laboratory will be continuously tested for application and feasibility. Clinical and biomechanical

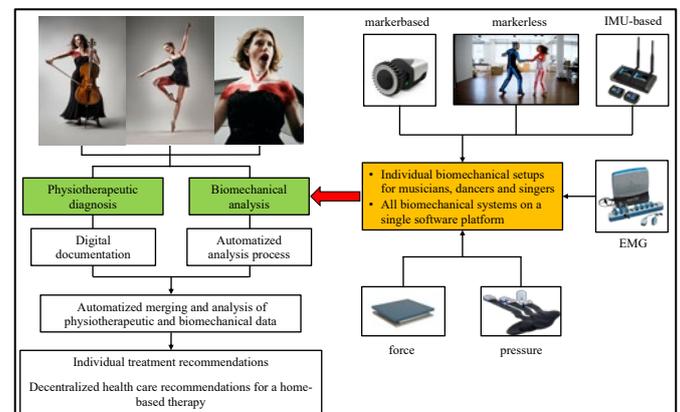

data will be merged and checked on the basis of individual case studies from various groups of performing artists.

As a part of an iterative agile software development process, the results flow back into the previous work packages in order to optimize them and then test them again.

**Figure 1:** Overview of the work packages and their content-related iterative interaction for the development of RefLabPerform.

The biomechanical setups are individually adjusted to the respective performing artist groups, so that an optimal data collection can take place from a temporal and qualitative point of view. Therefore, a mixture of different biomechanical capture methods is also considered (fig. 2).

**Figure 2:** Structure of data collection and application possibilities of the biomechanical assessments according to individual requirements of the performing artists.

## Results and Discussion

At the end of this project a functional and proven reference laboratory for the comprehensive clinical and biomechanical analysis of performing artists will be developed.

## Conclusions

This reference laboratory will be specialized for the diagnosis and treatment of neuromusculoskeletal disorders of performing artists using manual physiotherapeutic assessment methods and the biomechanical motion analysis.

# Step length asymmetry is associated with fear of falling activity avoidance in persons with unilateral transtibial amputation

Noah J. Rosenblatt<sup>1</sup>,

<sup>1</sup>Center for Lower Extremity Ambulatory Research, Rosalind Franklin University of Medicine and Science, North Chicago, USA

Email: [noah.rosenblatt@rosalindfranklin.edu](mailto:noah.rosenblatt@rosalindfranklin.edu)

## Summary

The extent to which gait symmetry in persons with transtibial amputation (pTTA) should be a rehabilitation goal is questionable. Given that step length (SL) asymmetry in pTTA may impart stability, we explored the extent to which gait asymmetry in this population was associated with perceptions of gait that can impact activity. Symmetry indices (SI) for spatiotemporal gait parameters were correlated with measures of balance and gait self-efficacy, based on which we conclude that longer prosthesis side steps and single support time may promote self-efficacy and limit fear of falling (FoF)-related activity avoidance

## Introduction

Low balance confidence and FoF are prevalent yet overlooked issue among prostheses users [1] that can significantly limit activity. Many studies have evaluated gait characteristics associated with FoF in intact older adults, but, to our knowledge none have done so in pTTA. Whereas older adults display fairly symmetric gait, asymmetry is common in persons with amputation. For example, pTTA often display greater SL with their prosthesis. However, as this may represent a functional adaptation to, rather than a negative consequence of, amputation that helps to maintain stability and prevent a backward [2], leveraging SL asymmetry to ensure stability may facilitate balance confidence and reduced FoF; SL asymmetry may serve as a marker of self-efficacy. We evaluated the association between i) step length asymmetry and ii) measures of balance and gait self-efficacy as well as FoF-related activity avoidance. We also evaluated the associations between symmetry indices for other gait characteristics associated with FoF in intact older adults and the latter outcomes.

## Methods

This is a secondary analysis of data collected on 17 pTTA (5 F/12 M, 58.8±12.6 yrs) at the start of a larger intervention trial, prior to any intervention. Passive reflective markers were placed on body, after which participants walked across a 10m laboratory walkway 10-20 times at a self-selected pace. For each limb, the following were averaged across steps: SL; step width (SW); step time (ST); percent single support (%SS); single support time (SST); percent double support (%DS) and double support time (DST), consider only for the DS phase following heel strike of a given limb. Symmetry indices (SI) were calculated as the between-limb difference relative to the between-limb mean (SI>0 indicates

prosthetic side (P) values greater than non-prosthetic (NP) side). The following surveys were completed: i) Activity-specific Balance Confidence (ABC) scale to assess balance self-efficacy, a strong correlate of FoF; ii) Modified Gait Self Efficacy Scale (mGES) to assess gait self-efficacy; iii) Fear of Falling Avoidance Behavior Questionnaire (FFABQ), e.g. level of agreement with “due to my FoF I avoid walking”; iv) One item from the Prosthetic Evaluation Questionnaire (PEQ) that states “Over the past 4 weeks, rate how satisfied you have been with how you are walking”. Gait variables and survey measures were correlated.

## Results and Discussion

PSL but not NPSL was significantly associated with all survey measures (Table 1). However, only FFABQ, was associated with SL SI. Neither limb-specific measures nor SI measures for SW, ST, % SS, %DS or DST were significantly associated with any survey measures. However, SST SI was significantly associated with ABC and PEQ walk (Figure 1); greater PSST relative to NPSST was associated with greater confidence and gait satisfaction.

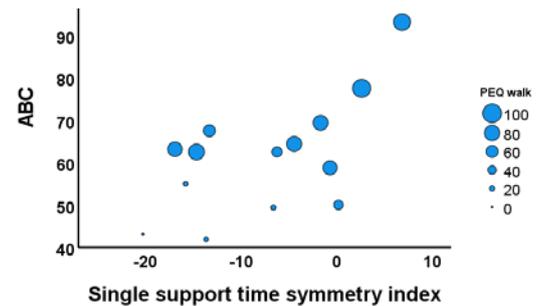

Figure 1: ABC vs. SST SI; bubble size relative to PEQ question.

## Conclusions

Longer P side steps (reliant on NP push off) and longer relative PSST (reliant on P side balance) may promote self-efficacy and limit FoF-related activity avoidance. Fostering symmetry in rehabilitation may not be desirable.

## Multi-digit Force Coordination in Patients with Trigger Digit using Machine Learning and Deep Learning

Kien Tran<sup>1</sup>, Hsiao-Feng Chieh<sup>1</sup>, Chien-Ju Lin<sup>1,2</sup>, Po-Tsun Chen<sup>3</sup>, Fong-Chin Su<sup>1,2</sup>

<sup>1</sup>Department of Biomedical Engineering, <sup>2</sup>Medical Device Innovation Center, National Cheng-Kung University, Tainan

<sup>3</sup>School of Physical Therapy, Chang Gung University

Email: tkien.billy@gmail.com

### Summary

This research presents a machine learning approach to analyze multi-digit force coordination in subjects with and without trigger digit symptoms.

### Introduction

Trigger digit (TD) is a common symptom in hand, that affects motor coordination, and results in hand functional impairment. Previous studies used cylindrical grasp to investigate finger force coordination during precision grasping of TD patients. Data characterizing five-digit force coordination is commonly high-dimensional, complex, and dynamic. There is a lack of studies to process this type of data in dynamic and multivariate ways. To compensate for this problem, it will be interesting to utilize machine learning method of predictive models for data mining.

The purpose of this study is to first develop a machine learning and deep learning model to classify healthy subjects and trigger digit patients. After that, we analyze the post-trained model to investigate applied force differences between two group of subjects

### Methods

Forty-four healthy subjects (39.5 years  $\pm$  7.6) and fifty-four TD patients (57.6 years  $\pm$  8.0) with involved digit were included in this research. Patients with affected digit include 11 patients with thumb, 7 patients with index finger, 17 patients with middle finger, 12 patients with ring finger, 3 patients with index and ring fingers, and 4 patients with middle and ring fingers.

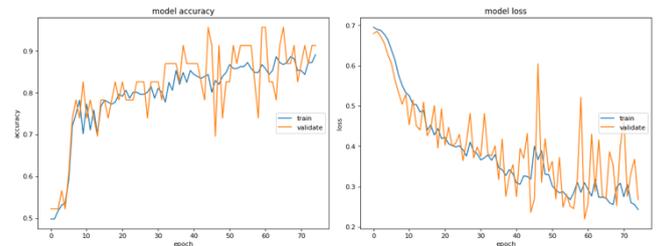

The participants performed a grasping task: grasped and lifted the simulator to the height of 20 cm then hold it stably for at least three seconds and lowered it to the original position.

A machine learning model (Random Forest) and a deep learning model (1D-CNN) are used to map force data to given subject status. Two models are trained and validated by 10-fold cross-validation in intra-subject (trial-mixed) and inter-subject (subject-mixed) datasets. A separated testing set was also used to test the performance of the two models. The Random Forest model is analyzed by feature importance calculation. The 1D-CNN model is analyzed by Grad-CAM.

### Results and Discussion

Cross-validation and testing mean accuracy of RF are 79% and 85% for intra-subject while 81% and 86% for inter-subject. Cross-validation and testing accuracy of 1D-CNN are

84% and 85% for intra-subject while 71% and 77% for inter-subject.

**Figure 1:** Accuracy and loss graph of model training.

Feature importance shows that the duration of trials is the most important. Grad-CAM model shows that the model pays most attention to the holding phase

### Conclusions

By using machine learning methods, we can classify healthy subjects and trigger digit patients. The duration of trials is an important factor that should be controlled in the experiment setting. The stability holding phase reveals important features and should be investigated in future studies.

## Inter-session repeatability of markerless motion capture gait kinematics

Robert Kanko<sup>1</sup>, Elise Laende<sup>1</sup>, W. Scott Selbie<sup>2</sup>, Kevin J. Deluzio<sup>1</sup>

<sup>1</sup>Mechanical and Materials Engineering, Queen's University, Kingston, Canada

<sup>2</sup>Theia Markerless, Inc., Kingston, Canada

Email: r.kanko@queensu.ca

### Summary

This study examined the repeatability of lower limb gait kinematics measured using *Theia3D* markerless motion capture software and compared the results to previously reported repeatability of marker-based systems [1-4]. Subjects' joint angle waveforms were found to be consistent across multiple sessions. The average inter-trial variability (2.5°) was slightly greater and the average inter-session variability (2.8°) was slightly lower than previously reported for marker-based systems, indicating that markerless motion capture is somewhat less affected by multi-session protocols than marker-based systems.

### Introduction

Three-dimensional (3D) human movement analysis is a widely used tool to quantify individuals' movement patterns, particularly gait. These data have typically been collected using marker-based motion capture, which relies on skin-mounted markers that require expert operators for their placement, dedicated laboratory space for their use, non-negligible subject preparation time, and the sacrifice of subject comfort while collecting data.

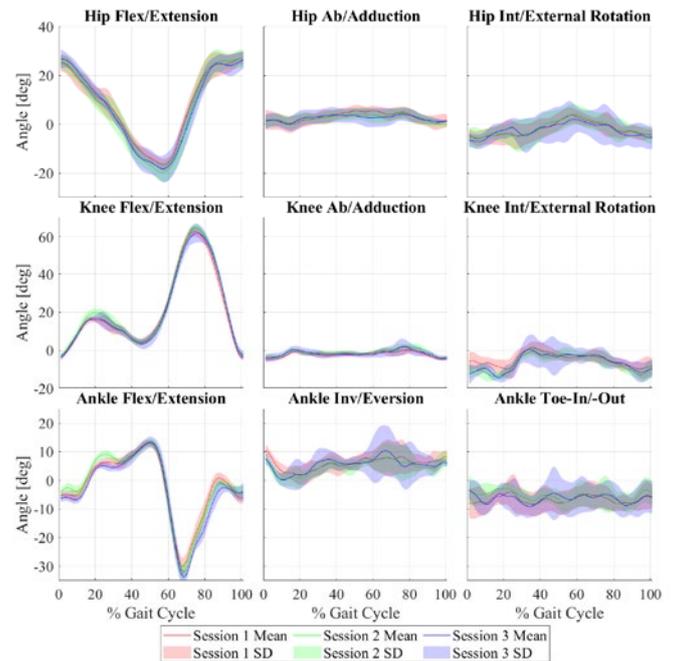

Markerless motion capture is a quickly evolving technology that offers an alternative to measure human movement with fewer practical limitations. *Theia3D* (Theia Markerless Inc., Kingston, Canada) is one such system which uses deep neural networks trained on >500,000 labelled images of humans in the wild to estimate the position of subjects' anatomical landmarks in videos recorded by an array of synchronized cameras. The objective of this work was to determine the repeatability of lower-limb gait kinematics measured using *Theia3D* and compare the results to previously reported values for marker-based systems.

### Methods

Eight healthy adults (2/6 female/male, mean: age 30.3 years, height 173.8 cm, mass 69.0 kg) each attended three separate collection sessions separated by an average of 8.5 days, wearing their own everyday clothing of choice. During each session, subjects performed five over-ground walking trials at self-selected speeds while synchronized video data were recorded using eight Sony RX0 II video cameras (Sony Corp., Minato, Japan). Videos were processed in *Theia3D* to obtain 3D pose estimates which were further analyzed in *Visual3D* (C-Motion Inc., USA). Measures of inter-trial and inter-session variability of lower limb joint angles were calculated based on an established method [1] and compared to previously reported values for marker-based systems [1-4].

### Results and Discussion

The time required for each session was typically between five and ten minutes. Session average joint angle waveforms showed that subjects' gait patterns were measured consistently across all three sessions (Figure 1).

**Figure 1:** Mean +/- SD joint angle patterns for three sessions from one representative subject, measured using *Theia3D*.

The average inter-trial variability of the markerless gait kinematics was 2.5°, the largest among the included studies by a margin of 0.1°. The average inter-session variability of the markerless gait kinematics was 2.8°, the smallest among the included studies by a margin of 0.2°.

### Conclusions

The results demonstrate that gait kinematics measured using *Theia3D* are somewhat less affected by the use of a multi-session protocol compared to marker-based systems. The slight increase in inter-trial variability in combination with the decreased inter-session variability and ease of data collection is an acceptable compromise because of the potential for substantially more accessible data collections.

## Summary

The overall goal of this work was to develop an inexpensive and portable tool capable of quantifying lumbar spine motion in the field using a red-green-blue-depth (RGB-D) time-of-flight camera. Specifically, we created a novel framework that takes the RGB-D data and manipulates them to measure 3-D lumbar spine kinematics during dynamic trunk flexion. To achieve our goal, we carried out two independent research studies: 1) the development and validation of a custom computer vision method to track infrared (IR) reflective markers from raw depth data to calculate 3-D spine angles; and 2) development and validation of a custom four module convolutional neural network (CNN; SpineNet) to track and automatically segment regions of each participant's back to calculate 3-D kinematics without the use of any markers.

## Introduction

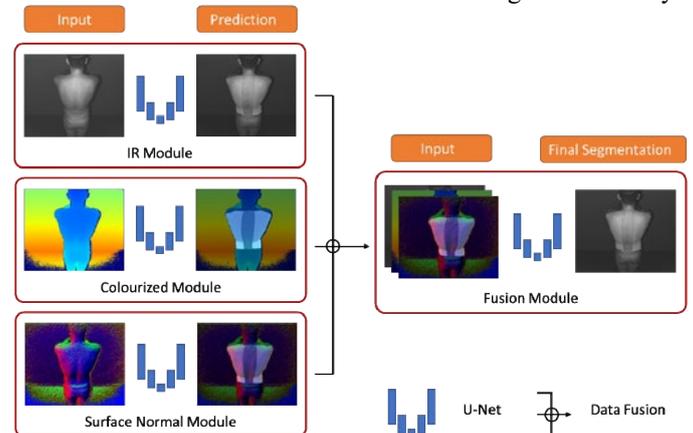

In order to better understand motor control and biomechanical differences between low back pain patients and healthy controls, researchers and clinicians often observe movement patterns and quality during pre-defined tasks (e.g., trunk flexion-extension) [1]. Recently, a great amount of work has been undertaken to validate the use of portable inexpensive sensors such as inertial measurement units (IMUs) to measure 3-D spine motion during dynamic tasks in the field [2]; however, an alternative approach is to use RGB-D cameras [3]. While many research studies have been carried out in the biomechanical domain using RGB-D cameras [3], few have attempted to measure spine motion [4], and none have done so during dynamic trunk flexion tasks with or without markers. Through two studies we aimed to address this research gap.

## Methods

**Study 1:** 12 healthy young adults (6M, 6F) were recruited to perform repetitive spine flexion-extension, with infrared reflective marker clusters placed over their T<sub>10</sub>-T<sub>12</sub> spinous processes and sacrum, and motion capture data were recorded simultaneously by one RGB-D camera and a 10-camera optoelectronic motion capture system. Custom computer vision algorithms were developed to extract spine angles from depth data. Root mean square error (*RMSE*) was calculated for continuous Euler angles, and intraclass correlation coefficients (*ICC*<sub>2,1</sub>) were calculated between min, max, and average range of motion angles in all movement planes for both systems.

**Study 2:** A single RGB-D camera captured infrared, depth, and colour image data of 15 male participants performing two batteries of 10 cycles of repetitive trunk flexion-extension under two conditions: marked (i.e., hand drawn markers on key anatomical locations on the back) and unmarked. The collected data were used to create a custom four module convolutional neural network (CNN; SpineNet) (Figure 1 – based on [5]) to segment the back into upper, lower, and spine regions and then to extract lumbar spine kinematics. SpineNet

was trained and tested on ten marked participants in a train:test ratio of 80:20. Images of five additional participants without markers were used to evaluate model generalizability.

**Figure 1.** CNN architecture. Each RGB-D camera data stream was used as input for each of the three individualized U-Net modules. Individual modules' anatomical segmentation predictions were then fused and used as input for the final U-Net segmentation module.

## Results and Discussion

**Study 1:** *RMSE* in angles between the two calculation methods were very low across all movement axes ( $RMSE \leq 2.05^\circ \pm 0.97^\circ$ ), and *ICC*<sub>2,1</sub> values were good to excellent across all axes ( $0.849 \leq ICC_{2,1} \leq 0.979$ ). Bland-Altman plots revealed that, on average, the RGB-D camera slightly underestimated lumbar flexion-extension angles ( $-1.88^\circ$ ) and overestimated lumbar lateral bending and axial twisting angles ( $\leq 0.58^\circ$ ).

**Study 2:** Quantitative image segmentation analysis on marked data had good similarity (frequency weighted intersection over union  $\geq 0.8087$ ) and accuracy (mean pixel accuracy  $\geq 0.8855$ ) between the prediction and ground truth across all modules. Qualitative image segmentation analysis on unmarked data showed that colourized and surface normal modules presented a more robust class morphology throughout frames than infrared and fusion modules. Kinematic analysis on unmarked participants showed that flexion-extension angles exhibited movement profiles (i.e., shape, timing, and peaks) that are comparable to similarly collected data from previous research.

## Conclusion

This work provides proof for using a single RGB-D camera for assessing lumbar kinematics with or without markers.

## Summary

Fragile X Syndrome (FXS) is a genetic condition, mainly characterized by intellectual disability, behavioral problems and musculoskeletal alterations. In order to classify FXS subjects' motor deficits for assisting in clinical decision making, a supervised classification was performed by adopting kinematics and sEMG parameters combined together or isolated as input variables. The set of parameters that was more efficient in discriminating between FXS subjects and controls was determined.

## Introduction

FXS is the leading form of inherited intellectual disability and autism spectrum disorder, caused by a tri-nucleotide CGG repeat expansion in the promoter region of the FMR1 gene [1]. In these subjects, the frequent musculoskeletal manifestations, such as ligamentous laxity and flat foot [1], justifies a referral for gait analysis evaluation.

Supervised classification is generally used to find the relation between the input parameters and the target variable [2] that in our contest is represented by the presence of musculoskeletal alterations associated with FXS. The aim of the present study was to find out which set of gait and sEMG analysis parameters were the most useful to discriminate between controls and FXS subjects, for assisting in clinical decision making.

## Methods

After appropriate informed consent by the parents, 20 FXS children ((FX) mean ( $\pm$ SD) age and BMI respectively of 10,00 ( $\pm$ 3,74) years and 18,57 ( $\pm$ 3,46) Kg/m<sup>2</sup>) and 16 controls ((CS) mean ( $\pm$ SD) age of 10,22 ( $\pm$ 3,19) years and 22,84 ( $\pm$ 3,93) BMI of Kg/m<sup>2</sup>), were evaluated at the Bioengineering of Movement Laboratory of the Department of Information Engineering and at the Women and Children Health Department of the University of Padua. Kinematics and sEMG data were simultaneously acquired through four synchronized cameras (GoPro Hero3, 30fps) and an 8 channel sEMG system (FreeEmg, BTS, 1000Hz) that collected the activity of Tibialis Anterior (TA), Gastrocnemius Lateralis (GL), Rectus Femoris (RF) and Biceps Femoris (BF). Each subject performed several gait trials and at least three trials per subject were processed. The following sEMG parameters were extracted: duration of muscle contraction, onset and offset activation timing [3], peak of the envelope and its occurrence [4] and number of co-contractions and their occurrence. The following kinematic parameters were also estimated: minimum and maximum values of lower limb joints angles (hip, knee and ankle) and their range of motion

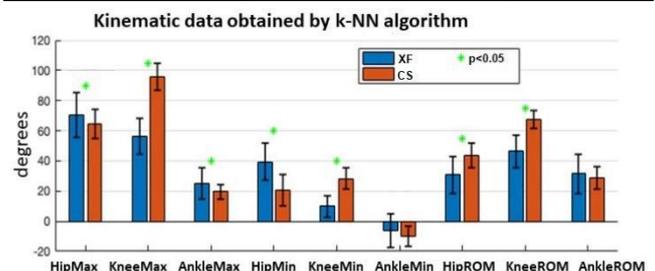

(ROM) [5]. Supervised classification by means of 7 different classifiers was performed: Decision Tree, Random Forest, CN2 Rule Induction, SVM, k-NN, Neural Network and Naïve Bayes on 3 different sets of vectors: S1 sEMG parameters only; S2 kinematic parameters only; S3 combined sEMG and kinematic parameters.

## Results and Discussion

The best classification on a training set (66% of subjects) were obtained by applying k-NN algorithm for S2 and Random Forest for S1 and S3; hence it was further tested on a test set (33% of subjects) (Table 1 and Fig. 1).

**Table 1:** Performance of the most performant classification algorithms on training and test data.

Set of vectors	S1	S2	S3
Algorithm	Random Forest	k-NN	Random Forest
Training set acc (%)	98,3	100,0	99,2
Test set acc (%)	98,3	100,0	96,7

**Figure 1:** Kinematic parameters in subjects classified as FX and CS by k-NN classifier, \*-statistically significant difference (p<0.05)

## Conclusions

All the analyzed solutions allowed a good classification of FXS subjects, yet using only kinematic data allowed a better classification. This suggests that the most evident differences in motor control between CS and FX subjects can be detected by analysing kinematic parameters.

# Ankle Joint Quasi-Stiffness of Quiet Unperturbed Standing in Chiari Malformation: A Fast Fourier Transform Approach

Brittany N. Sommers<sup>1</sup>, Brian L. Davis<sup>1</sup>

<sup>1</sup>Center for Human Machine Systems, Mechanical Engineering Department, Cleveland State University, Cleveland, Ohio, USA  
Email: b.n.sommers@vikes.csuohio.edu

## Summary

Ankle joint quasi-stiffness (AJ-QS) is a commonly reported parameter in gait but not upright standing. The AJ-QS calculation of upright standing is more ambiguous due to the instantaneous fluctuations of the center-of-pressure (COP). This abstract presents a novel technique for quantifying AJ-QS in upright standing via a Fast Fourier Transform (FFT). This method identifies the natural frequency of COP trajectories and uses the equations of motion of a second order inverted pendulum to calculate AJ-QS. This method is advantageous as it (1) is not influenced by instantaneous fluctuations of muscular noise, and (2) allows for consideration of the entire COP signal. This study involved 30-second, unperturbed standing trials on individuals with Chiari Malformation (CM), a neuromuscular condition arising from the cerebellum. Joint stiffness is a main qualitatively reported symptom of CM, however this is the first study to quantitatively report AJ-QS in CM.

## Introduction

Chiari Malformation (CM) is a congenital neuromuscular condition occurring from a descent of the cerebellar tonsils into the foramen magnum. There is no cure for CM, however a decompression surgery can be implemented to reduce pain from specific symptoms. Suboccipital headaches, joint stiffness, and loss of motor control are a few of the commonly reported symptoms of CM. [1]

During quiet standing, the ankle joint complex is influenced by rotations about the ankle to maintain alignment of the center-of-mass (COM) over the heel [2]. Often, the ankle joint is modeled as a single inverted pendulum, where center-of-pressure (COP) fluctuations are used to realign the COM [2]. In gait, ankle-joint quasi stiffness (AJ-QS) is calculated as the relationship between the ankle torque and ankle angle. This method in upright standing is not practical due to the instantaneous fluctuations of muscle dynamics on the COP. Thus, using a FFT to calculate the natural frequency of the COP, we can estimate AJ-QS from the relationship of undamped natural frequency, stiffness, and inertia. To the authors knowledge, this is the first study to (1) Quantify AJ-QS using an FFT, and (2) to Quantitatively report AJ-QS in individuals with CM.

## Methods

The study consisted of six CM participants with decompression surgery (CM-D) and six CM participants without (CM-ND). All participants were female. Participants were asked to stand on an AMTI force plate with their eyes open, feet together, and hands comfortably at their sides for 3, 30-second trials to obtain the anterior-posterior (AP) COP trajectories. Data were recorded at 1000 Hz, and down

sampled to 100 Hz for analysis. COP trajectories were zero-centered before applying the FFT to determine the natural frequency. Natural frequency ( $\omega_n$ ) and stiffness ( $k$ ) are then related by the equation:

$$\omega_n = \sqrt{\frac{k}{(I_T)/2}}$$

Where  $I_T$  is the total moment of inertia of the body, divided in half to account for the distribution of two feet standing on one force plate.  $I_T$  anthropometric values were obtained [2] and rotations were considered about the distal axis for each segment.

## Results and Discussion

The CM-D group presented higher average AJ-QS, natural frequencies ( $\omega_n$ ), and peak power spectral density (pPSD) values from the FFT than CM-ND. With the limited sample size, only pPSD was significant ( $p = 0.032$ ).

Table 1: Group averages of quasi-stiffness and FFT variables

Group	AJ-QS [kgm <sup>2</sup> s <sup>-2</sup> ]	$\omega_n$ [Hz]	pPSD [db/Hz]
CM-D	0.098 ± 0.089	0.098 ± 0.062	82.0 ± 47.9
CM-ND	0.068 ± 0.096	0.076 ± 0.046	23.5 ± 19.1

It is hypothesized that the CM-D group has more severe cerebellar damage than the CM-ND group, as decompression surgery is only performed for more severe malformations. Feedback to the cerebellum affects postural sway. Higher natural frequencies and greater power distributions are seen in the group with more neural pathway damage, and *vice versa*.

## Conclusions

To the authors knowledge, this abstract presents the first instance of quantifying ankle joint quasi-stiffness in quiet, unperturbed standing via FFT. This method eliminated the need for motion capture data and is not sensitive to muscular noise. This method revealed the affect of cerebellar damage on natural frequency of the system and mechanical stiffness of the ankle joint. The authors expect to have control data for comparison by the time of the conference.

## Ground Reaction Forces during Anteriorly-loaded Overground Walking

Jiyun Ahn<sup>1</sup>, Caroline Simpkins<sup>1</sup>, Meng-Wei Lin<sup>1</sup>, Feng Yang<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Health, Georgia State University, Atlanta, GA 30303, USA

Email: jahn12@gsu.edu

### Summary

This study examined the effects of anterior load carriage on ground reaction forces (GRFs) in the sagittal plane during overground level walking. The hypothesis was that anterior loading would change the GRFs during overground walking. Thirty healthy young adults were assigned into three groups (no load, 10%, and 20% body weight (bw)) and their GRFs were measured. The results did not show any significant group-related difference in the peak values of the vertical, forward (or propulsive), and backward (or braking) GRFs.

### Introduction

Falls are a significant workplace accident leading to a diverse outcomes such as injuries and economic strain [1]. The literature highlights the frontal load as one of the major occupational fall hazards. The existing studies about front-weighted walking mainly focused on the kinematic gait parameters. Despite meaningful, these parameters may not provide comprehensive information explaining the potential impact of front load carriage on gait. It is necessary to study how the front load carriage affects the kinetic aspect of human gait, in particular the GRFs. A recent study used the GRF as an outcome measurement [2]. It reported that the peak GRF increased among the loaded groups by an amount of the carried weight than unloaded groups. However, there are limitations associated with this previous study. First, participants in this past study walked on a treadmill. The controlled gait speed could have altered the natural gait pattern when walking over the ground. Therefore, the finding from the previous study may not be applicable to overground walking. Second, the GRFs were reported in Newtons but not normalized in the previous study. Given that the loaded groups carried an extra weight, it is intuitive that their absolute GRFs would be greater than the unloaded groups. To address these two limitations, we conducted this present study to test how frontal load alters the normalized peak GRFs during overground level walking. It was hypothesized that the frontal load carriage alters the peak GRFs during overground walking.

### Methods

Thirty healthy young adults ( $24.83 \pm 4.96$  y/o) were randomized into three groups: no load (Group 1), 10% (Group 2), and 20% bw (Group 3). Each participant had three walking trials on a 10-m walkway at their preferred speed without load. Then, Groups 2 and 3 walked three more trials with their assigned load assembled in a sandbag. During walking, the loaded groups were instructed to hold the sandbag against their abdomen using both hands in a symmetric way and try to maintain the height of the load. Group 1 completed another three normal walking trials without a load.

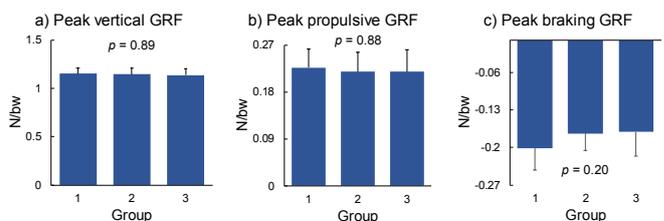

Two force plates (ATMI) embedded in the middle section of the walkway collected the GRFs during all walking trials. The vertical, forward, and backward GRFs were filtered and normalized by the weight of the body-load system (including the weight of the human body and the external load). The peak GRF in each direction was determined as the maximum value of the respective GRF over a gait cycle. One-way ANOVA compared the dependent variables (peak vertical,

forward, and backward GRFs) with the load level as the factor (0% vs. 10% vs. 20% bw). SPSS 25 (IBM) was used with a significance level of 0.05.

### Results and Discussion

The results did not show a significant load level-related effect on GRFs in all three directions ( $p = 0.89, 0.88,$  and  $0.20$  respectively for vertical, propulsive, and braking forces, Figure 1). Our hypothesis that the frontal load changes the GRFs while walking was not supported. A recent study reported significant differences in peak GRFs when participants carrying a front load walk on a treadmill [2]. However, the non-normalized GRFs in the previous study could introduce a confounding effect due to the variations in the body weight between groups. In the current study, the GRFs were normalized to the combined weight of the human body and the load. As stated, the normalized GRFs did not exhibit a load-related difference. Furthermore, participants in our study walked over the ground instead of on a treadmill. The GRF information should more closely reflect the natural human walking in our study than the previous one.

The finding of similar peak vertical GRF between groups in this present study did not agree with another previous study that reported an additional frontal load increases the normalized peak vertical GRF during walking [3]. The discrepancy could be due to the difference in selecting the peak vertical GRF between the two studies. In the previous study, the peak vertical GRF was determined as the maximum vertical GRF during the loading phase of the gait cycle, while the current study selected the global peak value over the entire gait cycle. Further studies should examine the change in the GRFs while carrying a front load heavier than 20% bw.

**Figure 1.** Between-group comparisons of the peak GRF in three directions: a) vertical, b) forward, and c) backward during overground walking.

### Conclusion

Anteriorly carrying up to 20% bw may not change the normalized peak GRFs in sagittal plane during overground walking among young adults.

## Automatic Identification and Segmentation of Balance-Related Tasks Using Markerless Motion Capture

Kieran J. Eveleigh<sup>1</sup>, Elysia Davis<sup>1</sup>, Elise Laende<sup>1</sup>, Scott Selbie<sup>2</sup>, Stephen H. Scott<sup>3</sup>, Kevin Deluzio<sup>1</sup>

<sup>1</sup>Department of Mechanical & Materials Engineering, Queen's University, Kingston, Canada

<sup>2</sup>Theia Markerless Inc., Kingston, Canada, <sup>3</sup>Department of Biomedical & Molecular Sciences, Queen's University, Canada  
Email: kieran.eveleigh@queensu.ca

### Summary

An algorithm was developed to identify the onsets and offsets of seven balance-related tasks performed consecutively in a circuit, using data from a markerless motion capture system. The algorithm identified events 116 times faster than two raters. Intraclass correlation coefficients for all task onsets and offsets were between 0.999-1.000.

### Introduction

Many clinical assessments of balance include multiple tasks that are performed in succession [1]. Patient performance is often assessed qualitatively. An alternate approach is to use motion capture systems, but it can be laborious to identify key task features such as the beginning and end of a motor action.

The purpose of this study was to (1) develop an algorithm to identify the starts and ends of seven distinct balance-related tasks using data from a markerless motion capture system and (2) to compare the algorithm's performance to manually identified tasks.

### Methods

This investigation was carried out in the Human Mobility Research Laboratory (Queen's University, Kingston, ON) and was approved by the institutional ethics review board. Fifteen adults (8 female, mean (SD) age: 34.5 (17.2) years, height: 172.0 (7.8) cm, weight: 75.0 (10.7) kg) participated in this study after providing informed consent.

Participants completed seven balance tasks as part of a larger circuit of clinical assessments. Balance tasks included: tandem stance (TS), functional reach (FR), single limb stance (SLS), shoulder abduction (SA) and rotation (SR), standing hip abduction (HA) and quiet standing on foam with eyes closed (QS). Each participant performed five trials of the circuit, while eight synchronized video cameras recorded video data at 60 Hz.

Kinematic measures were extracted from video data using Theia3D (Theia Markerless, Inc., Kingston, ON) and filtered in Visual3D (C-Motion Inc., Germantown, MD) using a generalized, cross-validatorspline smoothing and differentiation function with a cutoff frequency of 5 Hz. Matlab (MathWorks, Natick, MA) was used for data analysis.

Full body segment kinematic data were used to identify onsets and offsets of the tasks, regardless of the order in which they were performed. All tasks were identified according to the same approach: onsets and offsets of potential instances of a task were identified using primary kinematic features [2], and true occurrences of each task were identified using multiple secondary requirements. The algorithm was developed using pilot data, then tested using the data collected in this study.

Two raters independently used video data to identify the onset and offset of each balance-related task by frame number for one randomly selected trial from each participant. The time taken to label all tasks within a trial was recorded.

The algorithm's performance was compared to the two raters using a two-way, mixed-effects, absolute agreement, single measures intraclass correlation coefficient (ICC). All ICC estimates and their 95% confidence intervals (CI) were calculated using SPSS (SPSS Inc., Chicago, IL).

### Results and Discussion

The algorithm identified all seven balance-related tasks in each of the 15 trials. The average processing time for a single trial for the algorithm was 6 s, compared to 697 s for the raters. ICC estimates for all tasks (Table 1) showed excellent reliability [1], indicating that the algorithm can be used to replace the manual segmentation of multiple tasks within a dataset of kinematic measures.

### Conclusions

The algorithm introduced in this paper can identify the onsets and offsets of seven balance-related tasks commonly featured in clinical assessments. It shows potential to expedite the segmentation of tasks within large motion capture datasets from balance-related studies, without compromising the correct identification of task onsets and offsets.

## Improved Balance Control Following Distance Learning of Yoga in Novice Practitioners

Pranavi L. Depur<sup>1</sup>, Belle P. Ponce de Leon<sup>1</sup>, Andrew Y. Cho<sup>1</sup>, Joshua A. Vicente<sup>1</sup>, Jacob W. Hinkel-Lipsker, Ph. D.<sup>1</sup>  
<sup>1</sup>Move-Learn Lab, California State University, Northridge, California, USA  
 Email: movelearnlab@gmail.com

### Summary

Due to the recent COVID-19 pandemic, there is interest among the lay public to implement effective virtual fitness paradigms. Yoga is a common form of at-home exercise that can be instructed in multiple ways—including live (synchronous) sessions or asynchronous video. In this study we examined how novice yoga practitioners learned using these different pedagogical methodologies in terms of balance control over an 8-week intervention. Early results indicate that the group that practiced using a mix of synchronous and asynchronous modalities showed the greatest improvement in balance control, followed by synchronous, while the fully asynchronous group was least effective. These results indicate that yoga practiced in an online format improves balance control, which can be highly useful to those who do not have access to traditional in-person classes, and that distance learning should incorporate both asynchronous and synchronous components.

### Introduction

Yoga is known to have many health benefits such as improved flexibility, strength, and balance control [1,2]. However these benefits have been largely unexplored when yoga is practiced via distance learning. Due to the COVID-19 pandemic, most exercise forms have moved to an online platform. Methods of instruction are generally categorized into synchronous practice where the instructor and learner are practicing in real time, asynchronous practice, where learners practice on their own time utilizing content created by the instructor, or mixed practice, which integrates both methods [3]. Based on research in online (non-fitness) education, a blended approach is the most effective in learning outcomes [3]. Due to the growing proliferation of at-home exercise models it is necessary to determine which method of content delivery is the most effective for yoga practitioners. The purpose of this study was to assess the effects of synchronous, asynchronous and mixed online content delivery from an 8-week yoga program designed for novice yoga practitioners. We hypothesized that a blend of the two modalities would lead to the greatest improvement in balance control (e.g., center of mass sway and velocity).

### Methods

Fifty-three novice participants between the ages of 18 and 65 were recruited for the study to participate in an online 8-week yoga program. Before and after the intervention, participants met over video conferencing with a member of the research team and engaged in a series of balance tests randomized in order, which included a single leg stance pose with the eyes closed, a tree pose, and an eagle pose. Markers were placed on the participants' approximate center of mass in the frontal and sagittal planes. Participants were recorded

during performance of these poses, and two-dimensional motion analysis software was used to track center of mass (COM) position. Marker coordinate data were used to quantify center of mass excursion (displacement), velocity, and total distance traveled during each pose. Following baseline testing, participants were randomly assigned to either an asynchronous, synchronous or mixed group, all of whom were instructed to complete a minimum of two classes per week where attendance was recorded. After program completion, participants again met with a member of the research team virtually to perform the balance tests using the same methodology as before.

### Results and Discussion

Preliminary results ( $n = 3$ ) demonstrate that all approaches yielded improvement to balance control; however, the mixed approach was the most effective form of instruction as their COM velocity was slowest when comparing pre-testing results with post testing results (Figure 1). Similar improvements were observed in terms of COM total excursion as well as the total distance traveled during the balance poses.

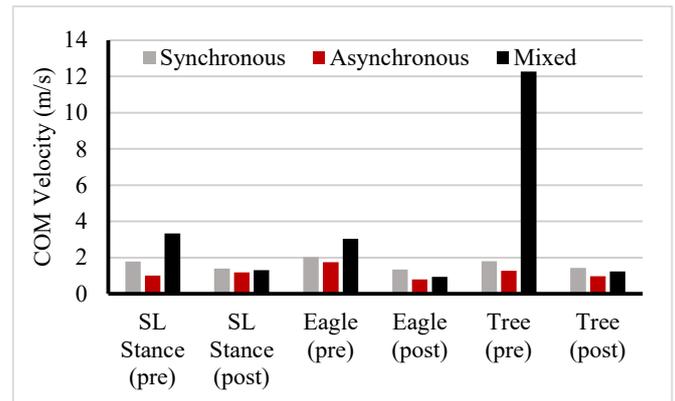

Figure 1: Pre and Post-test COM Velocity across all groups

### Conclusions

This study yielded large improvements in balance control, especially for those who used a mixed methodology. Future yoga interventions should implement both synchronous and asynchronous methods, and ensuing research should study whether different populations (e.g., older adults) respond similarly to this intervention.

## Summary

Preliminary results show that functional calibration methods are not only feasible in the clinical setting but also allow to improve the accuracy of the joint kinematics using inertial measurement units (IMU).

## Introduction

Measuring human movement in clinical settings has a long standing tradition in biomechanics. The systems vary and with the technological development movement analyses are more and more performed using IMUs. The IMUs however suffer from drift, introducing errors to the analysis. This becomes especially pertinent if gait parameters are assessed based on multiple sensors e.g. to evaluate the kinematics of a patient. Previous work has already provided solutions to overcome those problems for single sensor or single joint configurations [1] or either using post processing techniques to the lower body kinematic chain [2]. In this work we use a functional calibration method, an accelerometer-based correction tool, which ultimately allows to collect kinematic data in a magnetically disturbed spot.

## Methods

The Short Physical Performance battery (SPPB) was performed at the University hospital Kiel with healthy and neurogeriatric participants [3]. The SPPB assesses lower extremity physical function: 3 standing balance tests, a 4-meter walk at usual pace, and 5 unassisted chair stands. Participants were equipped with seven IMUs attached to the lower back, the thighs, the shanks and the feet. A functional walking trial was collected to overcome problems with magnetically disturbed clinical environment and applied to the SPPB trials. Data were collected using the MyoMotion data processing tool. The data collection is ongoing with a target sample size of 50.

## Results and Discussion

Currently 15 participants have conducted the SPPB in the clinical setting including the functional walking

calibration. The calibration procedure can be performed by all participants. Here, we show the data from one healthy participant (female, 50 years). The resulting walking kinematics are shown in (Figure 1).

Figure 1: Sagittal joint angles (hip, knee, ankle) and the corresponding inter-joint coordination plots (hip vs. knee angle) of the left and right side.

## Conclusions

The aim of this work was to present the feasibility of a calibration method to measure kinematics during the SPPB. The functional walking method proved to be feasible and produce stable results, is robust, and relatively simple to administer. Functional calibration methods are a promising direction for future wearable health monitoring systems when tracking motions in magnetically disturbed areas, such as the clinical ward [3].

## A Preliminary Study Comparing the Effects of Concurrent and Terminal Visual Feedback on Standing Balance in Older Adults

### Summary

Reductions in older adults' abilities to balance can lead to increased fall risk and other negative health effects. Balance training with a physical therapist improves balance performance and health outcomes, but access is limited by the cost and availability of physical therapy. Consequently, home-based training technologies may increase access to preventative and therapeutic balance training. This preliminary study compared the immediate and post-training effects of concurrent and terminal visual feedback to inform the design of a visual-feedback based home balance training technology.

### Introduction

Concurrent visual feedback increases training efficacy under certain conditions and has been implemented in research settings [1]. However, concurrent visual feedback cannot be used to support all types of balance training exercises (e.g., exercises performed with eyes closed or head movements). In contrast, terminal feedback has the potential to support a broader range of exercises and could be provided with ubiquitous technology such as a smartphone. The guidance hypothesis predicts that concurrent feedback yields greater immediate improvement and terminal feedback yields greater retention of improvement. However, these effects vary by task and type of feedback, and the differences in the effects of concurrent and terminal visual feedback during balance training are not well understood [2]. Therefore, the objective of this study was to perform a preliminary comparison of the immediate and post-training effects of concurrent and terminal visual feedback on older adult balance performance to inform the design of home-based balance training technologies.

### Methods

Nineteen healthy older adults participated in a single-day crossover study during which they performed multiple repetitions of standing with feet together on a foam surface while receiving either concurrent or terminal visual feedback. For each feedback type, participants completed 19 total trials consisting of four baseline trials (without feedback) followed by five repetitions of three trials (two with feedback and one without).

Postural sway data were collected using an inertial measurement unit (MTx, XSens) on the lower back and were used to calculate angular position and velocity performance features. The effects of both types of feedback were analyzed using linear mixed-effects models ( $\alpha = 0.05$ ). The effects of training with feedback (i.e., the effects of an increase in trial number with feedback) were evaluated using the model

results, and the post-training effects of feedback (i.e., the differences between baseline trials and the final trial completed without feedback) were evaluated using subsequent contrasts.

### Results and Discussion

Effects of training with feedback: Measures of sway angle (root mean square angle from vertical, RMS; 95<sup>th</sup> percentile confidence interval elliptical fit area, EA) decreased throughout the training session regardless of the type of feedback (RMS  $p < 0.001$ ; EA  $p = 0.001$ ). However, mean sway velocity increased with concurrent feedback ( $p = 0.009$ ) and decreased with terminal feedback ( $p < 0.001$ ), suggesting that participants used concurrent feedback to make many rapid postural corrections while they used terminal feedback to make fewer slow adjustments.

Post-training effects of feedback: Following the completion of the concurrent feedback training protocol, sway angles returned to baseline values (RMS  $p = 0.935$ ; EA  $p = 0.529$ ) and mean sway velocity decreased to below baseline values ( $p < 0.001$ ). In contrast, following the completion of the terminal feedback training protocol, sway angles and sway velocity both decreased to below baseline values (RMS  $p = 0.022$ , EA  $p = 0.007$ , mean velocity  $p < 0.001$ ).

### Conclusions

Both types of feedback yielded sway reductions during training. However, in the context of this study, only training with terminal visual feedback yielded small, short-term, single-task sway reductions following the completion of the training protocol. While the implication of these findings is limited by the short training duration, these preliminary results suggest that terminal visual feedback may be a viable alternative to concurrent visual feedback. Terminal visual feedback should therefore be further investigated for use in at-home balance training technologies because it may support a broader range of exercises, be compatible with smartphone platforms, and offer the potential for improved training retention.

## Changes in postural dynamics can be captured by a Wii Balance Board during standing tasks

Takashi Sado<sup>1</sup>, Kota Z. Takahashi<sup>1</sup> & Mukul Mukherjee<sup>1</sup>

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA  
email: tsado@unomaha.edu, web: <https://www.unomaha.edu/college-of-education/cobre/>

### INTRODUCTION

Variability during postural sway has been shown to characterize healthy and pathological systems. Specifically, persistence from center of pressure displacement (i.e., how variability of postural control fluctuates over time) is a useful description of postural control in healthy populations [1] and in the investigation of pathologies such as Parkinson's disease and developmental disorders. However, obtaining such measurements outside of a laboratory setting is not simple. This is because portable laboratory-grade force platforms are expensive.

Our previous study showed that the Nintendo Wii Balance Board (WBB), a cost-effective portable device was able to accurately quantify persistence and anti-persistence behaviors of postural sway in the anterior-posterior direction compared to force platform (FP) in healthy populations [2]. However, typically studies use the center of pressure displacement. In a recent study, the point-to-point velocity of the center of pressure (COPv) was shown to be more sensitive in capturing the persistence and anti-persistence behavior in postural control [3]. Therefore, the purpose of this study is to determine the effects of task conditions on postural dynamics measured using a WBB.

### METHODS

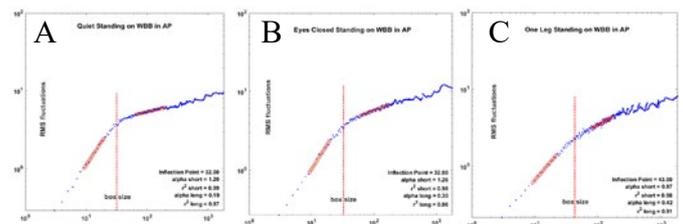

Seventeen healthy volunteers were recruited (3 females; mean age  $24.5 \pm 4.5$  years). All participants performed three different conditions for 3 minutes: quiet standing on both legs with eyes open, quiet standing on both legs with eyes closed and standing on one leg with eyes open.

The WBB was placed centrally upon a flush mounted laboratory grade FP. The data was collected at 600 Hz for the FP, while it was collected at 30 Hz for the WBB. The data from FP was down-sampled to 30 Hz. From the COP displacement data, COPv was calculated for the WBB and FP. DFA was used to analyze the persistence and anti-persistence characteristics of the COPv in the anterior-posterior and mediolateral directions. First, inflection point was determined manually as the first time the persistence behavior shifted to anti-persistence behavior. Based on this, the alpha value of the short-term scale region (persistence) and long-term scale region (anti-persistence) was calculated. The level of statistical significance was set at  $p < 0.05$ .

### RESULTS AND DISCUSSION

One-way repeated ANOVA revealed that there was a significant condition effect in alpha value of short scale region (alpha-short) in the AP ( $p = 0.014$ ) and the ML ( $p = 0.048$ )

directions. Inflection point, where the persistence behavior switched to anti-persistence behavior for the first time, also showed significant condition effect in AP ( $p = 0.001$ ) and ML ( $p = 0.014$ ). Post-hoc pairwise comparisons indicated that alpha-short for eyes closed standing was larger than one leg standing in AP ( $p = 0.015$ ). Although there was no statistical significance ( $p = 0.051$ ), it is interesting to see that in comparison to quiet standing, eyes closed standing has higher persistence. The eyes closed standing also showed earlier inflection point compared to the quiet eyes open standing ( $p = 0.027$ ). In ML, one leg standing showed smaller alpha-short value compared to the eyes open quiet standing ( $p = 0.004$ ), and had much earlier inflection point compared to the eyes closed standing ( $p = 0.044$ ). These results showed that WBB can capture the changes in persistence behavior of COPv between the standing conditions.

**Figure 1A-C:** Representative DFA data of COPv on WBB in AP of the same participant performing quiet normal standing with eyes open (1A), eyes closed standing (1B), and one leg standing (1C).

### CONCLUSIONS

In this study, postural sway variability of COPv from WBB was analyzed using DFA. It was found that WBB can capture the changes of persistence in velocity of postural sway and is sensitive to task conditions. Future studies will compare how accurately WBB captures the persistence and anti-persistence of postural sway (COPv) compared to the gold standard, the FP.

## Evaluation of Postural Sway for Remote Monitoring of Vestibular Rehabilitation

### Summary

Vestibular rehabilitation is an effective treatment for reducing dizziness and falls in older individuals. In this study, we investigated measurements from a low-cost commercial inertial sensor (IMU) as the basis for assessing postural sway during remote treatment. We found that an outcome measure based on jerk is dependent on sensor placement but effectively distinguished between some balance tasks and may be effective for tracking patient progress.

### Introduction

Vestibular rehabilitation is effective in reducing dizziness and falls in older individuals and improving gait and overall quality of life [1]. Rehabilitation targets head and eye coordination (e.g., vestibular ocular reflex (VOR) exercises) as well as balance, such as standing on one foot. However, patient adherence remains a major problem due to frequency of visits required and accessibility to care [2]. With the recent increased acceptance of telehealth solutions, tools are needed to quantitatively assess patients' progress remotely. In this study, we explored the use of a parameter based on jerk (time rate of change of acceleration) as an indicator of the smoothness of postural sway to distinguish between different balance conditions [3]. In addition, we evaluated different sensor locations to determine whether a sensor placed on the head could be used to assess both VOR and balance exercises.

### Methods

To determine the validity of using jerk to assess postural sway during balance exercises, we had one healthy subject (male, 26 years old) perform 12 trials of 3 balance exercises after providing written informed consent to a protocol approved by the IRB at CFD Research: neutral standing posture, standing on one leg only with eyes open, and standing on one leg only with eyes closed. Half of the trials were performed with a sensor fixed to the head, and the other half while the sensor was fixed to the lower back. The subject was instructed to perform the exercise for one minute while looking straight and remaining as still as possible. Accelerometer data were collected using a MetaMotionR (MbiEntLab Inc, San Francisco, CA) sensor secured at either the 5<sup>th</sup> lumbar vertebrae level (L5) using a Velcro strap or on the forehead using a headband.

Accelerometer data were filtered using a 4<sup>th</sup> order zero-phase shift low-pass Butterworth filter with a 3.5Hz cutoff. To assess postural sway the integral of the square of the magnitude of jerk in the anterior/posterior and medial/lateral directions was used [3]:

$$\frac{1}{2} \int_0^t \left( \left( \frac{dAccAP}{dt} \right)^2 + \left( \frac{dAccML}{dt} \right)^2 \right) dt \quad (1)$$

where *AccAP* and *AccML* are accelerations in the anterior/poster and medial/lateral directions respectively. Lower values tightly controlled postural sway.

Unpaired t-tests were performed to determine the difference between means of conditions. A Bonferroni pair-wise correction was applied to account for multiple comparisons ( $\alpha=0.05/3=0.017$ ).

### Results and Discussion

Results indicated a statistically significant difference between balancing on one foot with eyes closed compared to balancing on one foot with eyes open and neutral standing when using a sensor placed on L5 (Table 1). For all other conditions, the difference in means was not statistically significant after Bonferroni correction. While a head sensor would be especially advantageous for assessing vestibular rehabilitation exercises, as most other exercises involve repetitive head movements, we were unable to distinguish between the three conditions using a sensor placed on the head.

**Table 1:** Mean (S.E.) jerk parameter value in each condition with sensor on the head or 5<sup>th</sup> lumbar vertebrae (L5). Significant differences ( $p<0.017$ ) relative to eyes closed indicated by '\*'.

	<u>Postural Sway Smoothness (m<sup>2</sup>/s<sup>5</sup>)</u>		
	Standing	Eyes Open	Eyes Closed
L5	1.2·10 <sup>-3</sup> (2.6·10 <sup>-4</sup> )*	5.9·10 <sup>-2</sup> (1.9·10 <sup>-2</sup> )*	1.1 (0.23)
Head	6.6·10 <sup>-3</sup> (1.4·10 <sup>-3</sup> )	0.11 (3.1·10 <sup>-2</sup> )	1.5 (0.46)

### Conclusions

We demonstrated that postural sway can be accurately assessed using data from a low-cost IMU sensor placed on the lower back to compute a jerk-based parameter. The head-mounted sensor did not distinguish between conditions, so our results suggest that an L5-mounted sensor is necessary. These results provide justification for future studies to test the effectiveness of this method to assess severity of vestibular dysfunction and track patient progress over time.

Email: [h.osman@vikes.csuohio.edu](mailto:h.osman@vikes.csuohio.edu)

### Summary

We identified minimal performance characteristics under which our treadmill gait perturbation protocol (FLP) was feasible for individuals post stroke. For those able to complete the protocol, it was able to demonstrate fall resistance improvements. Participants who did not meet the minimal conditions were included as a gait speed only group (GSP). Despite the unsuitableness of the protocol for people with extremely slow gait speeds or otherwise very impaired gait, our full protocol was in fact feasible for adults' post stroke with generally slower gait speeds and significant balance challenges, the group for whom this type of measure is useful.

### Introduction

Treadmill-based gait perturbation protocols have been shown to hold potential as balance assessment tools using simulated slips to induce adaptive full body stability responses and falls reduction [1].

Research has found that high-intensity, treadmill-slip training improved older adults' gait speed and another study found that a progressively-increasing intensity protocol had advantages over the progressively-decreasing protocol as not all participants could tolerate such high intensity training [2].

However, these protocols were not individualized to meet each person's balance and motor ability. Thus, our goal was to scale the initial perturbation magnitude based on the individual's maximum gait speed and balance ability as measured by the Mini-BEST.

### Methods

Participants were asked to identify when their comfortable, natural, but safe speed (NWS) on the treadmill had been reached. After resting as needed, they were asked to walk to find their maximum walking speed (MWS). The treadmill then ran at each participant's NWS throughout the perturbation testing sessions.

To scale and ensure appropriateness to each individual, the initial perturbation was based on the individual's maximum gait speed and balance ability as measured by the Mini-BEST. The initial perturbation magnitude (mPer) was calculated based on the participant's MWS and their Mini-BEST score: for scores from 19 – 23, mPer = 55% of MWS, 24 -25 mPer = 75% of MWS, and 26 - 28 mPer = 95% of MWS.

The same initial mPer was used for pre-and post- intervention testing. A stepwise progression based on trial outcome was followed to modulate the mPer for subsequent trials.

### Results and Discussion

We identified conditions under which this full perturbation protocol (FLP) was feasible for individuals post stroke. Specifically, necessary conditions are: (1) gait speed greater than 0.2 m/s to generate a noticeable perturbation; (2) able to walk on the treadmill without holding the handrail for the 90 sec trials to elicit solely a stepping strategy for recovery; and (3) able to walk on both force plates (each foot landing consistently on its side of the treadmill) to trigger perturbations under the unaffected leg. Participants who did not meet these conditions were included as a gait speed only protocol group (GSP). Mini-BEST score was higher in the FLP than GSP group (Figure 1).

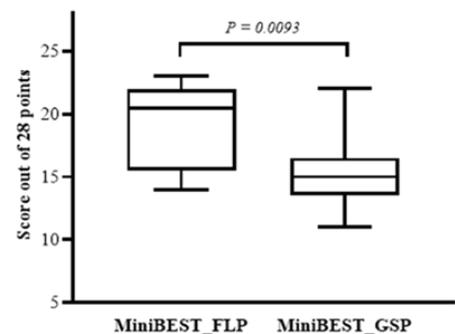

Figure 1: Mini-BEST score was higher in the FLP than GSP group.

Twenty-two participants completed pre- and post-testing: 12 were able to complete the FLP and 10 completed the GSP only. NWS was different from MWS at pre and post-test and NWS was faster at post-testing than pre as was MWS.

### Conclusions

The present study has enhanced our understanding of the possible use of this methodology as a direct approach for assessing reactive responses and potentially could be used as an alternative to fall data collection.

## Multifractal Analysis of Quiet Standing in the Young and Old

John H. Challis

Biomechanics Laboratory, The Pennsylvania State University, Pennsylvania, United States

Email: [jhc10@psu.edu](mailto:jhc10@psu.edu)

### Summary

The center of pressure during quiet standing can reveal insights into the control of movement. This study analyzed quiet standing with eyes open and eyes closed for a young subject group and an older subject group. The multifractal spectra of the center of pressure data were computed, and indicated that all signals were multifractal in nature. This property is indicative of the processes controlling quiet standing operating at different time scales – the system has multiplicative cascade dynamics.

### Introduction

When human stand still, they do not stand perfectly still they have body sway. This body sway is typically analyzed by extracting various metrics from the motion of the center of pressure. It has been suggested that the center of pressure motion reflects two processes operating over different time scales [1]. These results suggest that the control of standing has multiplicative cascade dynamics, that is that system behavior is dependent on the interactions from system components which operate over different time scales. For such a system the output should demonstrate multifractal fluctuations. Therefore, the purpose of this study was to examine the multifractal properties of center of pressure data to examine if quiet standing demonstrates multiplicative cascade dynamics, and to determine if there were different properties between young and old subjects.

### Methods

The analysis was performed on a public data set of force plate data of human quiet standing [2]. The analyzed data came from 27 young subjects, (height:  $1.71 \pm 0.11$  m; mass  $70.3 \pm 17.8$  kg; age:  $23.1 \pm 4.3$  years; 15 males and 12 females) and 22 older subjects (height:  $1.61 \pm 0.09$  m; mass  $68.7 \pm 11.2$  kg; age:  $67.8 \pm 6.1$  years; 11 males and 11 females). The subjects stood still for three 60 s trials with their eyes open, and a further three trials with their eyes closed. Force plate data were collected at 100 Hz for all trials.

Center of pressure data were tested for data normality using the Jarque-Bera test [3]. The Detrended Fluctuation Analysis (DFA) determines for a signal its statistical self-affinity, thus revealing underlying signal properties [4]. A drawback of the DFA of a signal is that second moment-fluctuations only are assessed but by considering higher order moments a multifractal DFA (MDFA) can be determined [5]. Therefore, for these data the MDFA was used and from that analysis the multifractal spectrum determined. From this spectrum the multi-fractal spectrum width, range of the  $q^{\text{th}}$ -order singularity exponents, was computed as an indication of the range of different scale invariant structures in the time series. In addition, the average velocity of the center of pressure

was computed as was the area of the center of pressure motion [6].

### Results and Discussion

All data demonstrated a lack of normality, as indicated by the Jarque-Bera test. Normality is a necessary condition for data demonstrating fractal like properties. It also indicates data which is not well described by basic statistical analyses (e.g., computation of signal mean and standard deviation).

The center of pressure velocity was greater with eyes closed than with eyes open, it was statistically different between these conditions for each subject group ( $p < 0.05$ ). Comparison between groups indicated a greater center of pressure velocity for the older subjects compared with the younger subjects, these differences were statistically different for each condition ( $p < 0.05$ ).

For the center of pressure area there was no statistically significant differences between conditions for each subject group, or between groups for the same condition. The method for determine center of pressure area assumes normality of the data [6], which is violated for these data.

The multifractal spectra of the center of pressure data indicated that the signals for both groups and all conditions were multifractal, indicative of processes operating at different time scales. For standing there are multiple systems contributing to the maintenance of upright standing, with both neurological and physiological processes operating at different speeds and therefore time scales. The multi-fractal spectrum widths were not statistically different between groups or conditions, except for the older group when eyes closed was compared with eyes open ( $p < 0.05$ ). For the older group the spectrum width narrowed with eyes closed, possibly due to the removal of one source of feedback.

### Conclusions

Center of pressure data from quiet standing contains multiple fractal processes, indicating that the center of pressure arises from multiplicative cascade dynamics.

## Simple model of arch support: relevance to Charcot Neuroarthropathy

Shaye M. Tiell<sup>1</sup>, Brian L. Davis<sup>2</sup>, G. R. McMillan<sup>3</sup>, L. P. Goss<sup>3</sup>, J. W. Crafton<sup>3</sup>

<sup>2</sup>Cleveland State University, Cleveland, OH, USA

<sup>3</sup>Innovative Scientific Solutions Inc., Dayton, OH, USA

Email: [smt125@uakron.edu](mailto:smt125@uakron.edu)

### Summary

Charcot neuropathy is a common complication resulting from poorly controlled diabetes and peripheral neuropathy leading to the collapse, and ultimately breakdown, of the midfoot. Mechanically, a compromised arch support is likely associated with slippage at the distal and proximal interface regions of the foot's plantar surface and the adjacent support surface. Systems for monitoring interface shear stresses could potentially assess this slippage. However, correlation between arch collapse and interface shear stresses needs verified. Thus, a model was developed using a multi-body dynamics package. The model's predictions matched interfacial shear stresses during upright stance. Of clinical relevance, when the stiffness of the plantar spring (representing aponeurosis and intrinsic muscles) was reduced by 10%, the frictional force difference increased by about 6.5%. Clinical implications are that, while arch lengthening of less than 2mm might be difficult to measure in a gait lab, using shear sensors under the foot should allow repeatable assessment of arch support.

### Introduction

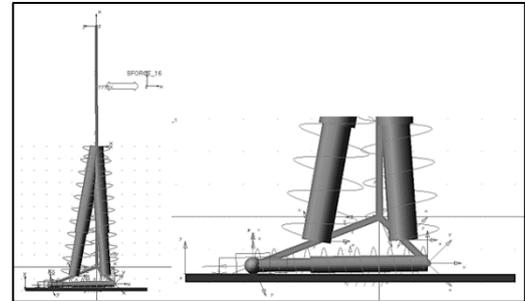

Charcot neuropathy is a common complication resulting from poorly controlled diabetes and peripheral neuropathy leading to the collapse, and ultimately the breakdown, of the midfoot. Mechanically, it is likely that a compromised arch support would be associated with slippage at the distal and proximal interface regions of the plantar surface of the foot and the adjacent support surface [1-4]. This slippage, although difficult to quantify with standard motion capture systems used in a gait laboratory, could potentially be assessed with systems for monitoring interface shear stresses. However, before investing in such systems, a correlation between arch collapse and interface shear stresses needs to be verified.

### Methods

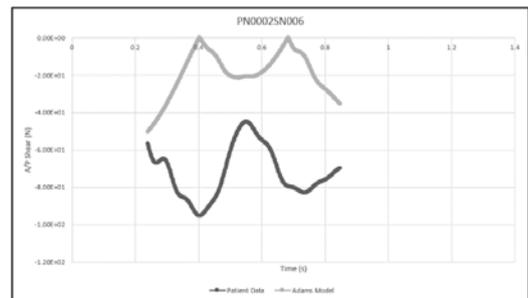

A sagittal plane model of a foot was developed using a multi-body dynamics package (MSC Adams). This model mimicked a subject swaying back and forth, and was constructed to show the dependence of interface stresses on altered arch support (see Figure 1).

### Results and Discussion

The model's predictions matched typical interfacial shear data: lengthening of the arch of 1-2mm, sway oscillations of 0.22-0.33 seconds and frictional force differences (calcaneus relative to forefoot) of 60N (see Figure 2). Of clinical relevance, when plantar spring stiffness (representing aponeurosis and intrinsic muscles) was reduced by 10%, the frictional force difference increased by about 6.5%.

**Figure 1:** Initial foot model developed with MSC Adams software: (left) An upright subject is represented, (right) close-up view.

**Figure 2:** Computational model compared to patient trial data. Note that the sign convention for the experimental data is arbitrary – in this case, the negative peaks of the experimental data match the positive peaks in the model data.

### Conclusions

The clinical implications of this study are that, while arch lengthening of less than 2mm might be difficult to measure reliably in a gait lab, using shear sensors under the forefoot and hindfoot should allow arch support to be assessed in a repeatable manner. For patients at risk for arch collapse, measuring shear differences between forefoot and hindfoot regions may provide opportunities for early intervention.

### Summary

Sarcomere length non-uniformities are thought to be the primary cause for many mechanical properties of skeletal muscle. However, despite its importance, it is not known if sarcomere length non-uniformities occur randomly or are determined by structural and contractile properties of muscles. In this study, we identified that passive sarcomere length non-uniformities are not random and are likely associated with the properties, isoform and concentration of titin molecules in sarcomeres.

### Introduction

Sarcomeres in muscles, fibres, and myofibrils are known to be non-uniform in skeletal muscle of vertebrates [1-3]. These non-uniformities differ substantially between passive and active muscles. Sarcomere length non-uniformities have been associated with major functional and mechanical properties of skeletal muscles, such as muscle “creep” extension of the plateau of the force-length relationship, residual force depression, and residual force enhancement. Despite this apparent importance of sarcomere length non-uniformities in muscle function, the factors determining these non-uniformities are unknown. It is not even known if these non-uniformities arise randomly from the proposed instabilities of sarcomeres on the descending limb of the force-length relationship, or if they are determined uniquely by structural and/or contractile sarcomeric proteins in the passive and active muscle state. The purpose of this study was to determine if sarcomere non-uniformities in passive myofibrils arise randomly or are determined and similar for multiple activation/deactivation cycles.

### Methods

18 myofibrils with 356 individual sarcomeres were used for this study. Myofibrils were obtained from psoas muscles of seven female rabbits age  $\geq 6$  months. Prior to each experiment, the average sarcomere lengths of the myofibrils were set at 2.7  $\mu\text{m}$ , 3.2  $\mu\text{m}$ , and 3.6  $\mu\text{m}$ . The individual sarcomere lengths at these initial lengths were measured and are referred to as R<sub>0</sub>. Myofibrils were then activated for 5s, and relaxed for 2 minutes, and this activation/relaxation process was repeated for three times, giving three additional individual sarcomere lengths in the relaxed state referred to as R<sub>1</sub>, R<sub>2</sub>, and R<sub>3</sub>. For visualization (Figure1), sarcomeres were divided depending on their initial, R<sub>0</sub>, lengths into short, n = 76, SL = 2.5  $\pm$  0.27  $\mu\text{m}$  (black); short-medium, n = 116, SL = 2.9  $\pm$  0.25  $\mu\text{m}$  (red); medium-long, n = 111, SL = 3.4  $\pm$  0.24  $\mu\text{m}$  (green), and long, n = 50, SL = 3.9  $\pm$  0.31  $\mu\text{m}$  (yellow). Sarcomere lengths at R<sub>0</sub>-R<sub>3</sub> were measured between the centroids of the A-bands using light microscopy (Zeiss Axiovert 200M, Zeiss, 40x, NA

0.75  $\times$  2.5 Opti-over), and a custom-designed program that identified the A- and I-bands based on light intensity patterns.

### Results and Discussion

Sarcomere lengths tended to return to their initial values following three activation and deactivation cycles; that is, short sarcomeres tended to remain short and long sarcomeres tended to remain long. Approximating the first (R<sub>0</sub>) and the last (R<sub>3</sub>) sarcomere length values for all 356 sarcomeres, a regression line through a zero y-intercept has a slope of nearly 1.0 and a coefficient of variation  $r^2$  of, indicating that sarcomeres tend to return to similar lengths, and definitely do not go to arbitrary lengths after each activation/deactivation cycle. This result then suggests that sarcomere length non-uniformities are governed by some structural component inherent to the sarcomere.

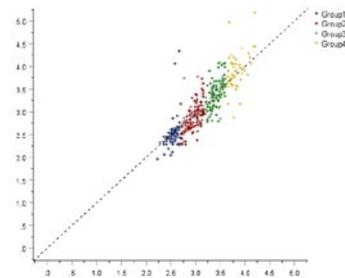

Figure 1: Linear Regression of R<sub>0</sub> and R<sub>3</sub> for the Four Groups.

Since the structural protein titin is the virtually exclusive provider of passive force, and since all sarcomeres in a myofibril are arranged in series, and thus must transmit the same force, it seems reasonable that the number of titin molecules in a sarcomere might determine its passive length.

### Conclusions

We conclude from the results of this study that passive sarcomere length non-uniformities are not random but are caused by passive structural element non-uniformities at the level of sarcomeres, likely associated in some way with the number or inherent stiffness of titin molecules.

# Classification of Autism Gait Patterns in Children Using Multisegment and Single Segment Foot Kinematic Data

Ashirbad Pradhan<sup>1</sup>, Victoria Chester<sup>1</sup>

<sup>1</sup>Andrew and Marjorie McCain Human Performance Laboratory, Faculty of Kinesiology, University of New Brunswick, Fredericton, Canada

Email: [ashirbad.pradhan@uwaterloo.ca](mailto:ashirbad.pradhan@uwaterloo.ca)

## Summary

This study examined the retrospective classification of gait patterns in children with autism using both traditional single segment foot (SSF) and multisegment foot (MSF) kinematic data. Results suggest that gait patterns in autism and controls can be classified with a high accuracy of 90.7% using features from a combination of MSF data. MSF data could provide a better understanding of atypical ankle motion in children with autism.

## Introduction

Previous research has shown that children with autism walk with atypical ankle kinematics and kinetics<sup>1,2</sup>. To date, no studies have examined multisegment foot kinematics in children with autism. The purpose of this study was to: 1) determine the optimal multisegment foot kinematic features for classifying autism/control gait patterns in children, and 2) determine whether SSF angle data, MSF angle data, or both combined are more accurate for classifying autism/control gait patterns in children.

## Methods

Nineteen children (n=19) diagnosed with autism between the ages of 6-15 years (16 males, 3 females, age=10.4±2.9 yrs; height: 1.42±0.1 m; weight: 41.2±17.0 kg) and twenty-four controls (n=24) between the ages of 6-18 years (12 males, 12 females, age=12.1±3.34 yrs; height: 1.51±0.1 m; weight: 47.0±17.0 kg) participated in the study. A 12 camera T160 Vicon motion capture system (Oxford Metrics Group, Oxford, UK), sampling at 100 Hz, was used to track the 3D trajectories of 36 reflective markers (9mm diam.) placed on each participant's skin. The MSF model<sup>3</sup> consisted of 4 rigid segments, including the shank (Sha), calcaneus (Cal), midfoot (Mid), and forefoot (Met). The SSF<sup>3</sup> consisted of the shank and foot. For all relative angles in each model, a feature-set was generated that included the angular value at heel-strike (HS) and toe-off (TO), range-of-motion (ROM), maximum (MAX) and minimum (MIN) angle during stance (ST) and swing (SW), and the corresponding time of occurrence. The feature-sets from each angle served as input for linear discriminant analysis (LDA) models for classifying gait patterns between the two groups. For the performance evaluation, a leave-one-out cross-validation was employed, and the mean accuracy, sensitivity, and specificity were reported. Additionally, the entire feature set was ranked according to their F-score values to determine predictor importance. All data analysis was performed using Matlab (Mathworks, Inc. Natick, MA, USA).

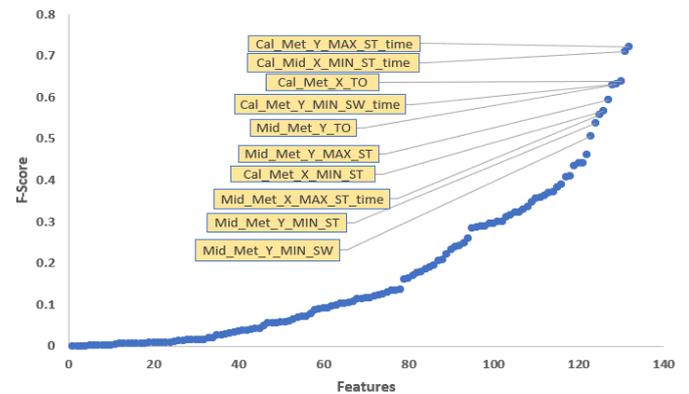

## Results and Discussion

Maximum accuracy of 90.7% and sensitivity of 89.5% were obtained for classifying autism and control groups using

features from Cal\_Met+Cal\_Mid+Mid\_Met+Sha\_Cal (Table 1). This was higher than the accuracy of individual feature sets which ranged from 70.9%-79.1% including the SSF model (75%.6). However, when all feature subsets were combined the accuracy reduced slightly (89.5%). The reduction was distinct in the sensitivity values which reduced to 86.8%. This suggests that the MSF angles have better classification performance than the SSF angle for classifying autism and control gait patterns. Also, a combination of MSF feature-sets is found to have better performance than individual models.

**Table 1:** Classification of Autism/Control gait patterns.

MSF Angles	Accuracy	Sensitivity	Specificity
Sha_Foot (SSF)	0.779	0.658	0.875
Cal_Met (MSF)	0.791	0.737	0.833
Cal_Mid (MSF)	0.791	0.684	0.875
Mid_Met (MSF)	0.709	0.447	0.792
Sha_Cal (MSF)	0.756	0.605	0.750
Cal_Met+Cal_Mid+Mid_Met+Sha_Cal	0.907	0.895	0.917
All features (MSF+SSF)	0.895	0.868	0.917

**Figure 1:** F-Score ranking of MSF angles-based features.

## Conclusions

Examining MSF data may help identify atypical gait patterns in children with autism, thus leading to a greater understanding of foot mechanics and function. This would assist in more effective treatments and thus provide an improved quality of life.

## Firefighter turnout gear limits the ability to lift while maintaining a neutral spine posture

<sup>2</sup>Toronto Fire Services, Toronto, Canada

Email: [danielle.carnegie@mail.utoronto.ca](mailto:danielle.carnegie@mail.utoronto.ca)

### Summary

This study assessed the effect that wearing motion-restricting firefighter turnout gear had on maximal reach distance when constrained to lift with a neutral lumbar spine posture. Firefighters performed a series of maximal reach tasks while wearing pieces of turnout gear required on-duty (i.e., fire protection gear and station wear). The results indicated that wearing fire pants and/or fire jacket reduces how far firefighters are able to reach for an object without rounding their spine. In contrast, fire boots and station wear did not significantly influence reach distance. This suggests that the motion-restricting effects of required protective equipment limit firefighters' ability to reach for low-lying objects without flexing the lumbar spine.

### Introduction

Low back disorders (LBD) account for 68% of all injuries sustained by emergency responders (e.g., firefighters, paramedics) [1]. In firefighters, 43% of LBD have been linked to manual lifting tasks (e.g., patient transfer, equipment handling, victim rescue) [1]. To reduce lifting related low-back disorder risk, it is often recommended to limit lumbar spine flexion during lifting tasks. However, there is also evidence that when lower extremity joint motion is experimentally restrained, greater sagittal plane lumbar spine motion is observed in order for performers to accomplish the same lifting task [2]. Further, there is some evidence to suggest that the protective turnout gear worn by on-duty firefighters reduces available joint range-of-motion [3] which may influence available movement solutions while on the job. However, the influence this restrictive gear has specifically on lifting mechanics is unknown. The purpose of the study was to determine the influence of each component of firefighter turnout gear on maximal reach distance attainable while maintaining a neutral lumbar spine.

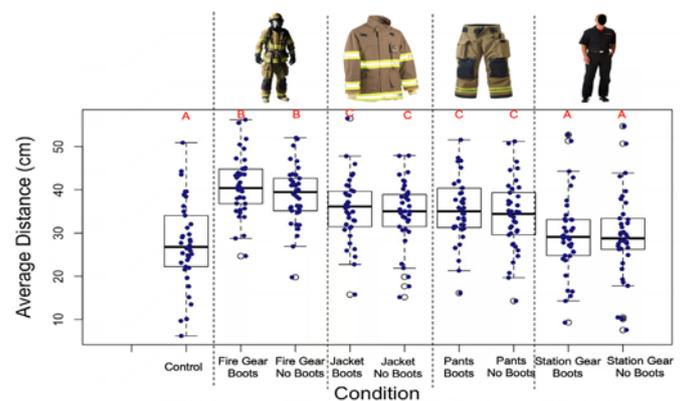

### Methods

Thirty-eight firefighters completed a series of maximal reach tasks, which involved lowering a wooden dowel as far as possible while wearing a custom spine motion restraint [4]. Four different combinations of fire gear were worn with and without boots: 1) station wear (innermost layer of protective equipment worn at all times); 2) fire pants only (worn overtop station gear when called to emergency); 3) fire jacket only (with air tank); and 4) full gear. Three repetitions of each condition were performed, and foot position was controlled. A control condition was also performed wearing comfortable shorts and a t-shirt. Maximal reach distances (i.e., the distance from the knuckles to the ground when the firefighter was at their lowest reach position) were averaged

across three repetitions then compared via general linear model with one within-participant factor (condition).

### Results and Discussion

Compared to the control condition, wearing fire pants or jacket alone (i.e., with and without boots) reduced maximal reach distance by 8 cm ( $p < 0.001$ ), while full gear reduced maximal reach distance by 13 cm ( $p < 0.001$ ). The influence of fire pants and fire jacket alone were not significant ( $p = 1.000$ ). Station wear did not significantly influence maximal reach distance, as compared to control ( $p = 0.294$ ). Within all tasks, wearing boots did not influence reach distance compared to not wearing boots ( $p > 0.05$ ) (Figure 1).

**Figure 1:** Maximal reach distance averaged across three repetitions for each condition. Control refers to comfortable clothing condition. Different letters indicate that conditions are significantly different ( $p < 0.05$ ). Box plots display group data with median, upper and lower quartiles, and whiskers display max and min values excluding outliers. Outliers (greater or less than 1.5 times interquartile range) are shown as black circles. Solid blue dots represent individual data points (mean value of three reps).

### Conclusions

Wearing fire gear reduces the depth firefighters can reach while maintaining a neutral lumbar spine. Thus, the general recommendation to limit spine motion when lifting may not be implementable by firefighters (or other first responders) who must wear motion-restricting protective equipment.

Email: inaemarcelo.aluno@unipampa.edu.br

### Summary

We set out to determine the influence of time of day on muscle strength assessment in men and women. Considering common parameters considered in the clinical evaluation of lower limbs strength, it seems that leg asymmetries and sex need to be considered in the clinical examination, but the time of the day has less influence on the results.

### Introduction

The maximal isometric strength can be higher in the late afternoon [1]. In the clinical context, an influence of the time of the day on strength may have impact on the assessment of injury risk factors, identification of leg asymmetries, and sports performance [2]. Here we determine whether the time of the day influences muscle strength in men and women.

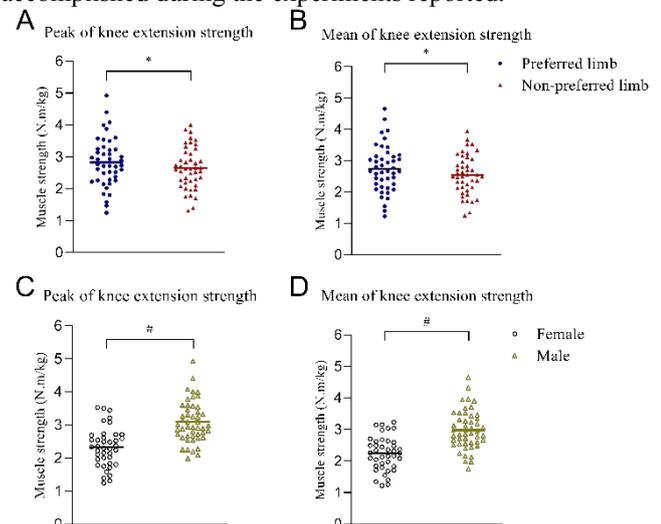

### Methods

Twenty-two men (n=12) and women (n=10) with mean±standard deviation age 27±5 years, height 1.69±0.11m, body mass 71±12kg, physically active, were assessed concerning the maximal isometric strength for knee extension and flexion, and hip abduction, bilaterally, by handheld dynamometry (Microfet 2). Muscle strength was measured in Newton and torques were estimated by the product of strength by shank (knee torque), and leg length (hip torque), and normalized to the individual body mass. The peak and mean values from three trials were considered. Each participant was evaluated in the morning (8:00AM to 12:00AM) and in the evening (6:00PM to 10:00PM) with at least 36 h in between, in randomized order for morning and evening, under controlled temperature and light. Generalized estimated equations with three factors, time of day (morning and evening), limb preference (preferred and non-preferred), and sex (male and female), were used to identify the main effects and interactions. The significance level was set at 0.05.

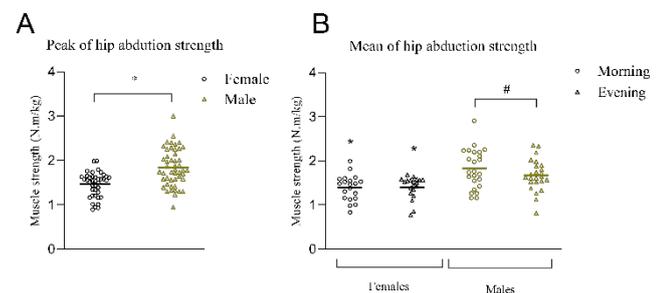

### Results and Discussion

Preferred leg showed higher peak (p=0.008, Figure 1A) and mean (p=0.002, Figure 1B) knee extension torques for both men and women. Men were stronger than women for peak (p=0.001, Figure 1C) and mean (p=0.001, Figure 1D) knee extension torques, and peak hip abduction torque (p=0.004, Figure 2A). The mean hip abduction torque showed an interaction between sex and time of day (p=0.048), with the men showing higher hip abduction torque in the morning (p=0.042, Figure 2B) and higher torques than women regardless of the time of the day (p≤0.024, Figure 2B). Knee flexors did not show main effects or interactions (p≥0.158). The higher torques found for men compared to women [3] and leg asymmetries between [4] agree with previous studies. It suggests caution when assuming one limb as representative of the contralateral. While an effect of the time of the day was not clear, the higher hip abduction torque in the morning deserves

investigation with a larger sample, which was not possible to accomplished during the experiments reported.

**Figure 1.** Effect of the limb (A-B) and sex (C-D) on peak and mean values of the knee muscle strength. (A-B) \* Indicates a difference between limbs. # Indicates a difference between sexes.

**Figure 2.** Effect of the sex (A-B) and shifts (B) on peak and mean values of the hip muscle strength. \*Indicates a difference between sexes. # Indicates a difference between shifts.

### Conclusions

Hip strength was influenced by the time of the day in men. Regardless of the time of the day, leg asymmetries require attention for both men and women.

# Gluteal Activation Cues Reduce Peak Acetabular Contact Pressure During Squatting in Persons with Femoroacetabular Impingement Syndrome: A Finite Element Analysis Study

Jordan Cannon, Christopher M. Powers  
 Division of Biokinesiology and Physical Therapy  
 University of Southern California, Los Angeles, CA  
 Email: [cannonjo@usc.edu](mailto:cannonjo@usc.edu)

## Summary

Diminished gluteal muscle activation in persons with femoroacetabular impingement syndrome (FAIS) has been proposed to contribute to symptomatic impingement. The purpose of this pilot project was to investigate if targeted gluteal muscle activation during squatting could reduce impingement kinematics and peak acetabular contact pressure. Our preliminary results suggest that cueing persons with FAIS to activate gluteal musculature reduces hip internal rotation and in doing so reduces peak acetabular contact pressure.

## Introduction

Femoroacetabular impingement syndrome (FAIS) is a motion-related clinical disorder resulting from abnormal hip joint morphology [1]. Mechanical impingement, in which the aspherical femoral head (cam morphology) abuts with the acetabular rim, is created with simultaneous deep hip flexion, internal rotation, and adduction. The area of impingement on the anterior-superior acetabulum corresponds with the location of intra-articular joint damage in FAIS [2]. The gluteal musculature are of interest in FAIS [3] given their ability to avoid impingement during squatting by producing hip external rotation and abduction motion. The purpose of this pilot study was to investigate if targeted gluteal muscle activation during squatting could reduce impingement kinematics and acetabular contact pressure, while shifting the location of peak contact pressure away from the anterior-superior acetabular rim.

## Methods

A 3D finite element (FE) model of the hip joint was developed from a male with a diagnosis of FAIS (32 years, 1.79 m, 70.9 kg). Kinematic, kinetic, and surface EMG of 6 hip muscles were collected while the participant performed two bodyweight squat tasks. First, an unconstrained squat to maximum depth with a self-selected stance width and foot position. Next, in the same stance position, the participant was provided coaching cues to increase gluteus maximus and medius activation. Nine squats were collected for each condition, with movement speed and arm position controlled. An EMG-driven musculoskeletal model estimated bone-on-bone contact forces at the hip joint during squatting [4]. Subject-specific input parameters to the FE model included 3D hip joint kinematics and bone-on-bone contact forces at peak hip flexion for each squat condition, as well as acetabulum and proximal femur geometry.

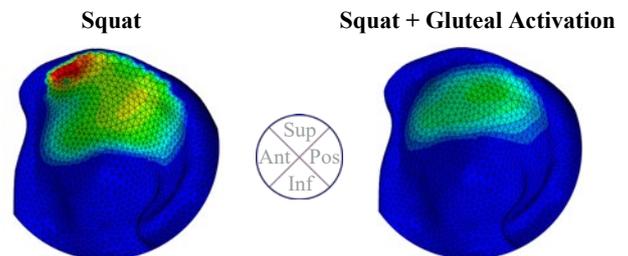

**Table 1:** Hip joint angles (°) at peak hip flexion input to the FE model.

	Flexion	Abduction	Internal Rotation
Squat	130	33	17
Squat + Gluteal Activation	128	31	10

Bony geometry was obtained from CT scans of the pelvis and proximal femur to create a 3D model of the symptomatic (left) hip. The acetabulum and femur were modelled using homogeneous, isotropic, triangular continuum shell elements with an elastic modulus of 17.0 MPa and a Poisson ratio of 0.30. Quasi-static loading simulations were performed using a nonlinear FE solver in Abaqus using a hard contact algorithm, with a surface-to-surface, finite sliding contact, and a surface coefficient of friction of 0.02. Peak contact pressure was analyzed at peak hip flexion during each of the squat conditions.

## Results and Discussion

Hip flexion and abduction were similar between squat conditions, however internal rotation was reduced by 7° during the trials with the gluteal activation cues (Table 1). In the cued trials, peak acetabular contact pressure decreased from 8.49 to 3.84 MPa and the location of peak pressure shifted away from the anterior-superior acetabular rim. (Figure 1). The findings of this preliminary analysis highlight the influence of hip internal rotation in contributing to mechanical impingement during squatting. Specifically, modest reductions in internal rotation resulted in a 55% decrease in acetabular contact pressure.

**Figure 1:** Acetabular contact pressure at peak hip flexion.

## Conclusions

Our preliminary results suggest that gluteal activation cueing during squatting reduces hip internal rotation and in doing so reduces peak acetabular contact pressure. This finding highlights the importance of the gluteal musculature in minimizing impingement kinematics during deep squatting.

Email: [kevin.valenzuela@csulb.edu](mailto:kevin.valenzuela@csulb.edu)

### Summary

Longitudinal effects of an Achilles repair due to bone spurs and Achilles tendinopathy remain unknown. Following a 16-week longitudinal analysis of lower extremity biomechanics, it was determined that pre-operative kinetic patterns return at approximately 12-weeks post-operative. Peak VGRF and plantarflexion moments during the push-off of stance phase during gait are reduced at 8 weeks post-op.

### Introduction

Achilles tendinopathy represents approximately 5-18% of injuries in distance runners [1]. Runners who exhibit Achilles tendinopathy display reduced gait speed during walking [2]. The injury presents a reduced peak dorsiflexion angle [3] but no differences on peak impact forces [4].

While restricted dorsiflexion is commonly seen, less is known about the longitudinal kinetic effects of Achilles tendinopathy following an Achilles repair surgery. Therefore, the purpose of this study was to longitudinally assess lower extremity kinetics following an Achilles repair.

### Methods

A 35-year old male (1.85m, 86.4kg) presented right Achilles insertional tendinitis and a large retrocalcaneal bone spur which had fractured and was partially embedded in the Achilles tendon. One week before the operation, the subject completed over ground walking trials at a gait velocity of 1.0m/s. Qualisys Oqus cameras and Bertec force plates were used to collect 3D marker data and ground reaction forces.

The subject then underwent an Achilles tendon repair and a bone spur excision. The excess calcaneal bone was removed and smoothed down. The fragments were removed from the tendon. An Arthrex Speedbridge was used to reattach the tendon under normal resting tension.

Following six weeks of no weight bearing, the subject was able to begin walking. The pre-operative testing was repeated at 8-, 12-, and 16- weeks post-operatively. Peak ankle, knee, and hip joint moments and vertical ground reaction forces (VGRF) were assessed during the stance phase of the operated limb.

### Results and Discussion

There was an inability to achieve a gait speed of 1.0 m/s at 8-weeks post-operation (0.89 m/s was the fastest achievable speed). Peak loading VGRF did not change post-operatively (Figure 1), however, push-off VGRF did significantly decrease at 8 weeks post-operatively. By 16 weeks it was close to pre-operative levels.

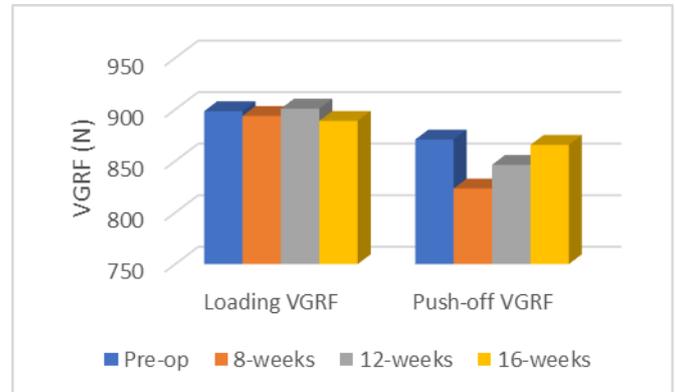

Figure 1: Peak loading and push-off VGRF (N).

There was a sharp decline in peak plantarflexion moments (push-off) at 8-weeks post-operative (Figure 2) but this returned closer to pre-operative levels by 16-weeks.

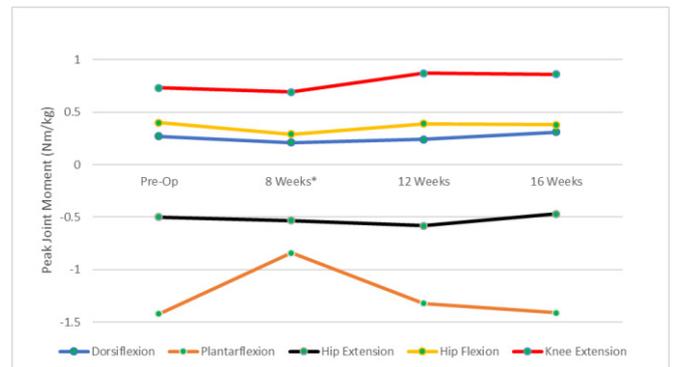

Figure 2: Peak joint moments (Nm/kg) during stance phase.

Six weeks of non-weightbearing caused reduced abilities in the performance of the ankle plantarflexors, which was evident in the reduced peak plantarflexion moment during push-off.

### Conclusions

Normal gait patterns are evident at approximately 12 weeks post-operatively in slow gait speeds. Push-off forces and peak joint moments return closer to pre-operative levels by 12-weeks. However, running was not occurring at 16 weeks.

## Is the dissipative energetic behavior of the human heel associated with thermal changes?

email: [npapachatiz@unomaha.edu](mailto:npapachatiz@unomaha.edu), web: [cobre.unomaha.edu](http://cobre.unomaha.edu)

### Summary

During walking, the heel's function is analogous to a shock-absorber that dissipates energy (negative net-work), which may be essential to minimize tissue damage. The laws of thermodynamics state that the dissipated energy may increase the heels' temperature. Although, our experimental setup increased the heel's negative work. The results showed no strong association between the heel's negative work and the heel's temperature changes. It is possible that the heel's mechanical work was dissipated as sound and not heat – although a direct measure of sound is needed to verify this conclusion. Additionally, we are currently investigating alternative hypotheses to determine whether other factors could explain increases in foot temperature, such as shear force and increased blood flow.

### Introduction

During human walking, the leading limb collides with the ground and performs negative work [1]. It is now well established that a large portion of this collision work is performed by the foot, particularly the heel [2,3]. Energy absorption (or dissipation) maybe be beneficial as a protective mechanism to minimize trauma or injuries [4]. However, it is currently unclear where the foot's energy goes or how the body absorbs or dissipates this energy. One possibility is that the heels' energy is dissipated as heat. The thermodynamics laws state that the dissipated energy may increase the heels' thermal energy (i.e., increase temperature), potentially explaining the increases in heel temperature during walking [5]. Currently, it is unclear whether the heel's mechanical energy can induce thermodynamic responses. Understanding the relationship between biomechanics and temperature regulation may be valuable for improving diagnoses for foot complications, such as the formation of diabetic foot ulcers that are thought to arise due to impaired ability to dissipate heat [6]. Here, we used walking with added mass to increase the heel's negative work [3] and investigated its effect on thermodynamic responses. We hypothesized that the heel's temperature would increase when walking with added mass. We also hypothesized that the increase in temperature is related to increased energy absorbed (i.e., negative work) and energy dissipated (i.e., net negative work) by the heel.

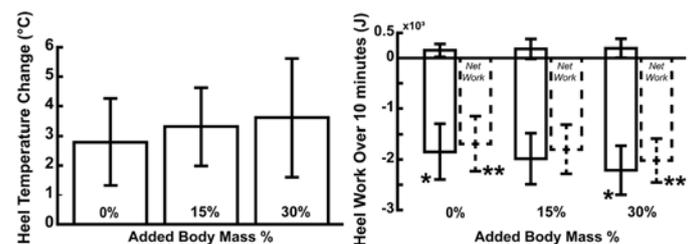

### Methods

A total of 20 healthy young adults (5 females, 15 males; age: 24.4±2.8 yrs; height: 1.74.61±0.07 m; mass: 83.6±21.2 kg; means± s.d.) walked over-ground on force plates and for 10 minutes on a treadmill (both at 1.25 m/s). Participants carried (via weight vest) three different levels of symmetrical loads: 0%; no added body mass, 15%, and 30% of their body mass. The over-ground walking conditions were used to collect foot mechanics data (kinematic & kinetic), whereas the treadmill conditions were used to measure the foot temperature data. We quantified the mechanical power and work done by the

foot using a unified-deformable analysis [7]. To isolate the heel contribution, we computed the work when the center-of-pressure was underneath the heel segment during the early stance phase [3,8]. An estimate of the total work over the 10 minutes of treadmill walking was calculated by multiplying the average work per step measured in over-ground trials by the number of steps taken in 10 minutes of treadmill walking. Temperature measurements were taken immediately before and after each treadmill condition at the bottom of the right foot, including the heel pad. We computed the change in temperature of the heel before and after each walking condition. A one-factor repeated-measures ANOVA was used to determine the effect of the added mass on the dependent variables. When a significant main effect was found, a Bonferroni post hoc analysis was conducted for pair-wise comparisons. We used a linear mixed models test to examine the relationship between foot temperature changes (before and after walking) and foot energy dissipation. The significance level was set to  $\alpha = 0.05$  for all the statistical tests.

### Results and Discussion

Our hypotheses were not supported as there was no significant increase in heel temperature between added mass walking conditions ( $p=0.138$ , Figure 1), despite an increase in the magnitude of negative work ( $p=0.003$ , Figure 1). Neither the negative nor the heel's net work was associated with increased heel temperature ( $p=0.535$  &  $p=0.661$ , respectively). Future studies are needed to test alternative hypotheses related to energy dissipation mechanisms such as sound, shear forces, and blood flow, which may lead to novel insights for understanding the causes of diabetic foot complications [6].

**Figure 1: (Left side)** The heel's temperature increased after 10min. of walking, but there was no significant effect of added mass on change in temperature ( $p=0.138$ ). **(Right side)** The added mass significantly increased the magnitude of the heel's negative ( $p=0.002$ ) and net ( $p=0.003$ ) work over 10 minutes of treadmill walking, but not the positive work ( $p=0.265$ ). The asterisks indicate significance (\*: negative work; \*\*: net work) (N=20).

Email: janesuelen@usp.br

## Summary

The reduction of strength of the foot muscles represents one of the main musculoskeletal alterations due to diabetic neuropathy. The implementation of an internet-based exercise protocol appears as a promising strategy to minimize these muscular alterations. This study provides insight into the effects of this internet-based foot-ankle exercises on foot strength in neuropathic patients.

## Introduction

Diabetic Peripheral Neuropathy (DPN) affects the muscle and joint structures of the foot and ankle [1]. These include alterations in the joints surrounding tissues, reducing their range of motion, and reduction in functionality and strength due to deterioration of the intrinsic foot and lower leg muscles [2]. Therefore, self-care strategies are an interesting option for prevention and treatment of more serious dysfunctions and complications, such as ulcer formation and amputation. We believe that an internet-based exercise protocol, focusing on strengthening the foot muscles, in which the person can self-manage, can be an efficient preventive strategy for further musculoskeletal dysfunctions in this population.

## Methods

At present, we are conducting a superiority randomised controlled trial on the efficacy of a 12-week internet-based foot-ankle therapeutic exercise program guided by the Diabetic Foot Guidance System – SOPeD ([www.soped.com.br](http://www.soped.com.br)) to treat musculoskeletal disorders in people with DPN at age between 18 to 65. The present abstract reports the results of a preliminary analysis of a total of 14 subjects, 6 in the intervention group and 8 in the control group.

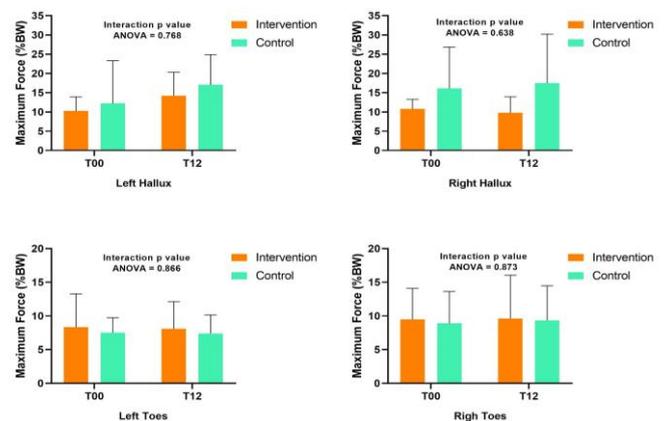

**Figure 1:** Hallux and toes strength test using an emed pressure platform (A-Baseline, B- after 12 weeks of intervention).

At the beginning of the intervention protocol, the user had a face-to-face supervision on how to perform the exercises, after the allocation by the physiotherapist in order to give the initial guidance on the use of SOPeD. The other sessions were followed remotely via software. All participants in the study received calls every two weeks. The strength of the participant's foot muscles was evaluated 2 times (T0 - baseline, T12 - after 12 weeks of treatment). The strength of

the flexor muscles of the hallux and toes were evaluated using an emed® -q100 pressure platform (Figure 1) [3].

## Results and Discussion

So far, no changes have been observed for foot strength (Figure 2). Others studies had observed an improvement in the ankle-foot complex muscle strength after applying a supervised foot exercise protocol for 12 weeks. However, the measures of strength evaluation used by these studies were different: Francia et al. [4] used ankle dynamometry that focuses on evaluating the strength of the extrinsic muscles. The study of Sartor et al. [5], although focusing on intrinsic musculature, used a manual strength test. In our study, we used a pressure platform, which can be considered a reliable method for measuring indirectly the strength of the foot intrinsic muscles. Thus, different outcomes can be expected when compared with the current literature. In addition, the data presented are from a limited sample, so significant changes in strength may not have been detected.

**Figure 2:** Comparison of the mean of the hallux and toes strength after 12 weeks of intervention.

## Conclusions

The implementation of an internet-based foot-ankle therapeutic exercise program emerges as a promising rehabilitation strategy, although these preliminary data do not demonstrate statistically significant differences in foot muscle strength.

### Summary

Contralateral or uninjured limbs are commonly used to compare quadriceps and hamstring strength data for return-to-play readiness in adolescents after sustaining an ACL injury. While it is useful to know if there is a between-limb strength deficit, it is also critical to determine how the growing patient compares to their maturing peer. As such, we present the change in isometric knee flexion and extension torque in adolescent male and female athletes over a year span. Results indicated a greater increase in torque between visit one and two for the dominant (D) limb knee extension compared to the non-dominant (nD) limb. Smaller differences in torque were observed for knee flexion.

### Introduction

Sustaining an ACL injury causes strength deficits that can be linked to arthrogenic muscle inhibition and muscle atrophy [1], leading to impairment in voluntary quadriceps and hamstring muscle activation [2]. This impairment affects both the injured and healthy contralateral limb as well [3]. Therefore, the practice of using the “healthy” contralateral limb as the “gold standard” when assessing readiness for return to sport is flawed, in particular in the maturing population where natural increases in strength are to be expected. The purpose of this study was, therefore, to describe the change in knee flexion/extension strength over a typical rehabilitation period (9-12 months) in healthy adolescent population. Strength may be affected by limb dominance and was also compared. We hypothesize that both flexion and extension would present significant between-limb differences across visits.

### Methods

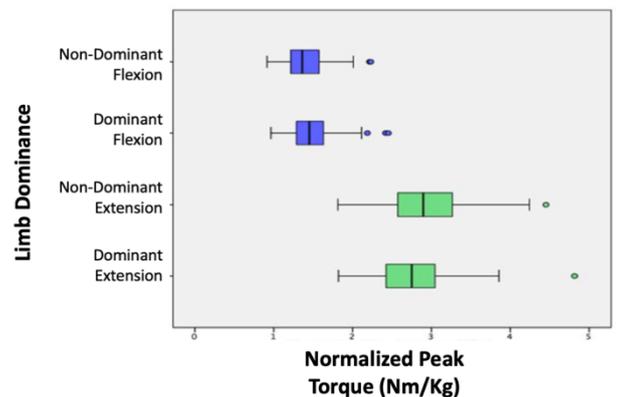

Seventy-one uninjured participants between the ages of 12 and 18 years were recruited via convenience sampling through sporting associations in the Ontario/Gatineau region. Thirty-six of these participants came for a second evaluation 7-15 months later. Participants had no previous ACL injury, and no lower extremity injury in the 6 months prior to testing and were experiencing no pain in the lower extremity prior to testing.

Limb dominance was defined as the leg they would choose to kick a soccer ball at a maximum distance. Maximum voluntary isometric contractions (MVICs) were recorded using an isokinetic dynamometer (Biodex System-4). Knee flexion and extension was tested in a seated position with the knee flexed to 60° and hip to 90°. Participants completed three trials per limb for each isometric contraction. Verbal encouragement and visual feedback encouraged participants to produce a maximum effort. The average of the three trials was normalized to body mass, and the peak torque value was used for data analysis. Limb symmetry was indicated by the

ratio between the nD and D torque values, with a ratio <.90 being deemed clinically significant.

### Results and Discussion

Data from the first (n=71) and second (n=36) were consolidated to provide normative data and evaluate limb symmetry. A paired t test revealed significant differences between limbs during flexion (D=1.48 Nm/kg, SD=0.289; nD=1.40 Nm/kg, SD=0.258, p<0.002) and extension (D=2.94 Nm/kg, SD=0.527; nD =2.79 Nm/kg, SD=0.498, p<0.001) (Figure 1).

**Figure 1:** Normative knee flexion and extension isometric torque values for adolescent athletes (“minimum”, first quartile (25%), median, third quartile (75%), “maximum”). Open circles are a representation of moderate outliers. (blue: flexion, green: extension; visit 1 and 2, n= 36)

A subgroup analysis of the participants with two visits (n=36), using a two-way ANOVA, indicated an interaction between limb dominance and visit number during knee extension, highlighting a significantly greater change in torque values for the D limb (150.5Nm) compared to the nD limb (136.5Nm) across visits (p < 0.001). Limb symmetry ratios revealed that after the second visit the number of cases that presented ratios less than .90 were doubled (Visit 1=11, Visit 2=22) indicating the importance of considering limb dominance in the maturing population.

### Conclusions

Our findings suggest that (1) strength increases over a 7-15 month period in youth maturation and (2) the effect of limb dominance on strength also increases. It is reasonable to conclude that youth with an ACL injury would normally experience similar changes. As such, using the contralateral limb strength to gauge readiness for return-to-sport after ACL injury is a flawed metric. These patients must also be considered with respect to the expected changes of maturation and limb dominance.

### Summary

Impairment in mechanical stability while walking contributes to falls in people with dementia [2]. The aim of this study was to determine if inter-segmental coordination of the upper and lower body segments during natural gait is predictive of stability and falls. Episodes of walking were captured using a vision-based system and analysed over the first 2 weeks to obtain a measure of the cross-correlation between upper and lower body segments. The cross-correlation between upper and lower body segments revealed a maladaptive pattern of walking.

### Introduction

People with dementia fall frequently and impaired mechanical stability while walking is an important predictor of falls in dementia [2,3]. Mechanical stability is the relationship between the center of mass (COM) and the boundaries of the base of support (BOS). In healthy individuals, shifts in the COM (upper body) outside of the BOS are stabilized through adaptations through foot placement (lower body) [1]. The coordination of the upper and lower body joints may thus be used to examine impairments in mechanical stability in people with dementia.

### Methods

We analyzed data from an observational study using a vision-based gait monitoring system, that incorporated a Kinect camera. Joint coordinates from 2 weeks of unsupervised walks of 52 individuals were used to derive measures of coordination. We examined the cross correlation between a spine marker and knee markers (right and left) in the frontal plane as the measure of coordination.

### Results and Discussion

Preliminary analysis of 30 participants (mean 7.83 walks per participant) revealed a median lag of -4.76% (range -16.21% to 6.52%), where negative lags indicate peak knee abduction occurs before peak spine abduction in a single gait cycle. Most participants (60%) had negative lags, representing a maladaptive gait pattern. To maintain the COM within the BOS, lateral foot placement should not precede COM movement. This may be indicative of impaired mechanical stability. Lag times were also highly variable within individuals (median lag time variability = 10.49%, range 7.64% to 16.38%).

### Conclusions

Most of the participants with dementia demonstrated poor temporal coordination of their upper and lower body segments, with significant variability. Future analyses will examine the relationship between upper and lower body inter-segmental coordination and mechanical stability and fall risk.

## Biomechanical improvement and timing for total knee arthroplasty surgery

Chang Shu<sup>1</sup>, Fangjian Chen<sup>1</sup>, Michael Bates<sup>2</sup>, Ronald W. Singer<sup>2</sup> and Nigel Zheng<sup>1</sup>

<sup>1</sup>The University of North Carolina at Charlotte, NC, <sup>2</sup>OrthoCarolina, NC, USA

### Summary

Patients with osteoarthritis are always wondering when is the optimal time for surgery. This study focuses on the timing of TKA surgery by analysis of young cohort and elder cohort who had undergone TKA preoperatively and postoperatively. The kinematics data from the motion capture system was compared between two groups. It is concluded that the young patients had better improvement in gait speed, balance test and expectation & satisfaction score.

### Introduction

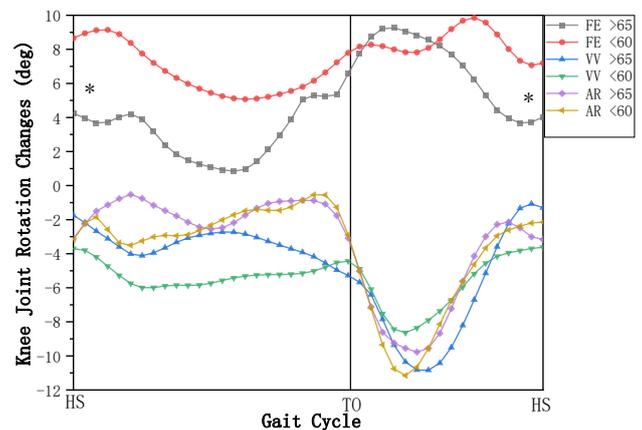

Patient age, radiographic, and symptoms are typically considered as the three crucial timing factors in choosing the osteoarthritic patients for total knee arthroplasty (TKA) [1]. Due to the limited lifespan of the knee implant, younger patient always treated with nonsurgical options first. However, it is reported that the younger TKA patients would potentially benefit from the surgery than the elder TKA patients [2]. The purpose of this study was to evaluate the associations among the age cohorts, the biomechanical outcomes and patient satisfaction and expectation score in order to comprehend the age factor in timing of TKA.

### Methods

39 posterior-stabilized TKA subjects were recruited and tested preoperatively (pre-op) and 21 of them postoperatively (post-op), with 7 subjects (age <60, 55±2.5) in young group and 10 subjects (age>65, 68±3) in elder group (Table 1). Motion data, clinical assessment (Time up-go, sit to stand, and balance test using BIODEX) and knee society score were collected during each visit. Motion data during walking was collected at 120 Hz (FX 40, VICON) and biomechanical variables were computed using a custom MATLAB program. The improvement was defined by the difference between preoperative and postoperative surgery. One-way ANOVA was performed and the significance level was set as 0.05.

### Results and Discussion

There were no significant differences in pre-op biomechanical variables between the two groups. There were significant differences in the flexion-extension improvement in the stance phase. Greater heel strike angle could explain that gait speed was significantly increased in young group (Table 1). Both groups had similar improvement in varus-valgus and axial rotation following TKA (Fig. 1). The young group had greater improvement in expectation and satisfaction than elder group (Table 1). Single leg (with implant) balance test results showed young group had better performance than elder group. Young group had 52% improvement and was significantly better than the elder group (14%). This indicated that the young patient restored their muscle strength much better.

**Figure 1:** Knee joint rotation improvement during walking. FE: Flexion(+)/Extension(-), VV: Varus(-)/Valgus(+), AR: Internal(-)/External(+). HS: heel strike, TO: toe-off. Statistical analysis was performed between young and elder group. \*: p<0.05.

### Conclusions

Both groups had very similar improvement on knee joint rotation except greater flexion at stance phase. The better subjective assessment was found in young patients. Overall, the young group had slight better outcomes.

**Table 1:** Subject demography and variables. \*: p<0.05 between the pre-op and post-op. #: p<0.05 between two groups post-op.

<sup>4</sup>Department of Surgery, Division of Orthopedic Surgery, University of Ottawa, Ottawa, ON, Canada

Email: [dbenoit@uottawa.ca](mailto:dbenoit@uottawa.ca)

### Summary

The purpose of this study was to determine if sex and/or anterior cruciate ligament (ACL) injury affect peak torque values produced during isometric and isokinetic knee flexion and extension tasks in ACL-injured (ACL*i*) and uninjured (CON) paediatric males and females. Uninjured controls display a higher mean limb symmetry index (LSI) for isokinetic extension torque compared to ACL-injured patients, however, the opposite is true for isokinetic flexion torque. There were no interaction effects found, therefore, strength deficits following an ACL injury are not dependent on the individual's sex. However, it was determined that leg dominance should be considered when assessing knee joint function as it relates to paediatric rehabilitation guidelines.

### Introduction

There is no consensus on appropriate ACL return-to-activity (RTA) guidelines for paediatric athletes [1]. Current practice may be inadequate given that 21.3% - 38.1% of paediatric patients sustain an ACL re-injury, and only 56-63% returning to preinjury level of sport participation [1, 2]. Through the use of isometric and isokinetic knee flexion and extension data, we can gain insight on muscular functional performance and thus rehabilitation status [3]. However, to date, no research has examined if interaction effects exist between sex and injury status regarding lower-limb strength in youth. Therefore, the purpose of this study was to determine if sex and injury status affect peak torque values produced during isometric and isokinetic knee flexion and extension tasks in paediatric male and females with and without an ACL*i*.

### Methods

Sixty-five (46 females) ACL*i* patients with confirmed ruptures and 70 (39 females) control participants were recruited to participate in this study. All participants performed maximal voluntary isometric and isokinetic knee flexion and extension tasks on an isokinetic dynamometer (System 4 Pro, Biodex Medical Systems, Inc., New York, USA). Isometric contractions were performed in a seated position with the knee joint held at 60° of flexion. Isokinetic knee flexion and extension was performed at 60°/s for a total of 44 repetitions. Peak torques were identified during the

isometric and isokinetic tasks and normalized to each participant's body mass (Nm/kg). Limb symmetry indexes (LSI) were then calculated for each limb (non-dominant/dominant and injured/contralateral limb). Two-way ANOVAs ( $\alpha=.05$ ) were used to evaluate the effect of sex (male vs. female) and injury status (ACL*i* vs. CON) in isometric and isokinetic torques and LSIs.

### Results and Discussion

Uninjured controls had higher mean LSIs for isometric extension torque compared to ACL*i* patients ( $p<.001$ ; Table 1). For the isokinetic task, control participants had higher mean LSIs for isokinetic extension torque compared to ACL*i* ( $p=.002$ ); however, ACL*i* patients had a higher mean LSI for isokinetic flexion torque ( $p=.013$ ). As well, males demonstrated a higher mean LSI compared to females for the isokinetic flexion torque ( $p<.050$ ). No interaction effects were seen in either task.

The results indicate that strength deficits (LSIs) following an ACL injury are not dependent on the individual's sex. The higher isokinetic flexion LSI in the injured individuals is likely due to the confounding factor of leg dominance. Since the dominant limb is typically stronger (Table 1), and 60.4% of the ACL-injured patients injured their dominant limb, the resulting strength deficit would not appear in the LSI.

### Conclusions

Leg dominance significantly affects isometric and isokinetic torque measurements at the knee in adolescent males and females. Since these measures are commonly used to assess rehabilitation in ACL*i* patients by comparing the injured to healthy limbs, those results may be biased by this limb dominance effect and must be considered. Further research is needed to evaluate the influence of limb dominance in ACL*i* strength deficit measures and how these may be used to inform the rehabilitation process and RTA evaluations.

### Summary

The purpose of this study was to compare the knee joint kinetics of unilateral total knee arthroplasty (TKA) patients during stationary cycling. The results display that replaced limbs have a decreased peak knee extension moment (KEM) compared to their non-replaced limbs, which is consistent with results during gait.

### Introduction

TKA patients walk with decreased peak KEM in their replaced limbs [1]. This unloading is indicative of quadriceps weakness or pain during motion. Stationary cycling is a common exercise task used for TKA rehabilitation due to the lower tibiofemoral compressive forces [2]. However, there is limited information on whether the peak KEM inter-limb differences found during gait are present during stationary cycling. The purpose of this study was to examine the knee joint kinetics of TKA patients during stationary cycling.

### Methods

Fifteen unilateral TKA patients (10 males, 5 females, 64.3 ± 8.2 yrs) were recruited from an orthopedic clinic and were operated by the same orthopedic surgeon (8.6 ± 2.4 months post-op, cruciate retaining = 14, bi-cruciate stabilizing = 1).

Participants cycled on stationary cycle ergometer (Excalibur Sport, Lode B.V., Groningen, Netherlands) in two randomized workrate conditions (80 and 100 Watt) at a cadence of 80 RPM. The ergometer was adjusted for each participant. Participants cycled for one-minute in each condition, with data collection occurring in the final 10 seconds. Three-dimensional motion capture (240 Hz, Vicon Motion Inc., Oxford, UK) and pedal reaction force (PRF) data (1200 Hz, Type 9027C, Kistler, Switzerland) were collected.

Five individual revolutions were truncated for data analysis and processed in Visual3D (C-Motion Inc., Germantown, MD, USA). A 2 x 2 (limb x workrate) repeated measures ANOVA was run with an alpha of 0.05.

### Results and Discussion

There was a main effect of limb for peak KEM ( $p = 0.034$ ) as well as for peak vertical PRF ( $p = 0.038$ ). The replaced limbs had a 21.3% lower peak KEM and 5.3% lower peak vertical PRF (Table 1). Additionally, replaced limbs had a significantly lower peak posterior PRF ( $p = 0.018$ ) compared to non-replaced limbs. Inter-limb differences found for peak KEM were similar to those during gait, with decreased KEM in replaced limbs. The KEM in replaced limbs could be due to decreases in both vertical and posterior PRFs. Interestingly, increases in workrate by 20 W did not alter knee joint moments, which has been previously reported [3]. There were no differences between limbs for peak knee abduction moment (KAbM) ( $p = 0.376$ ). There was only a main effect of workrate for peak vertical PRF ( $p < 0.001$ ) with a larger force at 100 Watt compared to 80 W (Table 1).

### Conclusions

Unilateral TKA patients cycled with a reduced peak KEM in their replaced compared to non-replaced limbs. This indicates an unloading of the replaced limbs, similar to findings in gait. When increasing intensity via workrate in cycling, increments of 20 W may be ideal to not exacerbate inter-limb loading differences found in peak KEM.

# Evaluating Muscle Recruitment during Lower Trapezius Early-Stage Exercises Performed below 90° Shoulder Elevation

Herrera. Maria C<sup>1</sup>, Garcia. Jonathan,<sup>1</sup> Dickerson. Clark<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada

Email: m6herrer@uwaterloo.ca

## Summary

sEMG activity from serratus anterior (SA), lower trapezius (LT), middle trapezius (MT), and upper trapezius (UT) was recorded from 32 healthy participants while performing four shoulder rehabilitation exercises targeting LT strengthening. No exercise performed below 90° of shoulder elevation had statistically similar LT activity as the gold standard overhead Y Prone exercise. However, side lying external rotation and wall angel exercises still achieved low UT/LT ratios. Wall angel and the side lying external rotation exercises may be useful early-stage shoulder rehabilitation protocol exercises to promote LT activation while achieving a low UT/LT ratio.

## Introduction

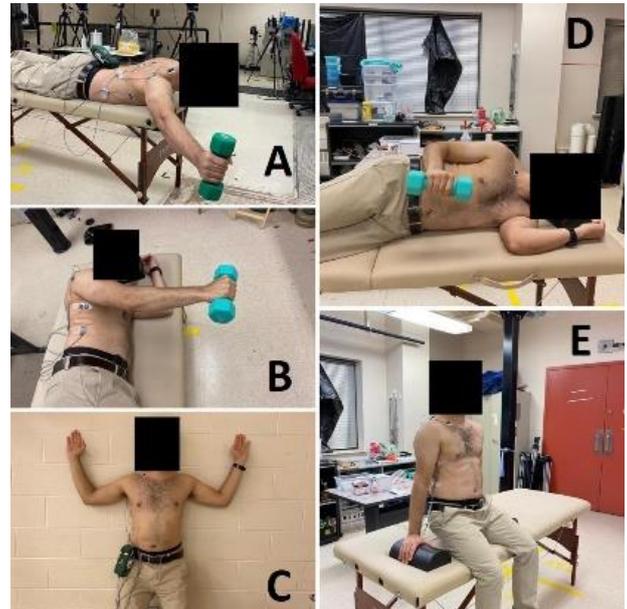

LT assists scapular control and rotation and is often weak with scapular dysfunction [1]. LT strength development is crucial in scapular control dysfunction. Protocols often include high shoulder elevation exercises, which are often impossible in dysfunctional shoulders. “Y prone” is one of the most common exercises [Figure 1] [2]. A lack of research on more feasible LT exercises below 90° shoulder elevation exists. Exercises with high activation of LT and lower activation of UT are recommended to optimize scapular muscle balance [1]. This study compared EMG activity four periscapular muscles and the UT/LT ratio during low arm elevation exercises with the Y prone exercise.

## Methods

Thirty-two (15M/17F) right hand dominant healthy persons participated. sEMG was recorded during five exercises (seated press up, side lying external rotation, side lying flexion, and wall angel, and Y prone) [Figure 1]. One-way repeated measures ANOVAs were used to compare muscular recruitment and UT/LT ratio across exercises ( $p < 0.05$ ). A Post-hoc Tukey-Kramer test was used to find significantly different means from each other ( $p < 0.05$ ).

## Results and Discussion

No exercise performed below 90° of shoulder elevation had similar lower trapezius activity as Y Prone ( $p < 0.0001$ ).

**Figure 1:** A: Y prone, B: Side lying flexion, C: Wall angel, D: Side lying external rotation, E: Seated Press Up

However, side lying external rotation and wall angel exercises demonstrated the highest LT activation peak and a low significant UT/LT ratio [Table 1].

## Conclusions

Wall angel and the side lying external rotation exercises are considered safe and feasible to be implemented in an early-stage shoulder rehabilitation protocol to promote a combination of high LT muscle activation with a low UT/LT ratio.

## Acknowledgments

This project was partially funded through an NSERC Discovery Grant held by Dr. Clark Dickerson, 311895-2011.

<sup>4</sup>The Biomechanics Initiative, Parent Organization of National Biomechanics Day, Earth

Email: [lisa.macfadden@sanfordhealth.org](mailto:lisa.macfadden@sanfordhealth.org)

### Summary

National Biomechanics Day (NBD) has grown over the last five years into a worldwide celebration of all things biomechanics. Biomechanists have participated in 392 NBD events in [28 nations](#), reaching over 29,000 students and 950 teachers. Through its unprecedented growth as a unique, fun-filled Biomechanics STEM and STEAM event, NBD has become part of the Biomechanics firmament. Here we present a brief history of NBD, review current initiatives and successes, and present our vision of the future.

### From small beginnings come great things – Proverb

National Biomechanics Day (NBD) began in 2016 with the distant goal of teaching biomechanics in high schools across the U.S. and its *raison d'être* was fully explained in the visionary, "[Why National Biomechanics Day](#)," [1]. The first NBD event was an unqualified success with over 2,000 high school students and teachers participating in 48 biomechanics experiences across the United States. Stemming from this success, the NBD outreach initiative grew to hundreds of synchronous events around the world. To date, over 29,000 students and teachers have participated in ~400 NBD events in 28 countries. Inspirational photos and videos from NBDs across the years and around the world can be seen [HERE](#).

### The future depends on what you do today – Ghandi

Since 2016, NBD has connected biomechanics labs around the world through coordinated events broadcasted on social media channels, innovative and creative competitions, articles in lay and science journals, newspaper and television news stories, music playlists, fun and wild graphics advertisements, among other exposures. NBD has also supported and collaborated with 17 different biomechanics societies and 37 commercial biomechanics companies. Anecdotally, faculty and students have commented that the value of annual society meetings has increased because of the relationships fostered through NBD, creating more opportunities for networking and collaborating. We suspect that the less formal guidelines for promoting an NBD event may have positively impacted people involved with biomechanics, which felt comfortable to promote small events, of low budget, and leveraging new ideas and initiatives to popularize and share biomechanics content.

Today, many individual and student driven outreach events now exist due to the impact and leadership of NBD. These include the Biomechanics On Our Mind ([BOOM](#)) podcast, [The Biomechanist](#) network for biomechanics, and the [Sports Biomechanics Lecture Series](#). Newly formed, focused biomechanics societies have energetically affiliated with

NBD, including the Black Biomechanist Association (BBA) and International Womxn in Biomechanics (IWB). NBD has also introduced students from historically underrepresented groups to biomechanics at a rate we hope will enhance diversity in biomechanics. By 2017, over 50% of student participants were female and 50% of student participants were non-Caucasian. We assume that NBD being promoted globally, including in developing countries, contributes to successfully reaching and promoting underrepresented groups.

As more high school students are introduced to biomechanics, and more graduate students, faculty, and private companies are connected through NBD, the community is developing a foundation that inspires young people to make their own impact on the field.

### The best way to predict the future is to create it – Lincoln

In 2019, The Biomechanics Initiative (TBI) was created as the parent organization for NBD. Through TBI, support for other initiatives has been possible thanks to donations from [sponsoring organizations](#). This year, TBI & NBD are offering funding opportunities in collaboration with biomechanics societies (ASB and ISB) and affiliates (BBA and IWB) to support NBD events that reached more diverse populations. Additional funding opportunities were provided in Australia and Brazil to support NBD events where financial limitations would have prevented schools from participating (Australia) and to promote biomechanics research opportunities for high school students (Brazil). Future grants and scholarships are planned to help young biomechanists impact biomechanics.

### Go forth and set the world on fire – Ignatius of Loyola

National Biomechanics Day has led to grassroots growth in biomechanics and spurred many new exciting directions for our outreach efforts. As we look to the future, we are excited about the opportunities that TBI and NBD will create for the biomechanics community. We aim to inspire others to share their passions with students and each other so that our community and impact on society can grow. A dream that started with the goal of integrating biomechanics into the high school curriculum has grown into a global vision that will continue to build communities, initiatives, and programs that revolutionize how we train future generations of biomechanists and inspire and support one another. Together, we will make Biomechanics the Breakthrough Science of the 21<sup>st</sup> Century!

## Development of a Hands-on, Wearables Course as an Alternative for Physiology Labs

Patrick Mayerhofer, Jim Carter, Max Donelan

Department of Biomedical Physiology and Kinesiology, Simon Fraser University, Vancouver, Canada

Email: pmayerho@sfu.ca

### Summary

Here we present a remote alternative to a traditional physiology lab course. We developed a customizable, inexpensive, microcontroller-based hardware kit with devices that can measure different physiological variables. We also developed open-access software to program the hardware for data collection and analyze the collected data, which we share in online repositories. With customizable lab manuals and supplementary video tutorials, all freely available online, students learn to conduct physiological experiments, by collecting and analyzing data (e.g.: EMG, ECG, kinematics).

### Introduction

Delivering a remote, hands-on lab course in physiology can be challenging. During the COVID-19 pandemic, we developed an inexpensive, customizable hardware kit along with fully open-source teaching resources to help educators deliver their physiology lab courses remotely. These resources allow educators to teach students how to do hypothesis-driven physiological experiments, without the need for students to have previous coding or electronics experience. Additionally, all of our resources are fully customizable, allowing educators to fit the requirements of their respective physiology courses.

### Course Principles

Before developing our course resources, we defined multiple key principles. First, the whole system must be wearable. All measurement systems should be able to run battery powered and store data. Second, students should not require technical experience for taking the course. Setting up the hardware should work without soldering, and the number of wires and devices for a measurement system should be small. Students also should not require prior coding knowledge to set up software for the measurement systems and the data analysis. Third, all resources should be financially accessible. The hardware kit should be relatively inexpensive (~cost of a textbook), all the software required should be open-source, and the instructional materials should be open-access. Lastly, the workload for educators to develop a similar course should be minimal. All hardware, software, and instructional materials should be customizable. Following these principles will allow students to conduct insightful experiments on different physiology systems.

### Course Design

Our hardware kit consists of commercially-available electronic components, with a microcontroller as its base and a suite of physiological sensors. The microcontroller is a small computer that reads, alters, and outputs signals from and to other devices in the system. To make the hardware kit wearable, a 9V battery powers the system and a data logger stores

the data on a memory card, eliminating the need to be tethered to a computer. To make the system solderless and minimize the number of wires, all devices in the kit connect to the microcontroller with no more than three wires. Digital, analog, or communication via a specific one-wire protocol called “Qwiic”, are all possible. Our particular hardware kit (Fig 1) is ~\$120 US. It can be customized with different sensors depending upon instructional needs.

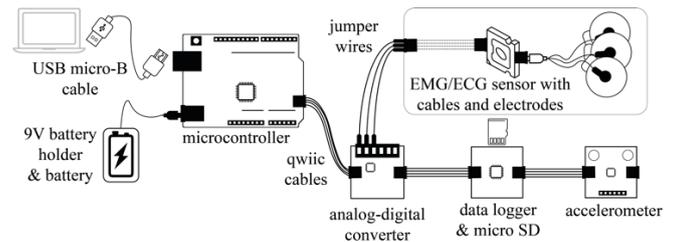

Figure 1: Components of our hardware kit.

To support students without prior coding experience, we share our codes in open-access GitHub repositories. To make all software open-source, we chose the Arduino Integrated Development Environment (IDE), a commonly used programming platform for microcontrollers, to program our hardware, and Python, the fastest growing programming language in the world, for data analysis [1]. Educators can download, customize, and share all code using GitHub. For lab manuals, we use open-access Google Docs to allow educators to copy and edit documents, as well as share them with collaborators and students. To help students set up measurement systems and analyze data, we created a YouTube channel with supplementary video tutorials. To customize this library, educators can create their own YouTube library with videos from our channel and their own additional content. These resources allow educators to rapidly implement labs for students to conduct EMG, ECG, and kinematics experiments. And they can be leveraged to develop new labs for different physiological systems.

### Conclusions

Our course resources are available online [2]. We taught this course for the first time in Fall 2020. In their homes, students learnt how to build measurement systems, acquire and analyze real physiological data, trouble-shoot problems, and interpret results. Our resources can support universities to set up their own hands-on, customized wearables physiology lab courses.

## Pilot study: Performance benefit of young athletes using a video-based feedback and instrumented starting blocks in athletics sprint start

Beat Göpfert<sup>1</sup>, Edith Bek<sup>1</sup>, Alina J. Tittel<sup>1</sup>

<sup>1</sup> Department Biomedical Engineering, University of Basel & University Children's Hospital Basel; Switzerland  
Email: beat.goeppfert@unibas.ch

### Summary

An Instrumented video-based movement analysis is rarely used in local teams with young athletes (U16), due to availability and knowledge. A pilot study, in which an athletic sprint start was done, showed, that young athletes today benefit in their practice because they are often used working with video-based teaching tool and thus were able to optimize their movement pattern.

### Introduction

In athletics, the sprint start from the starting block initiates the beginning of sprint race and is seen as an important part of the race. Especially in young athletes "A good start gives a good feeling for the race", but the movement pattern of the start is very demanding and requires a lot of practice, muscular coordination and power. As a fast and complex movement, it is also demanding for coaches to identify the optimal movement pattern for different athletes with different performance and skill levels. Nowadays video analysis methods are often used in high-performance athletes, but rarely in young athletes (U16). The goal of this pilot study was to evaluate the benefit of video-based feedback a with instrumented starting blocks during the sprint start in athletics.

### Methods

7 young athletes (14 y, 5 f, 2 m) of a local athletic team participated in this pilot study, while performing a sprint start over 10 m, using instrumented starting blocks with two 3D-forceplates (KI-Sprint-System, Kistler AG, Winterthur, CH). 3 starts were recorded with a high-speed camera (100 Hz) during 3 independent indoor practice sessions. There were 2 weeks of regular practice between each measurement session. After the first and second measurement session, each athlete got an individual written feedback incl. videos with proposed adjustments for the following measurement session. The changes in starting performance (force direction, step length, step time) were analyzed and compared between the 3 sessions.

### Results and Discussion

The results showed that most of the athletes had a smaller push-off force angle, resulting in an 8% increase of the horizontal push-off force and a slight longer first step of the rear leg of 10% (4 cm). Furthermore, in the set position the center of mass moved 17% (4cm) in direction of the starting line, which allows to produce higher horizontal force [1]. The individual temporal parameters of the ground-contact and flight phases have not changed much in the 3 sessions, except for the ground contact time of the first step, which became in avg. 0.012sec. longer. This resulted to an mean in-

crease of the total starting time for the first two steps of 0.015sec in Session 3 compared to Session 1. Unfortunately, due to the COVID-19 pandemic, the regular practice had to be interrupted for 3 months, 4 weeks after the 3rd measurement session. Therefore, the results of the few competitions in late summer are not very meaningful.

Figure 1: Athlete using the KI-Sprint-System during the pilot-measurement

### Conclusions

#### Conclusion for the start performance:

The results show that beside the maximum muscular power during push-off and ground contact: (a) Optimizing the push-off-angle more towards a more forward than upward movement [2] and (b) the maximal capable and controllable angular velocity and power in the hip-joint, are some of the critical factors for a good starting performance in young athletes in the athletics sprint start.

#### Conclusion for the coaching process:

The pilot measurement showed that young athletes today can improve their technique well with the help of video analyzes and biomechanical measurement. In addition, it is helpful for coaches to get objective parameters in order to set priorities in the training program. It should be kept in mind that in a possible future coaching career, athletes are more likely to use such technologies if they are already familiar with and could benefit from it.

### Acknowledgments

We thank the athletes for participating and Kistler AG, Winterthur for providing the KI-System in the pilot study

## Active learning strategies using surface electromyography improve the undergraduate student's understanding of neuromuscular human movement control

Carlos De la Fuente,<sup>1,2,3</sup> Álvaro S Machado,<sup>1</sup> Marcos R Kunzler,<sup>1</sup> Mauricio Delgado,<sup>2</sup> Felipe P Carpes<sup>1</sup>

<sup>1</sup>Applied Neuromechanics Research Group, Federal University of Pampa, Brazil; <sup>2</sup>Physical Therapy career, Health Sciences Department, Pontificia Universidad Católica de Chile, Chile; <sup>3</sup>Clinica MEDS, Chile.  
Email: delafuente@gmail.com

### Summary

Here we describe the potential of laboratory activities integrating theoretical and hands-on aspects using active methodologies and surface electromyography (sEMG) to improve comprehension about neuromuscular human movement control in undergraduate students without a previous background in biomechanics.

### Introduction

In many health sciences careers the initial studies of the human body involve the acquisition of biology and anatomy knowledge. However, these biological topics are often presented disconnected from mechanical elements of movement including the effects of gravity, inertia, or torques [1]. We hypothesized that combining a strategy to stimulate critical thinking skills and an active methodology of learning into biomechanics lab using sEMG would result in a better understanding of the link between the neuromuscular system and mechanical elements of human movement in undergraduate students without a previous background in biomechanics.

### Methods

Retrospectively, we analyzed the difficulties and advances of students to solve problems related to the links between the neuromuscular system and mechanical elements of human movement for 482 second-year physiotherapy students attending a human movement analysis course from 2013 to 2018. The problems included tasks such as bipedal standing, shoulder elevation, handgrip test, weightlifting, and walking. The sEMG signals were collected from the main superficial muscles that are active during the performance of these tasks under diverse conditions like altering workload, movement speed, amplitude, and fatigue level. sEMG signals were online processed during the classes and served to illustrate the concepts. We employed discussions in small groups, oral presentations of outcomes, and round tables with questions from the students. The difficulties and advances of students were qualitatively described. The students' grades in the lab activities, the overall course grades, and the students' self-reports were considered in the data analysis. All the students had no specific biomechanics background. To quantify how the grade in the laboratory activities explained the final grade of the overall course, we performed linear regression with an alpha set to 5%.

### Results and Discussion

Figures 1 and 2 summarize the results. Students reported difficulties when activities addressed aspects involving basic anatomy knowledge, the understanding of concentric and eccentric muscle actions, and the effects of an external and

internal couple of forces across the joints. Common difficulties involved lack of reasoning and discussion about how the joints are actively stabilized and generate movement from the muscle activation. However, better integration between muscle activation and mechanical outputs to control movements occurred after each activity. The laboratory grades explained the overall course grades ( $p < 0.001$ , R-square = 0.427).

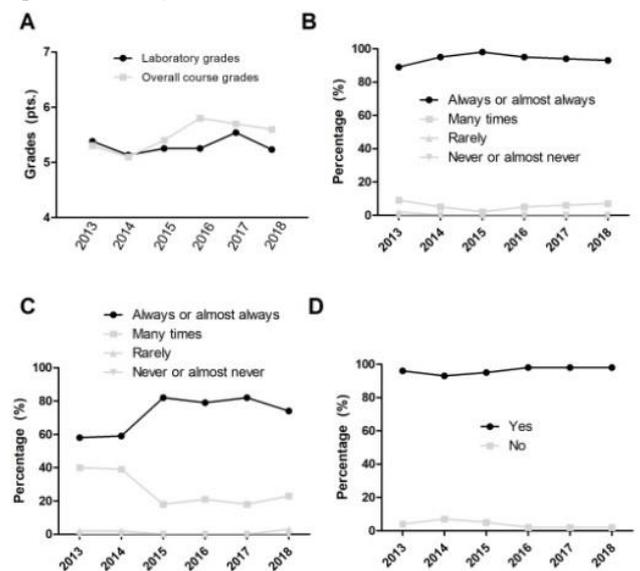

Figure 1: Self-reported time series. A. Grades. B. Real-life examples involved in the course. C. Critical thinking involved in the course. D. Satisfaction with the course.

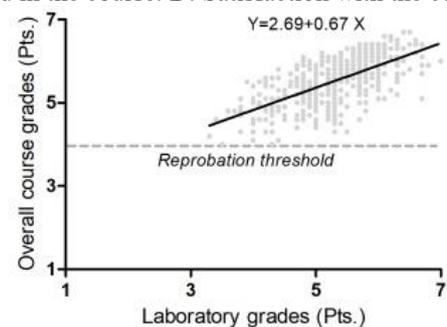

Figure 2: Regression analysis.

### Conclusions

Active learning strategies using sEMG facilitate the understanding of neuromuscular human movement control in undergraduate students without a previous background in biomechanics.

## Micromovements, low back pain, and computer task performance during prolonged sedentary postures

Liana M. Tennant<sup>1</sup>, Jackie D. Zehr<sup>1</sup>, Jessa Buchman-Pearle<sup>1</sup>, Jack P. Callaghan<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Waterloo, Waterloo, Canada

Email: liana.tennant@uwaterloo.ca

### Summary

Lumbar spine fidgeting early in standing and often in sitting are thought to reduce transient low back pain (LBP) related to these postures. Posture and LBP may also affect productivity. During two, 2-hour exposures, there was no effect of standing-induced LBP on the frequency of lumbar fidgets in either sitting or standing. For a data entry computer task, productivity was the same between LBP groups in sitting but was reduced in standing in participants with standing-induced LBP. There was no effect of posture or LBP group on typing performance or score on a reading comprehension test (GRE). Thus, performance of demanding computer tasks while standing may decline in individuals with standing-induced LBP performing the same task seated.

### Introduction

Micromovements of the lumbar spine, including fidgets, may have a complex relationship with transient low back pain (LBP) development in prolonged sedentary postures [1-4]. For sitting, lumbar fidgets may minimize sitting-induced LBP [1]; in standing, fewer fidgets in the first 15 minutes may predispose individuals to LBP [3]. Sitting or standing is thought to have little effect on productivity for typing tasks [5]. Our aim was to explore how fidget frequency may differ for individuals with standing-induced LBP in both sitting and standing, and the interaction of posture and LBP on computer task performance. We expected that standing-induced LBP developers would show similar fidget patterns regardless of posture, and that LBP may worsen task performance.

### Methods

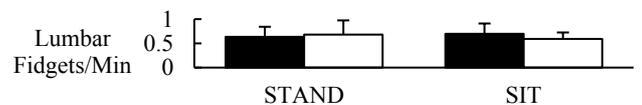

Twelve back-healthy adults (6 males, age:  $24 \pm 3$  y, height:  $1.70 \pm 0.12$  m, mass:  $66.8 \pm 12.7$  kg) completed two hours of data entry, typing, and an online simulated Graduate Record Examination (GRE) in equal time allotments and in a randomized order while standing and sitting on separate days. Lumbar spine posture was measured at 250 Hz with triaxial accelerometers at S1 and L1 (ADXL335, Analog Devices, MA, USA). LBP was recorded on a 100 mm visual analog scale every 20 minutes. LBP was noted if pain exceeded 10 mm from baseline [3].

Accelerometer data were filtered at a 1 Hz cut-off using a dual-pass low-pass Butterworth filter. Lumbar flexion angle was calculated as the difference in accelerometer inclination. Lumbar fidgets were identified by comparing each frame of angle data to the moving average, such that:  $|\bar{x}_w - x_i| > 3SD_w$ , where  $\bar{x}_w$  and  $SD_w$  are the average and standard deviation of a moving window (size  $w = 50$  s), centred on point  $x_i$  [2]. Maximum fidget duration was 4 s. Fidget frequency was normalized to time. Mixed general linear models were used to

investigate fidget frequency (fidgets/min), typing (words/min (WPM)), data entry (entries/min), and GRE score (%) between standing pain developers (PD) and standing non-pain developers (ND), in sitting and standing ( $\alpha < 0.05$ ).

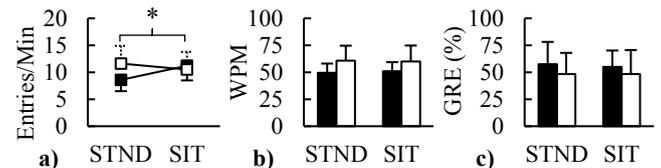

### Results and Discussion

Six participants developed LBP in standing. There was no difference in lumbar fidget frequency between postures ( $p = 0.84$ ). Contrary to our hypothesis, there was no difference in fidget frequency between LBP pain groups ( $p = 0.81$ ), nor an interaction effect ( $p = 0.25$ ) (Figure 1).

**Figure 1:** Fidgets in PDs (■) and NDs (□) in sitting and standing.

In partial support of our hypothesis, for data entry, productivity was similar for both pain groups in sitting but worsened in standing in the PDs ( $p < 0.01$ ) (Figure 2a). Neither posture nor pain group affected typing ( $p > 0.19$ ,  $n = 11$  – one outlier removed) or GRE score ( $p > 0.48$ ) (Figure 2).

**Figure 2:** a) Data entry b) Typing, and c) the GRE scores in standing PDs (■) and NDs (□), in sitting and standing (STND). Significant interaction effect ( $p < 0.05$ ) denoted with an (\*).

### Conclusions

Any relationship between lumbar fidgets and LBP may be too nuanced for gross fidget behaviour to be similar between standing and sitting [3]. Standing-induced LBP worsened performance in standing data entry, possibly due to the many demands of the task (attention, mousing, and typing) and pain distraction, as only one participant developed LBP in sitting.

## Sex-specific neuromuscular adaptations to fatigue in a repetitive pointing task while sitting on a sit-stand stool

Chen Yang<sup>1</sup>, Yiyang Chen<sup>1</sup>, Erika Renda<sup>1</sup>, Julie N Côté<sup>1</sup>

<sup>1</sup>Biomechanics of Occupational and Sport Laboratory, Department of Kinesiology and Physical Education, McGill University, Montreal, Canada

Email: [chen.yang4@mail.mcgill.ca](mailto:chen.yang4@mail.mcgill.ca)

### Summary

This study quantified the sex differences in muscle activation adaptation to fatigue when sitting on a sit-stand stool. Participants performed a repetitive pointing task until task terminal while we collected the electromyographic data of the upper body muscles. Results showed that females and males adopted different activation strategies. Females demonstrated greater activation and variability of the prime movers. This highlighted the importance of considering sex differences when recommending sit-stand stool as an alternative workstation.

### Introduction

Muscle fatigue can be induced by repetitive occupational task and may lead to neuromuscular adaptations [1]. Previous studies have noted alterations of muscle activation amplitude, variability, and frequency with fatigue [2]. Recently more and more ergonomic workstations have been recommended to avoid impairments from prolonged work. Sit-stand stools intend to avoid the disadvantages of both standing and sitting. Previous studies focused on the kinematic, physiological changes when adopting sit-stand stool. However, how the muscle activity adjusts with fatigue when utilizing a sit-stand stool remains unknown.

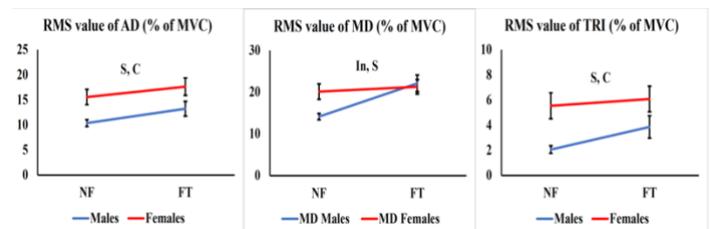

### Methods

Young healthy adults (n = 29, 15 males) were recruited to perform a repetitive pointing task (RPT) on a sit-stand stool (Muvman®, aeris-Impulsmobel GmbH & Co.KG, Germany) [3]. EMG data was recorded using a Delsys EMG system (Delsys Inc., Boston, MA, USA; Fs = 2000 Hz) using surface electrodes placed on: Upper Trapezius (UT), Anterior Deltoid (AD), Middle Deltoid (MD), Triceps Brachii (TRI), Biceps Brachii (BIC), and Left and Right Erector Spinae (LES and RES). EMG and perceived neck/shoulder exertion data was collected in the last 30 seconds of every minute during RPT. The task was terminated when perceived exertion score reached 8 out of 10. The first and last 30-second trials were recognized as the non-fatigued (NF) and fatigue-terminal (FT) trials.

EMG data were filtered (dual-pass 4th-order Butterworth bandpass filter, 20–500 Hz). Root mean squares (RMS) of EMG amplitude were averaged across forward movements to obtain one RMS value per muscle. The corresponding standard deviation (SD) of the RMS and Median Power Frequency (Mdpf) were also calculated. Generalized estimating equations (GEEs) were used to detect effects of sex and fatigue condition on EMG variables in each muscle.

### Results and Discussion

The RMS of all measured muscles increased after fatigue, confirming that the task induced fatigue in all muscles. The RMS of AD and TRI was greater in females compared to males. At NF, the RMS of MD was greater in females. However, the sex difference disappeared at FT. Sex differences were found in the RMS of AD (p=0.008), MD (p=0.003), and TRI (p=0.013) (Figure 1), i.e. in the prime movers only, rather than the stabilizer muscles. Similarly, the SD of activation in all the muscles increased after fatigue as well. Besides, females exhibited higher activation variability in AD (p<0.0001) and TRI (p=0.028) compared to males independently from fatigue. In terms of Mdpf, sex differences were observed in UT (p<0.0001), AD (p<0.0001), MD (p<0.0001), and BIC (p=0.023). Females showed higher firing frequency in these muscles compared to males. Combined with the RMS results of AD and MD, the greater activation amplitude and higher activation frequency in females may imply that females experienced a higher exertion at deltoid during the task. Besides, greater activation and variability of prime mover muscles (AD and TRI) suggest that the task was more demanding of the prime movers of females than those of males.

**Figure 1:** RMS results of AD, MD, and TRI. \*IN, S, and C stands for interaction effect, sex effect, and condition effect, respectively.

### Conclusions

Sex differences exist in EMG adaptations to muscle fatigue induce by a repetitive arm task while sitting on a sit-stand stool. Females may have experienced a higher exertion of prime movers during the task. Sex differences need to be considered when recommending sit-stand stools.

Email: Samuel.Lamanuzzi@mail.mcgill.ca

### Summary

Anti-fatigue lenses (AFL) claim to offer health benefits. However, no studies have measured their impact on discomfort, biomechanical outcomes, or computer work performance, or how these effects differ between the sexes. Twenty-four University students and regular computer users (n = 12 males) were recruited. Participants underwent two 90-minute computer sessions with AFL or placebo lenses. Visual analogue scales (VAS) for eye strain, neck/shoulder and other body discomfort were recorded, with performance measures, electromyographic (EMG) upper trapezius (UT) amplitude and variability and head/neck kinematics. Discomfort increased over time, more in females (eye strain and neck/shoulder:  $p < 0.001$ ; other body regions:  $p = 0.013$ ). UT EMG amplitude for females was negatively correlated to eye strain in the placebo group. UT EMG variability for males wearing AFL was negatively correlated to eye strain. Neck flexion was positively correlated to eye strain for males wearing placebo lenses, suggesting sex-specific effects of AFL.

### Introduction

AFL show multiple benefits, such as glare reduction and near vision magnification [1,2]. These benefits claim to reduce eye strain, neck pain, trapezius muscle activity and other symptoms associated with musculoskeletal discomfort [1,2,3,4]. However, no study has objectively examined the outcomes of AFL on performance, eye strain and musculoskeletal characteristics in university students and how they might differ between the sexes. The objective of this study was to determine the effectiveness of AFL on visual and musculoskeletal discomfort, EMG UT activity amplitude and variability, kinematics and performance outcomes in males and females. We hypothesized that AFL wear would reduce eye strain and musculoskeletal discomfort in both sexes. In addition, that AFL would improve the performance for both sexes while minimizing UT EMG activity, neck flexion and head protraction, while increasing UT muscle variability.

### Methods

Twenty-four university students and regular computer users (n = 12 males; mean age =  $23 \pm 2.3$  years) were recruited. Participants underwent two 90-minute seated computer sessions with either AFL or placebo lenses in random order. VAS for eye strain, neck/shoulder and other body discomfort were recorded, along with typing speed and errors. UT EMG activity was measured using surface electrodes (Delsys), and tridimensional head/neck kinematics was quantified using

motion capture (Vicon). Main and interaction effects of Condition (AFL vs. Placebo), Time and Sex were analyzed using ANOVA. Relationships between variables were analyzed using Pearson/Spearman's correlational analysis.

### Results and Discussion

Eye strain and discomfort to the neck/shoulder ( $p < 0.001$ ) and other body regions ( $p = 0.013$ ) significantly increased with time, more so in females. It has been speculated that extended periods of sustained computer work can stimulate low levels of constant muscle activity which could explain the observed musculoskeletal discomfort found in our study [5]. In the placebo lens condition, there was a negative correlation between UT EMG amplitude and eye strain ( $r(18) = -.49, p = .05$ ), with a greater impact in females ( $r(7) = -.681, p = .05$ ). UT EMG variability for males wearing AFL was negatively correlated to eye strain ( $r(9), -0.622, p = 0.041$ ). This is in line with past results suggesting a health-protective effect of high motor variability [6]. There was a significant positive correlation between eye strain and neck flexion in males wearing the placebo lenses ( $r(7), 0.705, p = 0.034$ ). Excessive glare during computer work of 10 minutes has been shown to increase UT muscle blood flow and induce a more forward-bent posture, eliciting a specific visual stress response [7].

### Conclusions

Sex-specific effects of AFL are suggested during a 90-minute seated computer task. There seems to be a clear, sex-specific link between the visual and musculoskeletal system while wearing AFL, since females experienced greater ratings of discomfort throughout the entire task. This could lead to sex-specific recommendations for AFL wear.

# Relationship between the global movement of the hand and the forearm muscles during typing

## Summary

This study aimed to examine the relationship between the global movement of the hand (GMH) and the forearm muscles during typing. Seven healthy adults input Japanese sentences. The Unchanging Typists (UT) group consisted of subjects with lower than average right-hand GMH, and the Changing Typists (CT) group consisted of subjects with higher GMH. There was a significant difference in GMH between the groups ( $p < 0.05$ ). There was no significant difference in muscle activities between the groups. These data indicated that although GMH can affect the spatiotemporal efficiency of typing movements, maintaining a static home position is not necessarily an explanatory factor that reduces the cost of forearm muscle activities during typing.

## Introduction

The fingers and hands used for keystrokes depend on the individual's typing style [1]. The UI and o keys are located on the right side of the QWERTY keyboard, so they are repeatedly inputted by the fingers of the right hand in the case of Japanese sentences. While most typists move their entire hand toward the key to be typed, the others have a spatiotemporally efficient strategy of keeping their hand in a static home position during typing. However, the relationship between these strategies and the forearm muscle activities is not clear. This study aimed to show the relationship between changes in the GMH and forearm muscle activities during Japanese text input.

## Methods

Seven healthy adults volunteered in the experiment. We used a 3D motion capture system, surface EMG and QWERTY keyboard. Infrared-reflecting markers were attached to landmarks and measured kinematics parameters (Figure 1). Surface EMG was attached to the right side of four forearm muscles (Table 1). Subjects entered the sentence of about 5,000 characters in Japanese. The UT group and the CT group data were compared using the unpaired  $t$ -test ( $p < 0.05$ ).

## Results and Discussion

The location mapping of the right wrist, hand, and index finger for UT and CT group (Figure 1).

Figure 1: Mapping of UT group (upper) and CT group (lower).

There was a significant difference in the GMH between the groups. ( $p < 0.05$ ). Comparisons of physical and kinematics parameters and muscle activities between groups showed no significant differences.

Table 1: Physical and kinematics parameters and muscle activities.

	Unchanging (n=3)	Changing (n=4)	p
global movement of the hand: GMH (mm/sec)	15.6 ± 0.2	40.7 ± 10.2	*0.02
Wrist width (cm)	6.6 ± 0.1	6.7 ± 0.5	0.93
Index finger length (cm)	8.9 ± 0.4	9.7 ± 0.7	0.17
Typing time (sec)	533.3 ± 270.0	209.8 ± 25.6	0.22
Changes of Wrist radial/ulnar deviation (deg/sec)	5.2 ± 1.6	11.8 ± 4.9	0.14
Changes of MP abduction/adduction deviation (deg/sec)	15.2 ± 3.8	25.4 ± 4.5	0.07
%MVC : Flexor carpi radialis (%)	1.0 ± 0.3	1.6 ± 0.6	0.27
%MVC : Flexor carpi ulnaris (%)	0.6 ± 0.2	1.0 ± 0.7	0.45
%MVC : Extensor carpi radialis (%)	3.0 ± 1.5	1.3 ± 0.4	0.13
%MVC : Extensor carpi ulnaris (%)	4.0 ± 2.8	2.7 ± 0.8	0.51

In the CT group, the index finger entered the 'u' key and vowels such as 'i' and 'o' key, and the home position was changed at any time. This strategy may be controlled by changes in hand posture due to forearm muscle activities and changes in segment position due to proximal muscles. Therefore, we did not observe an increase in forearm muscle activities.

## Conclusions

The GMH can affect the spatiotemporal efficiency of typing movements. Maintaining a static home position is not necessarily an explanatory factor that reduces the cost of forearm muscle activities during typing movements.

# Combining wearable sensors and machine learning to monitor low back loading and injury risks in material handling

Emily S. Matijevich<sup>1,\*</sup>, Peter Volgyesi<sup>2</sup> and Karl E. Zelik<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Vanderbilt University, Nashville, TN, USA

<sup>2</sup>Institute for Software Integrated Systems, Vanderbilt University, Nashville, TN, USA

## Summary

We discovered a promising wearable solution for practical, automated, and accurate monitoring of low back loading during manual material handling. Using signals from a trunk inertial measurement unit and pressure insoles together with a Gradient Boosted Decision Tree algorithm has the potential to provide a practical (relatively few sensors), accurate (up to  $r^2 = 0.89$ ), and automated way (using wearables) to monitor time series lumbar moments across a broad range of material handling tasks. This promising wearable solution has the potential to transform low back injury risk assessment, monitoring, and prevention in various industries. Full results and discussion are published in [2].

## Introduction

Low back disorders are a leading occupational health problem and about one in four workers reports dealing with low back pain [1]. Overexertion injuries are consistent with a fatigue failure process due to repetitive loading on the low back. There are opportunities to use low back loading and fatigue failure insights to understand and reduce the risk of overexertion injuries (e.g., through ergonomic assessments, or continuous, personal monitoring of injury risk). While wearable sensors provide a promising tool for unconstrained, continuous monitoring of low back loading, there remains a need for a solution that requires a small number of wearable sensors (to be practical to implement in industry) and provides validated estimates of low back loading for a range of work-relevant tasks (to ensure accuracy).

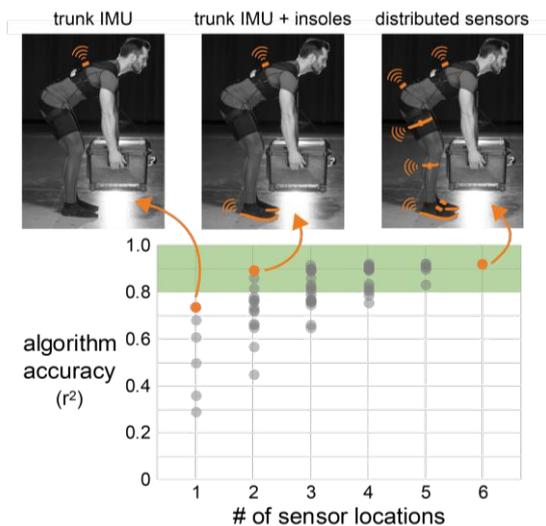

## Methods

Ten participants each performed about 400 manual material handling tasks (lifting, lowering and moving boxes of varying masses) in a motion analysis lab while we synchronously collected data from lab-based instrumentation and from wearable sensors. Wearable sensors included inertial measurement units (IMUs) and pressure insoles. Then, we developed wearable sensor algorithms using various combinations of wearable sensor signals (algorithm inputs), machine learning techniques, and our lab-based gold-standard estimates of low back loading, specifically lumbar extension moment (algorithm target). We quantified how the number of sensors used influenced algorithm estimation accuracy and identified the most important subset of sensors for low back load estimation.

## Results and Discussion

As expected, maximum algorithm accuracy increased with the number of sensor locations (Fig. 1). While single sensor solutions (e.g., using a trunk IMU only) provided moderate

correlations of lumbar moment (up to  $r^2 = 0.74$ ), these solutions failed to capture increases in lumbar loading when objects of varying mass were lifted. Alternatively, an algorithm using two sensors (e.g., a trunk IMU and pressure insoles) provided more accurate estimates of lumbar moment (up to  $r^2 = 0.89$ ) and captured key trends in elevated back loads when objects of varying mass were lifted. Additionally, this two sensor solution sacrificed minimal accuracy compared to an algorithm using sensors distributed over six body locations ( $r^2 = 0.89$  vs.  $r^2 = 0.92$ , respectively). For monitoring lumbar loading during manual material handling there appears to be a sweet spot for accuracy and practicality that uses pressure insoles and a single IMU.

**Figure 1:** Maximum algorithm accuracy increased with number of sensor locations. Algorithm accuracy is average coefficient of determination across participants ( $r^2$ ). Orange dots represent the distributed sensor algorithm (right) and the highest accuracy algorithms using one (left) and two (center) sensor locations.

## Conclusions

Combining a trunk IMU and pressure insoles with a Gradient Boosted Decision Tree algorithm has the potential to provide practical, automated, and accurate monitoring of low back loading, opening new opportunities to manage and reduce low back injury risks in material handling.

## Correlation Between Wear Region of Shoes and Contact Region During Early Gait

Rosh Bharthi<sup>1</sup>, Sarah L Hemler<sup>1</sup>, Kurt E Beschorner<sup>1</sup>

<sup>1</sup>Department of Bioengineering, University of Pittsburgh, Pittsburgh, United States

Email: roshbhar@pitt.edu

### Summary

As shoe treads wear over time, people are exposed to increased risk of slip and fall accidents. Identifying the time during a gait cycle when wear occurs is needed to better understand shoe wear progression to develop design changes that mitigate its effect. The purpose of the study was to determine the timepoint in a gait cycle where the contact region best aligns with the shoe wear region. The results show that these regions match well for some individuals at early in stance (~17 ms after heel contact). Other individuals have poorer matches between the worn region and the contact region occurring later in stance (33 ms - 83 ms after heel contact). Future directions include determining if the bimodal distribution is representative with a larger sample size and determining the wear mechanisms relate to shoe wear for both these wear conditions.

### Introduction

Shoe treads exhibit wear over time, notably in the heel region. As a result, the drainage capacity and the friction performance of these shoes degrades, which can lead to slip and fall accidents [1]. Predicting shoe wear can provide insight on tread design changes that will improve tread durability. An impediment to developing these predictions is a lack of understanding of the gait cycle times that contributes to wear. The goal of the study was the determine the timepoint during the gait cycle that is most relevant to wear.

### Methods

Four participants were provided with two shoe designs (SR Max, SafeTStep). Participants walked over a frustrated total internal reflection (FTIR) plate, while a camera beneath the plate recorded tread contact regions during stance. Participants then wore each pair of shoes in their workplace for up to 12 months. At the end of the wear period, pictures were taken of the worn heel tread to record the worn region. Custom image analysis code (MATLAB) was used to identify the contact region from the FTIR images and the worn region from the shoe tread pictures. For the FTIR images, the image was cropped to isolate the contact region, and brightness thresholds were used to identify the contact region. For the worn region, a user used a spline crop to identify the region with visible wear. The centroid of the contact and wear regions were recorded to the heel. Nine FTIR images (encompassing the first 83 ms of stance) were analyzed for each shoe and participant to capture the shoe contact region over time. To describe the timepoint most relevant to wear, the resultant distance between the contact centroid and the wear region was calculated for each frame. The frame where this distance was minimized was selected as the most relevant time. This time and the resultant distance were described.

### Results and Discussion

The distribution for the stance time that best matched the wear region was bimodal: participants with centroid overlap occurring at 17 milliseconds (early stance wear) and participants with centroid overlap at timepoints greater than 30 milliseconds (ranging from 33 ms to 83 ms). For the early stance wear group, strong agreement exists between the worn region and contact region at 17 milliseconds (Figure 1). For the other group, the wear regions did not match as well despite the centroid coordinates matching closely. Commonly, the wear region would be located at the lateral edge of the heel, yet the contact region spans the entire width of the shoe, encompassing a larger portion.

**Figure 1:** Comparison of contact region 17ms after heel contact (left) and wear region after 10 months of use (right). The blue cross indicates the heel marker, and the red and green crosses indicate the centroids. Both regions are located at the lateral edge of the heel.

This analysis shows that the location of wear exists in the shoe region that is in contact early in the gait cycle (i.e., within the first 100 milliseconds after heel contact). Shoe wear models can be developed to incorporate biomechanical parameters (shoe angles, forces, etc.) at these earlier time points to predict wear location and pattern [2]. Additionally, the bimodal distribution of relevant times suggest that different gait styles may lead to different types of wear. Some wear may occur due to the shoe sliding at heel contact at foot contact (abrasion wear), while other wear may occur due to the normal and shear loading that occurs later in stance (fatigue failure) over a time range instead of a specific time [3,4]. This finding may suggest different wear mechanisms or patterns for each group.

### Conclusions

The wear region is correlated with early instances in the gait cycle for some but not all participants. Further analysis, especially with a larger sample size, could help determine if this categorization is required for accurate shoe wear models.

## A Scoping Review on the Applications of Machine Learning for Primary Work-Related Musculoskeletal Disorder Prevention

Victor C.H. Chan<sup>1</sup>, Gwyneth B. Ross<sup>1</sup>, Allison L. Clouthier<sup>1</sup>, Steven L. Fischer<sup>2</sup>, Ryan B. Graham<sup>1</sup>

<sup>1</sup>School of Human Kinetics, Faculty of Health Sciences, University of Ottawa, Ottawa, Canada

<sup>2</sup>Department of Kinesiology, Faculty of Health, University of Waterloo, Waterloo, Canada

Email: [vchan017@uottawa.ca](mailto:vchan017@uottawa.ca)

### Summary

To determine the applications of machine learning (ML) used for the primary prevention of work-related musculoskeletal disorders (WMSDs), a scoping review was conducted using seven literature databases. Of 3,201 unique results, 122 original articles were deemed relevant for inclusion. Articles were classified as a contribution to one of six steps within a primary WMSD prevention research framework [1]. The steps with the most contributions from ML techniques were the development of interventions (35.2%), followed by risk factor identification (23.0%); the fewest contributions were for intervention implementation (4.1%). Over a quarter (25.4%) of all articles were published in 2020. These findings provide a mapping for the use of ML techniques in primary WMSD prevention and should help identify future opportunities.

### Introduction

Primary WMSD prevention is a leading focus for researchers, clinicians, and organizations alike, and the growing feasibility to collect and process large amounts of data welcomes ML techniques. Such techniques can model non-linear interactions between numerous variables and may be better suited for understanding the complex etiology of WMSDs and subsequently prevent their occurrence. As the use of ML techniques for these purposes are relatively novel, a scoping review was conducted. The purpose was to determine how ML techniques have been used for primary WMSD prevention in the steps outlined by van der Beek et al. [1].

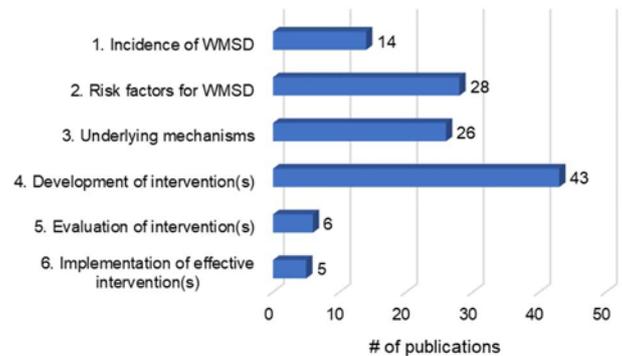

### Methods

A literature search strategy centred around machine learning, musculoskeletal disorders, and occupation was developed using the Medline database then translated to Embase, Cochrane Central Register of Controlled Trials, PsycInfo, IEEE Xplore, SPORTDiscus, and Scopus databases. The seven databases were searched on December 3, 2020 and articles were included if: 1) they were published on January 1, 1990 or later; 2) they were original research; 3) ML technique(s) were used to develop their system/framework and/or used to produce the final results; and 4) the work represents an effort to prevent WMSD occurrence, as defined using the WMSD prevention framework [1]. Title & abstract screening and full-text review were completed by two researchers using Covidence systematic review management software (Covidence, Victoria, Australia), and the results were reported according to the PRISMA guidelines. Included articles were classified as contributions to one of six steps of the WMSD prevention framework [1] as outlined in Figure 1.

### Results and Discussion

The searches returned 4,627 results, with 1,426 identified as duplicates. The full-text of 246 articles were reviewed for eligibility, with a final of 122 articles included. The number

of articles classified to each step of the primary WMSD prevention research framework is presented in Figure 1.

**Figure 1:** The number of research articles employing ML techniques found at each step of the primary WMSD prevention framework [1].

Articles in step 1 used text and data mining techniques with large databases to autocode and quantify WMSD incidences. Step 2 articles were characterized by unsupervised learning algorithms (e.g., *k*-means clustering) to identify potential risk factors amongst subgroups. Most articles classified for step 3 augmented existing biomechanical methods used for studying WMSD etiology, such as developing load prediction models that do not rely on musculoskeletal modelling. Articles in step 4 primarily presented systems for automated, real-time, ergonomic worker assessment using wearable sensors or computer vision-based methods. Articles in step 5 generally evaluated ML-based interventions, and step 6 consisted of articles that used ML to determine which jobs face the highest risk for WMSDs, warranting intervention implementation. Artificial neural networks, decision tree-based algorithms, and support vector machines were the most commonly-employed ML techniques, present in 42.6%, 18.0%, and 13.9% of articles, respectively. Publications from 27 countries were included, and the United States of America published the largest proportion of relevant articles (42.6%).

### Conclusions

The use of ML techniques is rapidly growing in all industries, including for primary WMSD prevention. The most common usage has been to develop automated, real-time worker assessment systems. Many opportunities still exist at every step of WMSD prevention, especially for research regarding intervention evaluation and implementation.

## Drift-free algorithm for estimating muscle fascicle length from ultrasound images

Tim. J. van der Zee<sup>1,2</sup>, Arthur D. Kuo<sup>2,1</sup>

<sup>1</sup>Faculty of Kinesiology, University of Calgary, Calgary, AB, Canada

<sup>2</sup>Biomedical Engineering Graduate Program, University of Calgary, Calgary, AB, Canada

Email: [tim.vanderzee@ucalgary.ca](mailto:tim.vanderzee@ucalgary.ca)

### Summary

Ultrasound imaging is valuable for non-invasively estimating muscle lengths *in vivo*, especially when performed computationally to avoid subjective decision-making. An effective analysis technique is to use optic flow to track displacements from image sequences, but with sensitivity to integration drift for longer sequences. We here present an alternative algorithm that objectively estimates fascicle length from ultrasound images, without drift sensitivity. The algorithm estimates fascicle angles and derives their lengths between identified aponeuroses. Length estimates of human vastus lateralis in healthy subjects (N = 9) compared well (root-mean-square deviation, RMSD < 0.80 cm) to manual estimates from independent observers (n = 3). The algorithm had a higher coefficient of multiple correlation (CMC) with manual estimates than state-of-the-art optic flow algorithms (0.94 vs. 0.88-0.90 respectively), suggesting higher accuracy. The algorithm may extrapolate fascicle lengths that extend beyond the image frame, and requires minimal manual intervention.

### Introduction

Muscle fascicle length may be estimated from ultrasound images using automated techniques. A challenge for automation is that images are typically noisy and offer few identifiable features that may be tracked across successive images. The optic flow approach avoids feature tracking by accumulating flow across sequences to yield fascicle displacements. But longer sequences of images are subject to drift, so that the displacement at the end of a periodic contraction cycle may not match the beginning. Another challenge is subjective decision-making, with manual estimation of the first image as initial condition for subsequent automation<sup>[1,2]</sup>. We propose that fascicle lengths may be estimated without optic flow, and that automated identification of aponeuroses can reduce manual intervention. We demonstrate this approach with an open-source algorithm<sup>[3,4]</sup>.

### Methods

The algorithm uses a three-step procedure: (1) filtering for line detection, (2) fascicle angle detection, and (3) trigonometric extrapolation. We applied it to estimate fascicle lengths from vastus lateralis ultrasound images in healthy subjects (N = 9).

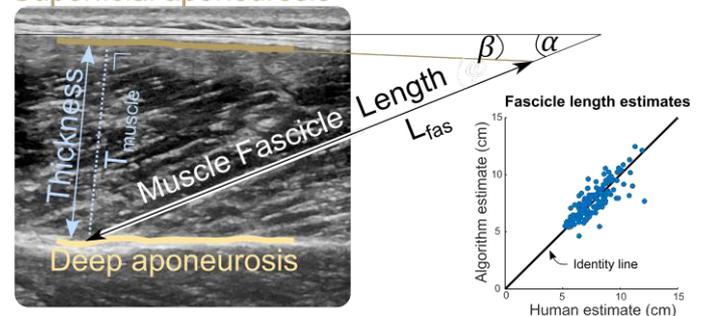

The image filtering step is to highlight line-like structures, namely the aponeuroses and fascicles. As with any filter, contrast and other parameters may be set manually, but we found it efficient to identify aponeurosis lengths and angles with a minimally trained support vector machine (SVM). For the fascicles, a technique known as the Hough transform<sup>[5]</sup> can identify lines and their angles without explicitly tracking

features. Finally, trigonometric extrapolation determines fascicle length  $L_{\text{fas}}$  from fascicle angle  $\alpha$ , aponeurosis angle  $\beta$  and the distance between superficial and deep aponeuroses  $T_{\text{muscle}}$  (see Figure 1). We devised the algorithm in Matlab and trained aponeurosis detection with only nine sample images (one each from nine subjects). We compared the algorithm's length estimates against manual estimates by independent human observers (n = 3).

### Results and Discussion

Algorithm fascicle length estimates increased with human observer estimates (slope:  $0.99 \pm 0.01$ , estimate  $\pm 95\%$  c.i., linear regression, see inset Figure 1), with algorithm-human differences comparable to human-human differences (RMSD: 0.77-0.79 cm vs. 0.66-0.82 cm respectively). The uncorrected CMC between algorithm and human estimates was 0.94, which is higher than reported for state-of-the-art optic flow algorithms (i.e. 0.88<sup>[1]</sup>-0.90<sup>[2]</sup>). In addition, algorithm estimates were produced considerably faster (107 images·min<sup>-1</sup>, i5 processor) than human estimates (~1-2 images·min<sup>-1</sup>). The algorithm may be used for objectively estimating muscle length changes.

### Superficial aponeurosis

**Figure 1.** Ultrasound image from vastus lateralis with identified aponeuroses and estimated fascicle angle. Trigonometric extrapolation then estimates fascicle length. Inset at right: algorithm fascicle length estimate versus mean of human observer (n=3) estimate.

### Conclusions

A freely available algorithm estimates muscle fascicle length from ultrasound images, with minimal manual intervention and no drift sensitivity, yielding accuracy comparable to state-of-the-art.

Email: jbroberg@uwo.ca

### Summary

This study compares groups of satisfied and dissatisfied total knee replacement (TKR) patients to determine if there are any objective differences in implant migration, kinematics, and patient function between groups. No major objective differences existed between satisfied and dissatisfied TKR patients, however patients dissatisfied with their function reported higher levels of pain and more unmet expectations.

### Introduction

TKR often successfully reduces pain and returns function to the affected joint, however one fifth of patients are still dissatisfied following their operation. It is unclear why many patients feel this way, but there are thought to be multiple contributing factors. Wearable sensors and radiostereometric analysis (RSA), a stereo x-ray technique used for obtaining implant migration and joint kinematics, are two modalities available that could uncover potential factors in patient dissatisfaction. The goal was to compare the implant migration, joint kinematics, and objective measurements of patient function between satisfied patients and dissatisfied patients to determine if any have a role in post-operative patient dissatisfaction following TKR.

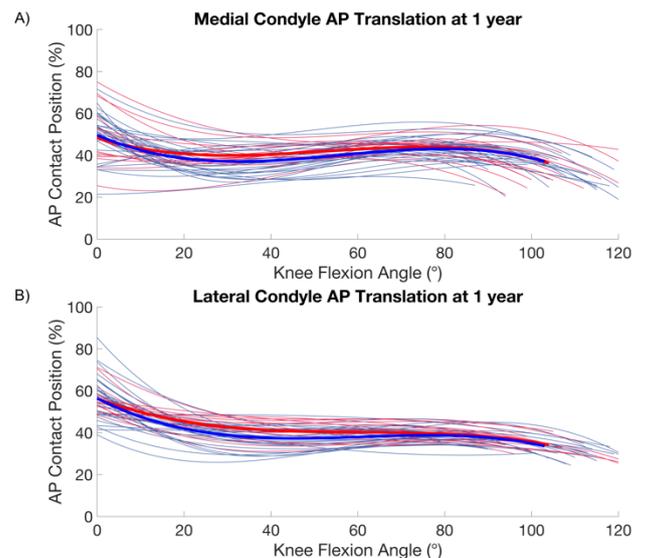

### Methods

Patients answered the Knee Society Score (KSS) and were split into "Satisfied" and "Dissatisfied" groups based on their response to three questions on functional satisfaction. RSA was used to measure implant migration at multiple time points up to 1-year post-operatively. At 1-year post-operatively, an additional series of RSA images were acquired at different knee flexion angles to investigate joint kinematics, including medial and lateral anteroposterior (AP) tibiofemoral contact and AP translation during early (0-40°), mid (40-80°), and deep (80-max) flexion, given as a percentage of the tibial baseplate (0% being most posterior, 100% being most anterior). A Timed-Up-and-Go (TUG) test was performed with wearable sensors pre-operatively and at 1-year post-operatively to obtain objective measures of function, including total test time and mean flexion range of their operative limb during the test. Patients also completed questionnaires including the Short Form 12 (SF-12), the Western and McMaster Universities Osteoarthritis Index (WOMAC), and the University of California, Los Angeles (UCLA) Activity Score, and the KSS.

### Results and Discussion

There were 31 patients in the Satisfied group and 18 in the Dissatisfied group. The Satisfied group had more tibial

migration at 6-weeks (mean difference (MD)=0.13 mm,  $p=0.002$ ), but not at 3-months ( $p=0.07$ ), 6-months ( $p=0.83$ ), and 1-year ( $p=0.17$ ). AP contact position throughout flexion can be seen in Figure 1. No differences were found between groups in medial AP translations in early flexion ( $p=0.29$ ), mid flexion ( $p=0.22$ ), or deep flexion ( $p=0.48$ ). Laterally, there were no differences in AP translation in early flexion ( $p=0.24$ ) and deep flexion ( $p=0.51$ ), but the dissatisfied group had more posterior translation in mid flexion (MD=2.7%,  $p=0.04$ ). No differences were found between groups in total TUG test time pre- ( $p=0.88$ ) and one-year post-operatively ( $p=0.80$ ), or mean flexion range pre- ( $p=0.79$ ) and one-year post-operatively ( $p=0.76$ ). From the questionnaires, the Dissatisfied group reported worse WOMAC Pain (MD=11.8,  $p=0.01$ ) and Function (MD=19.4,  $p=0.0003$ ) Scores, UCLA Activity Scores (MD=1.12,  $p=0.04$ ), and KSS Functional Expectations Scores (MD=2.62,  $p<0.0001$ ).

**Figure 1:** AP contact position on the A) medial and B) lateral condyles throughout flexion. Blue lines indicate satisfied patients and red lines indicate dissatisfied patients. Thicker coloured lines represent the means of the groups.

### Conclusions

No major differences existed between satisfied and dissatisfied TKR patients when considering implant migration, joint kinematics, and objective measurements of patient function. However, patients dissatisfied with their function reported higher levels of pain and more unmet expectations, suggesting that to improve the functional satisfaction rate of TKA, focus should be on managing residual pain and setting realistic expectations.

## Investigation of the Biofidelity of the MIL-Lx Foot

Julia de Lange<sup>1</sup>, Cheryl E. Quenneville<sup>1,2</sup>

<sup>1</sup>School of Biomedical Engineering, McMaster University, Hamilton, Canada

<sup>2</sup>Department of Mechanical Engineering, McMaster University, Hamilton, Canada

Email: quennev@mcmaster.ca

### Summary

Injury risk to the lower leg as a result of car crashes is evaluated in the tibia using Anthropomorphic Test Devices (ATDs). The axial impact response of three lower leg representations, cadaveric ‘intact’ specimens, the ‘MIL-Lx’ ATD and an ‘adapted’ legform (combining cadaveric feet with the MIL-Lx tibia) were assessed. They were fitted with an instrumented boot and impacted at sub-failure energies. Results suggest that the MIL-Lx foot is stiffer and dissipates less energy than cadaveric feet. This study provided regional loading data for the isolated cadaveric foot, for improved future ATD foot designs.

### Introduction

Foot and ankle injuries from car crashes continue to increase in severity and incidence [1]. Injury risk to this region is grouped and evaluated using load cells in the tibia of Anthropomorphic Test Devices (ATDs). Although the impact response of the ATD tibia has been investigated to improve biofidelity (leading to the development of the MIL-Lx), the foot has historically been ignored. As load is transmitted through the foot/ankle to the tibia, injury assessments are directly affected by the biofidelity of the foot. Furthermore, while ATDs are valuable tools with load cells to collect forces and act in a repeatable manner, they do not undergo injuries. In contrast, cadaveric testing is advantageous as it allows for the identification of fracture limits, locations and mechanisms. The objective of this study was to develop a technique to mount cadaveric feet to an ATD tibia, to isolate the foot and investigate the potential differences in load transmission.

### Methods

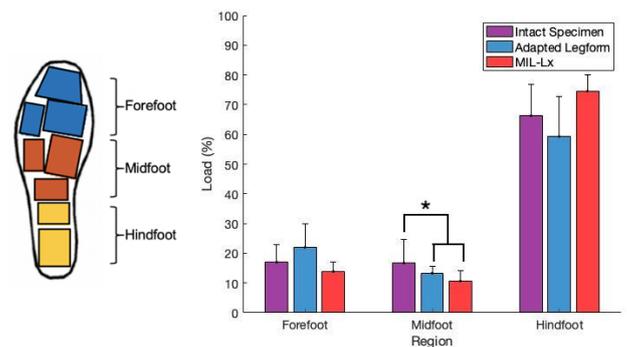

Six cadaveric lower legs (‘intact,’  $80 \pm 12$  years, 3 male) were supported in a pneumatic impacting apparatus and fitted with an instrumented boot. The boot insole has an array of eight piezoresistive sensors, divided into fore-, mid-, and hindfoot regions. They were axially impacted at 5 m/s (sub-failure energies), and force distribution and net force on the boot insole were recorded for each impact.

The Military Lower Extremity (‘MIL-Lx’, Humanetics Innovative Solutions) was similarly impacted, with boot measures as well as tibia load cell forces and moments recorded. The cadaveric specimens were then disarticulated at the ankle joint, preserving surrounding soft tissue. The distal tibia and fibula were optically scanned to 3D print a mating surface for the talus (minimizing unnatural stress concentrations). The 3D printed component was mounted to the MIL-Lx and included attachment points to suture tendon and ligament bundles. Each cadaveric foot was mounted to the

adapted structure (‘adapted’) and tested at similar impact conditions, with boot measures and tibia load cell measurements recorded.

### Results and Discussion

No significant differences in net boot forces were found among lower leg representations, suggesting that overall reaction force at the plantar surface was comparable ( $p=0.5$ ). No statistical differences were found among lower leg representations for the forefoot force ( $p=0.7$ ) or hindfoot force ( $p=0.2$ ) regions, however the intact specimen midfoot readings were significantly higher than the ‘adapted’ and the MIL-Lx midfoot readings ( $p<0.05$ , Figure 1). Furthermore, the proximal and distal tibia load cells recorded significantly higher forces in the MIL-Lx than the ‘adapted’ leg, ( $p<0.05$ ), suggesting the MIL-Lx foot is stiffer and dissipates less energy than cadaveric feet.

**Figure 1:** Regional loading comparisons of lower leg representations (\* =  $p<0.05$ ).

Forces measured on the plantar surface of the foot were over 35% higher than forces measured in the tibia, which is unsurprising when considering the direction of loading. By focusing on isolated cadaveric feet, while also collecting tibia load data, this study assessed the impact characteristics of feet specifically.

### Conclusions

This study developed a technique that combines collecting the realistic loading response of cadaveric feet with industry relevant ATD metrics and used it to impact three lower leg forms. Results suggest the MIL-Lx foot may be an overly stiff representation of cadaveric feet, so these data may be used for an improved ATD foot design.

## Occupant Kinematic Prediction Model During Rear End Collisions

Kyle Van Housen<sup>1</sup>, Sean D. Shimada, PhD<sup>1</sup>

<sup>1</sup>Biomechanical Consultants of California

### Summary

The goal of this paper was to determine continuous equations representative of time-dependent acceleration and velocity profiles for an occupant's head during rear-end collisions. These curves were designed to be generated based on the change in velocity of the vehicle. These results can be used for injury prediction and calculations of HIC.

### Introduction

Rear end collisions are the most common form of motor vehicle collision. The National Highway and Traffic Safety Administration (NHTSA) reported there were over 2 million rear-end collisions in the United States in 2019 [1]. Thirty-one percent of the occupants sustained injuries, while seven percent were fatal [1]. Creating a model to accurately recreate occupant head kinematics during a motor vehicle accident would assist in determining injury thresholds and improving upon injury analyses. Ultimately, the outcome of the model can be used to improve occupant safety during motor vehicle crashes.

### Methods

Atarod et al. [2] mounted accelerometers to the heads of ATD's and performed rear-end impacts at vehicle speeds ranging from 22.2 to 31.9 kph. Head acceleration traces from these crashes were imported into MATLAB, and a rational equation (Eq. 1) was fit to the waveform (Figure 1). Of the possible fits available in MATLAB, the polynomial fit was significantly better than other tested models. Through manipulations for individual parameters, it was found that the q3 coefficient had the most significant effect on peak value of the curve without drastically affecting other aspects of the curve's shape. By holding all other coefficients constant, we solved for q3 in terms of peak value which was used to scale the model to the appropriate head acceleration. The peak head acceleration point for different ΔV values were plotted from multiple sources [2], [3] and a linear regression was fit (R<sup>2</sup> = 0.9). Combining the regression between ΔV and peak head acceleration, and adjusting q3 based on this peak value allows the polynomial equation to adjust and give a continuous model for head acceleration. Integration of this model generates a graph for head velocity.

$$\frac{p1x^3 + p2x^2 + p3x + p4}{(x^2 + q1x^2 + q2x + q3)}$$

Equation 1. Fitted rational equation for head acceleration.

HIC was subsequently calculated based on the generated head acceleration curves using a standard 36 millisecond time interval with the peak value at its center.

### Results and Discussion

Figure 1 shows the modeled head acceleration curve for a vehicle crash speed at 31.9 kph (peak acceleration of 38.5 g; HIC 62.7). To extend the range of speeds that this model can predict, more accelerometer data as acquired from Pasquesi et

al. [3] who tested rear-end crashes from 5.6 – 19.5 kph. Comparing the peak head accelerations from both sources [2],[3] to the values calculated from the model shows a correlation of 0.92. When overlaying the accelerometer data and the mathematically calculated acceleration, they overlap continuously in the general area where peak forces occur. During the interval after the peak head acceleration (t = 0.2-0.45) all the accelerometers record a dip below the x-axis. The model was unable to re-create this phenomenon while maintaining accuracy for the rest of the curve.

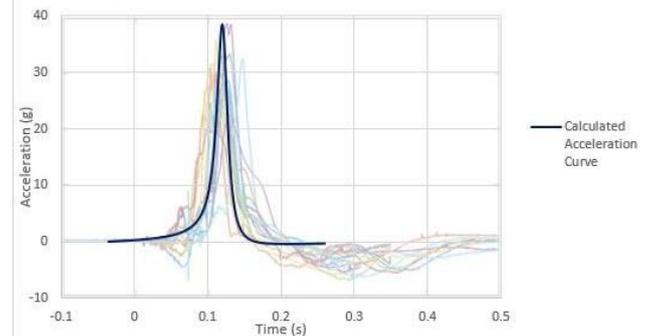

Figure 1. Modeled head acceleration for 45.5 kph crash overlaid on data from [1].

### Conclusions

The resulting biomechanical model accurately recreated the peak value and general waveform of occupant head acceleration during a rear-end collision. However, this model was only validated for changes in velocities of 5.6 - 31.9 kph. The use of a continuous equation allows for subsequent mathematical operations to be performed. Although the generated curves do not recreate an early dip observed experimentally, forces acting during this time are unlikely to cause head injury. More work is needed to test this model in for a wider range of velocities. The generated HIC values also need to be further validated.

# Most Severely Injured Body Regions in Near Side Motor Vehicle Collisions Involving Head Impact

Rachel L. Tanczos<sup>1</sup>, Sean D. Shimada<sup>1</sup>  
<sup>1</sup>Biomechanical Consultants, Davis, CA  
 Email: rltanczos@ucdavis.edu

## Summary

The National Automotive Sample System Crashworthiness Data System's (NASS-CDS), a publicly available database, was used to determine the most severely injured body regions of nearsided occupants during lateral motor vehicle collisions. The investigation was restricted to brain injured and non-brain injured occupants with evidence of a direct head impact. Brain injured occupants were more likely to have severe injuries to their torso, while non-brain injured occupants had higher frequency of severe spinal and extremity injuries.

## Introduction

Motor vehicle accidents are one of the most prevalent causes of traumatic brain injury. Data from studies comparing frontal and lateral motor vehicle collisions supports an increased risk and severity of brain injuries in lateral collisions [1,2]. This investigation aimed to identify differences in the most severely injured body regions of brain and non-brain injured occupants who sustained head impacts in nearside collisions. The results may be used to identify potential differences in crash conditions and occupant kinematics in order to improve vehicle safety from lateral impacts.

## Methods

MATLAB® was used to compile and filter datasets from NASS-CDS's publicly available database for the years 2001 to 2015. Concussive and internal organ injuries of the head were identified based on the Abbreviated Injury Scale (AIS) classification system. Injuries due to head impact were selected for using the database's direct contact variable (DIRINJ = 1). Occupants that were involved in a rollover, not between 16 and 60 years of age, or in a vehicle other than a passenger car were excluded. In addition to meeting all other filtering criteria, the group considered to be non-brain injured were required to have some other type of direct contact injury to their head.

The database variable "BODYREG" was used to identify the body region where occupants sustained their most severe injury. A normalized frequency of occurrence was then calculated. Multiple entries were recorded for occupants' injuries of the same AIS severity across multiple body regions. Database years that used AIS 1990/1998 Update (AIS98) vs. AIS 2005 Update 2008 (AIS08) were analyzed separately and displayed as side-by-side histograms representing brain and non-brain injured occupants.

## Results and Discussion

229 brain injured and 228 non-brain injured occupants met the filtering criteria. The head/skull region was the most common and severely injured body region for all occupants (Figure 1). For both the AIS98 and AIS08 analyses, compared to their respective non-brain injured occupants, brain injured occupants had higher normalized frequencies for the abdomen, chest, and head/skull. The non-brain injured occupants had higher normalized frequencies for the cervical spine, lower extremity, shoulder, thoracic lumbar spine, and upper extremity. These results suggest brain injured occupants are more likely to be involved in more severe collisions that also cause their torso to contact the interior of the vehicle. Non-brain injured occupants may more frequently use their extremities to brace for impact. The face and hip regions had contrasting trends between AIS98 and AIS08 data.

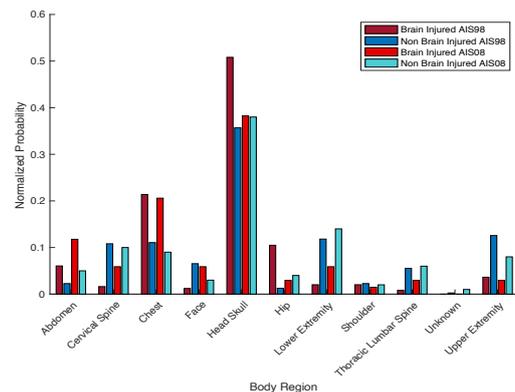

Figure 1: Distribution of most severely injured body regions in nearside collisions involving direct head contact.

## Conclusions

When direct head contact occurs, nearsided occupants were most likely to sustain their most severe injury to their head or skull. Brain injured occupants were more likely to have severe injuries to their torso, while non-brain injured occupants had higher frequency of severe spinal and extremity injuries. To further update the analysis and resolve trend discrepancies for the face and hip, future work will convert AIS98 codes to AIS08 codes for a combined dataset. Comparing the severity scores of the most severe occupant injuries would add another layer of analysis.

## High Risk Glenohumeral Joint Forces During Three Pull-Up Techniques

Caryn A. Urbanczyk<sup>1</sup>, Joseph A.I. Prinold<sup>1</sup>, Peter Reilly<sup>2</sup>, Anthony M.J. Bull<sup>1</sup>

<sup>1</sup>Musculoskeletal Mechanics Lab, Dept. Bioengineering, Imperial College London, London, UK

<sup>2</sup>Imperial NHS Trust, Imperial College London, London, UK

Email: c.urbanczyk17@imperial.ac.uk

### Summary

Descriptive laboratory study of loading patterns during performance of three different pull-up variants using optical motion capture and computational modelling. Glenohumeral (GH) joint stress and stability patterns vary across techniques, but all achieve torso elevation as a primary objective and arm depression as a secondary event. Relative upper limb and torso positioning is clinically relevant in upper extremity injury rehabilitation. Alleviating dysfunction and increasing strength relies on managing stress.

### Introduction

There are strong links between overhead activities and shoulder pathology. Common injuries among athletes regularly performing such activities include impingement, tendonitis, and rotator cuff tears [1]. Heavily loaded training tasks, such as pull-ups are an effective strength training and rehabilitation exercise that require high muscle force maintained over a large range of motion [2]. However, care should be taken in progressing pull-ups to the loading rates in functional demands. This study used computational modelling to examine loading patterns during pull-ups and highlight risks to vulnerable musculoskeletal structures.

### Methods

Optical motion tracking (200Hz) and a force platform (1000Hz) under a free-standing pull-up apparatus, captured kinematics and kinetics of 11 male subjects without history of shoulder pathology, during 5 trials each of 3 different pull-up types: pronated front grip, pronated wide grip, and supinated reverse grip. Recorded data provided input to the UK National Shoulder model (UKNSM) [3]. GH joint forces and glenoid contact patterns were analyzed by repeated measures ANOVA with Tukey HSD ( $\alpha < 0.05$ ). Further results from these study methods are described in [4].

### Results and Discussion

GH joint reaction forces were similar in front and wide pull-ups ( $p=0.11$ ), but the *reverse* pull-up was significantly larger (Figure 1;  $p < 0.025$ ). Peak GH joint force was 3.1 times body weight (xBW) in the front pull-up, 2.6 xBW in the wide pull-up, and 8.8 xBW in the reverse pull-up.

All glenoid contact patterns start in the posterior / inferior quadrant at the bottom of the pull-up motion and move diagonally into the anterior / superior quadrant at the top of the pull-up motion. Contact patterns near the glenoid rim indicate decreased relative shoulder stability. Wide pull-ups show highest percent of frames within 0.5mm of the glenoid rim ( $16.1 \pm 11.4\%$ ) at the start of the pull-up (Figure 2c). Front pull-ups show fewer frames near the glenoid rim ( $10.8 \pm 9.6\%$ ) but indicate instability at bottom and top of pull-up motion (Figure 2a). Reverse pull-ups display the most centralized

force locus, with substantially fewer frames near the glenoid rim ( $4.4 \pm 8.1\%$ ; Figure 2b). Differences between mean glenoid contact patterns are reflected in the Fréchet distance, where distance from wide to front and reverse patterns was  $27.01 \pm 7.5\text{mm}$  and  $35.5 \pm 6.3\text{mm}$ , respectively, while Fréchet distance between front and reverse was  $22.8 \pm 11.1\text{mm}$ .

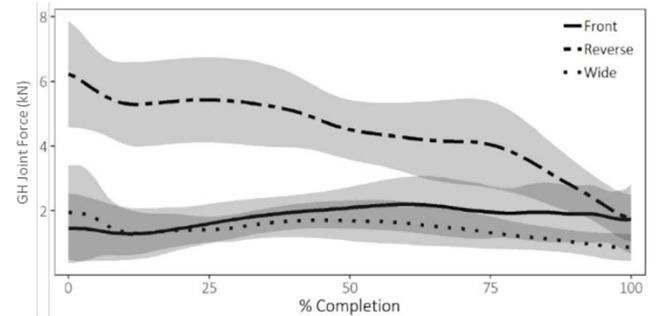

Figure 1: Resultant GH joint force in each pull up type (mean  $\pm$  sd)

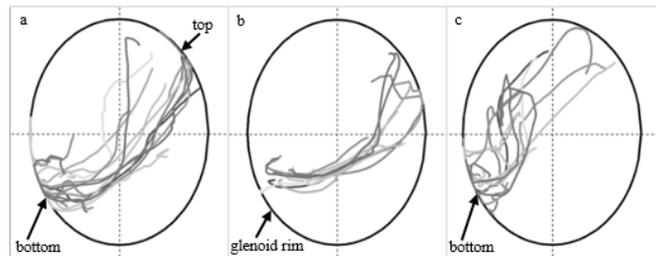

Figure 2: Glenoid contact patterns for each subject in the a) *front*, b) *reverse*, & c) *wide* pull-ups, arrows indicate pattern locations near the glenoid rim at start (*bottom*) and end (*top*) of pull-up motion.

### Conclusions

Pull-ups promote shoulder strength by leveraging extreme scapulohumeral positioning. All variants prioritize teres major and latissimus dorsi to depress the arm, but each also uses other muscles. Wide pull-ups show humeral head translation near the glenoid rim indicating instability. The predominately posterior pattern implies activation of middle deltoid, while the centralized pattern in the reverse pull-up suggests rotator cuff activity to stabilize the GH joint; a necessity when supporting much higher joint forces. Shoulder rehabilitation and strength & conditioning programs should incorporate all three pull-up variants with systematic progression to provide global strengthening of torso and upper limb musculature.

## Classification of ACL Reconstructed Running Dynamics Using Common Gait Features

Yannis K. Halkiadakis<sup>1</sup>, Helia Mahzoun Alzakerin<sup>1</sup>, Kristin D. Morgan<sup>1</sup>

<sup>1</sup>Department of Biomedical Engineering, University of Connecticut, Storrs, CT 06269 USA

Email: [yannis.halkiadakis@uconn.edu](mailto:yannis.halkiadakis@uconn.edu)

### Summary

The objective of this study was to employ machine learning to classify between healthy and pathological gait. Common gait features such as stride time, peak knee angle, and loading rate, extracted during running, were determined to successfully differentiate between healthy controls and post anterior cruciate ligament reconstruction individuals with an accuracy of 92%. The resulting model has the potential to be utilized in the clinic to evaluate successful rehabilitation.

### Introduction

Post anterior cruciate ligament reconstruction (ACLR) patients continue to show altered running gait years after surgery [1-3]. This altered gait is associated with the development of knee osteoarthritis, thus restoring normal gait would be a step forward in limiting the onset of this disease [1]. Machine learning can be a valuable tool in this field because it aids in the identification of gait parameters that can be used as measures of successful rehabilitation. This type of machine learning model can be used to assess running performance to determine if the post-ACLR individuals' gait has normalized. Differences in spatiotemporal parameters, sagittal plane kinematics, and limb loading between healthy and post-ACLR individuals are all clinically meaningful measures to evaluate healthy biomechanics. Therefore, we hypothesized that these common gait parameters can be used to create a strong machine learning model that can classify between healthy controls and post-ACLR participants.

### Methods

Fifteen post-ACLR participants (age:  $18.7 \pm 4.4$  yrs; height:  $1.7 \pm 0.1$  m; mass:  $68.1 \pm 10.5$  kg; running speed:  $2.7 \pm 0.3$  m/s) and 15 healthy controls (age:  $18.5 \pm 3.7$  years; height:  $1.7 \pm 0.1$  m; mass:  $66.7 \pm 11.3$  kg; running speed:  $2.7 \pm 0.4$  m/s) ran on an instrumented treadmill collecting at 1200 Hz (Bertec Corporation, Columbus, Ohio). Participants were fit with fifty-six markers and a 10-camera motion capture system (Motion analysis Corporation, Santa Rosa, CA) collected marker data at 200 Hz. Marker placement followed the protocol described by Noehren et al. (2013) [3].

After a five-minute warmup, participants ran at a self-selected speed for one minute. Stride times, swing times, and average loading rate were extracted from the vertical ground reaction force (vGRF) data. Loading rate was normalized by body weight (BW). The marker trajectory data was used to calculate the sagittal plane knee angle. The knee angle upon impact and peak angle during swing were recorded. T-tests were performed to compare the gait parameters between the two groups ( $\alpha=0.05$ ). A 60%-40% training-testing split was used to develop, train, and test the model. Multiple algorithms including the support vector machine (SVM) model were tested using the training data. Model performance was based

on the assessment of the receiver operating curve (ROC) using test data.

### Results and Discussion

The stride time, swing time, and sagittal plane peak knee angle during swing phase were significantly lower in the post-ACLR individuals than the controls, while the average loading rate and the knee angle at impact were significantly greater (Table 1).

**Table 1.** Comparison of the mean gait parameters of interest for the healthy controls and post-ACLR individuals.

Gait Parameters	ACLR Group	Control Group	P-value
Stride Time (s)	$0.35 \pm 0.02$	$0.39 \pm 0.05$	0.02*
Swing Time (s)	$0.07 \pm 0.02$	$0.09 \pm 0.03$	0.05
Peak Knee Angle Swing (°)	$95.6 \pm 8.2$	$103.3 \pm 11.2$	0.04*
Knee Angle at Contact	$21.6 \pm 4.8$	$16.0 \pm 5.0$	<0.01*
Loading Rate (BW/s)	$12.1 \pm 5.5$	$6.1 \pm 3.4$	<0.01*

\*Indicates the means are significant different ( $\alpha=0.05$ )

The SVM model outperformed other models in every category, showing an accuracy of 92%, recall of 86%, precision of 100%, and area under the ROC curve of 0.93. The results supported the hypothesis as common gait parameters were able to classify between healthy controls and post-ACLR individuals. Looking at the parameters, loading rate was significantly higher in the post-ACLR participants with no significant difference in impact peak, indicating an altered limb loading strategy. The post-ACLR group also landed with greater knee angle at contact, possibly to help redistribute the load at the knee. Lastly, the post-ACLR group exhibited decreased stride and swing times, even though running speed was not significantly different between groups suggesting that a greater percentage of the running gait cycle was spent in stance, helping to maintain balance.

### Conclusions

This study demonstrated that common gait parameters are strong enough metrics to effectively delineate between altered running strategies in healthy controls and post-ACLR individuals. The model can be integrated in a clinical setting to assess rehabilitation performance. Future models could introduce measures of asymmetry between the reconstructed and non-reconstructed limbs to improve model performance.

### Acknowledgments

We would like to thank Dr. Brian Noehren for providing the data for this study.

<sup>2</sup>Department of Mechanical Engineering, University of Nevada Las Vegas, Las Vegas, NV, USA

Email: christian.ison@unlv.edu

## Summary

Exercise under reduced gravity conditions is used by clinicians for individual recovering from lower extremity injuries. The effect of reduced gravity exercise on kinetics and kinematics of lower extremities and plantar pressure have been observed. However, the relationship between variations in the center of pressure (COP) under reduced gravity conditions is not well understood. We used pressure-measuring insoles to better understand this problem.

## Introduction

Rehabilitation of persons experiencing a lower extremity injury requires careful assessment and monitoring. Full body weight bearing activities may potentially exacerbate pain and disrupt recovery due to the magnitude of forces applied to the injured tissues and joints [1]. Therefore, limited weight bearing activities are often implemented, which requires full understanding of gait and how loads are transmitted. Researchers have suggested that COP path length and width may determine preventative fall risk strategies, especially among the geriatric population [2]. We explored the changes of COP under different gravity conditions to understand this supposition and consider its potential clinical application.

## Methods

Plantar pressure was measured using pressure measuring insoles (Medilogic GmbH, Schonefeld, GE). Gravity conditions were simulated on a treadmill (AlterG, Inc., USA). Twenty-nine healthy, (27 males, 2 females; age  $24.7 \pm 4.04$ ; mass =  $72.36 \pm 13.52$  kg; height =  $1.67 \pm 0.04$  m) volunteers participated in this cross-sectional experiment. After providing informed consent (IRB#1510671-2), participants completed two 3.5-minute walking trials on the treadmill at 100% (normal gravity) bodyweight (BW), 40% and 20% (reduced gravity) BW. The plantar pressure insole data were recorded under each of these gravity conditions and sensors' location and coordinates were identified following the specifications of the insole manufacturer. The sensor data were processed as previously described [3]. Processed data were used to generate the COP coordinates. More details can be found in [4]. Each COP length and width were normalized with respect to the length and width of the insole the participant wore during the experiment. Two one-way repeated measures ANOVAs ( $\alpha=0.05$ ) were used to test COP length and width differences across gravity conditions.

## Results and Discussion

Table 1 shows the mean normalized COP length and width over the three gravitational conditions. A repeated measures

ANOVA with a Greenhouse-Geisser correction determined that average COP path length differed significantly ( $p<0.05$ ) among gravity conditions (Table 1). Post hoc tests using the Bonferroni correction revealed that the 100% BW condition was significantly greater than the 40% and 20% BW conditions. However, there were no significant differences observed between 40% and 20% BW conditions ( $p=0.259$ ). A repeated measures ANOVA with a Greenhouse-Geisser correction determined that average COP path width differed significantly among gravity conditions ( $p<0.05$ ; Table 1). Post hoc tests using the Bonferroni correction revealed that the 100% BW condition was significantly different than the 40% and 20% BW conditions. There were no significant differences observed between 40% BW condition and the 20% BW condition ( $p=0.134$ ). While COP length decreased with unweighting, COP width increased. This latter observation may be useful to increase stability and decrease fall susceptibility for those recovering from injury.

**Table 1.** Normalized center of pressure length and width in mm (mean  $\pm$  standard deviation) for each gravity condition.

	100% BW	40% BW	20% BW
<b>COP Length</b>	0.63 $\pm$ 0.06	0.45 $\pm$ 0.19	0.39 $\pm$ 0.17
<b>COP Width</b>	0.11 $\pm$ 0.02	0.15 $\pm$ 0.03	0.17 $\pm$ 0.22

## Conclusions

We found that a walking task at three gravitational conditions in healthy individuals is mainly characterized by a decrease in COP path length and increase in COP width as gravity is reduced (Table 1). Reduced gravity minimizes heel contact and requires more effort for lateral stabilization. The findings from this study may prove beneficial for clinicians as they develop rehabilitation strategies to effectively unload the individual's body weight to perform safe exercises. Future studies are needed to further corroborate the findings from this study.

## Summary

Neurodynamic mobilizations (NM) in rehabilitation are commonly used in the treatment of peripheral nerve neuropathies. NM can be used to exploit biomechanical principles to induce displacement and strain on nerve tissue to influence neuropathic pain. To date, there is no evidence about the effectiveness of NM technique sequence for the treatment of neuropathies of the superficial fibular nerve (SFN). We used displacement transducers to measure linear displacement to calculate strain of the SFN while applying a specific NM of the SFN, applied in different hip positions, in unembalmed cadavers in order to evaluate its biomechanical influence. Results showed that adjacent joint (ankle) motions are the most important in order to produce linear strain in the SFN.

## Introduction

The incidence of SFN entrapment neuropathy is about 3,5% in people presenting with chronic lower limb pain [1]. Although surgery has a success rate of about 80% [2], surgery presents risks and may not be readily available. Conservative management can include physical rehabilitation and manual therapy. Among manual therapy modalities, NM can have a prevalent role in the assessment of entrapment neuropathies. These techniques are based on biomechanical principles in order to assess mechanosensitivity in patients by inducing linear strain to a specific nerve [3, 4]. For the moment, no data supports the ability of the technique proposed in the literature for inducing SFN strains.

**Objective 1:** To evaluate strain on the SFN using a sequence described in reference literature. **Objective 2:** To determine if a difference in strain exists at different Straight Leg Raise (SLR) position during a complete sequence.

## Methods

The SFN from three lower limbs of two unembalmed cadavers were exposed at the exit from the crural fascia on the lower 1/3 of the antero-lateral leg. A displacement sensor was inserted into the SFN 2cm distally from the emergence point to measure linear displacement during the application of the specific NM. Strain ( $\epsilon$ ) was measured using displacement data using standard linear strain equation:  $\epsilon = \Delta L/L_0$ . The specific sequence of movement applied at four different SLR positions (0°/30°/60°/90°) was: Maximal ankle plantar flexion (PF) followed by maximal ankle inversion (INV), SLR and 35° of hip ADD. Each position was maintained two seconds to obtain stable data. Normalization of strain was performed after INV at 100% in order to eliminate inter-subject variability and obtain SLR data. Optitrack motion capture system was used to control range of motion during the experiment.

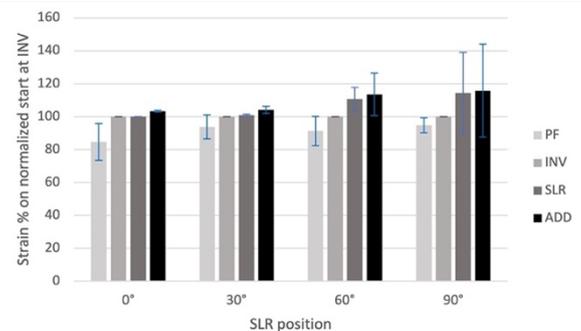

## Results and Discussion

The preliminary results demonstrated that the specific NM sequence tends to produce strain at all hip positions described previously (Figure 1). Hip SLR and ADD seem to have a lesser influence on total strain when compared to ankle PF and

INV who are the main contributors of strain. PF is constantly the most contributing movement to the overall strain during NM followed by INV. Although producing a positive amount of strain, ADD seems to be the least contributing motion of all the NM sequence (Table1). SLR position has an influence on total strain (Fig. 1) with 90° producing the most at 14,3% when normalizing data after max FP+INV.

**Table 1.** Relative contribution % of motions on total strain (SD) at different SLR positions.

Motion	SLR position			
	0°	30°	60°	90°
PF	78.3 (10,5)	88.9 (7.10)	76.9 (14.8)	77.7 (16.6)
INV	18.6 (11.0)	8.1 (7.0)	10.8 (6.5)	9.1 (5.6)
SLR	0.0	0.9 (0.5)	8.6 (5.2)	11.3 (11.2)
ADD	3.1 (0,5)	2.1 (2.1)	3.7 (4.6)	1.9 (2.3)

**Figure 1.** Evolution of normalized strain during mobilization. 100% is considered the normalized start following INV

## Conclusions

Ankle motions may be considered the most important in order to evaluate mechanosensitivity. Although the lumbar plexus is known to pass medially to the axis of ABD/ADD, hip ADD is a contributor (weak) to SFN strains during NM and evaluation. This could be explained by an “anchor” at the ischial tuberosity/hamstring tendon acting as a pulley modifying the proximal set point of the sciatic nerve. There seems to be an effect of different SLR position on total linear strain as higher angles of hip flexion seem to produce more strain.

## Acknowledgments

## Drop height and sex differences in anterior cruciate ligament force during unilateral drop landings

Jake A. Melaro<sup>1</sup> & Joshua T. Weinhandl<sup>1</sup>

<sup>1</sup>Dept. of Kinesiology, Recreation and Sport Studies, University of Tennessee, Knoxville, TN, USA

Email: [jmelaro@vols.utk.edu](mailto:jmelaro@vols.utk.edu)

### Summary

Anterior cruciate ligament (ACL) injury rates are thought to be influenced by sex factors and movement intensity (i.e. drop height), though their combinatory effects are unknown. Male and female unilateral drop landing data were collected to model ACL loading. Analysis showed that ACL forces were actually greater in men than women and statistically similar at different drop heights.

### Introduction

120,000+ ACL injuries are diagnosed annually, of which 40% are non-contact injuries and 75% of all ACL injuries require surgery [1,2]. These injuries result in substantial losses in terms of playing time, and present a major economic burden. Further, sex differences and drop height have been implicated as non-contact ACL risk factors. Previous works have examined the isolated effects of sex and drop height on ACL loading and lower extremity joint biomechanics [3], yet interaction effects between these factors have yet to be investigated during unilateral drop landing tasks. Therefore, this study sought to elucidate any effects on ACL loading and lower extremity biomechanics due to sex, drop height, or their interaction during unilateral drop landings.

### Methods

Forty college-aged, recreationally-active men (n=20, 80.35±11.26 kg, 1.80±0.05 m) and women (n=20, 61.32±8.08 kg, 1.63±0.05 m) completed unilateral landings off of 30- and 50-cm tall boxes while GRF (2000 Hz, Bertec) and 3-D positional (200 Hz, Vicon) data were collected.

These data were exported to Visual3D for lower extremity joint kinematic and kinetic calculations. Peak joint moments and angles, as well as joint angles at initial contact were identified. Joint angle and moment data were then imported into OpenSim (v3.3, <http://simtk.org>) where the static optimization tool was used in conjunction with a modified 3 *degrees-of-freedom* knee model. The static optimization analysis produced estimated muscle forces needed for knee-spanning muscles subsequently input into a previously established knee model [4] to estimate 3-D ACL forces and stress. Individual 2×2 repeated measures ANOVAs were used to assess drop height (within-subject) and gender (between-subject) differences for ACL loading and lower extremity joint kinematic and kinetic variables. *A priori* significance was set at  $p < 0.05$  and Cohen's *d* effect sizes were reported for effect size interpretations.

### Results and Discussion

No interaction effects were observed, though unilateral drop landings exposed men to significantly greater peak sagittal ( $p=0.001$ ;  $d =0.51$ ) and resultant ( $p=0.005$ ;  $d =0.45$ ) ACL forces than women.

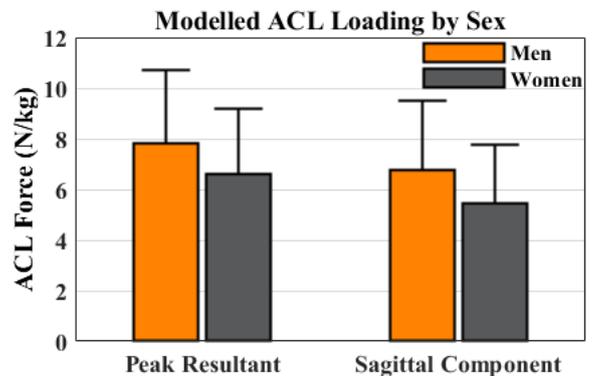

Figure 1: Modeled ACL resultant and sagittal forces.

Men also exhibited greater peak knee internal rotation ( $p=0.016$ ;  $d =0.38$ ) but smaller hip abduction ( $p<0.001$ ;  $d =0.67$ ) moments than women. Interestingly, women landed with greater peak hip internal rotation ( $p<0.001$ ;  $d =0.59$ ), peak knee flexion ( $p<0.001$ ;  $d =0.63$ ) and abduction ( $p<0.001$ ;  $d =0.76$ ), and plantarflexion at initial contact ( $p<0.001$ ;  $d =0.59$ ) compared to men.

The 50-cm drop height conditions produced greater peak hip ( $p=0.001$ ;  $d =0.55$ ), knee ( $p<0.001$ ;  $d =1.09$ ), and ankle ( $p<0.001$ ;  $d =0.70$ ) extension moments than the 30-cm drop height. Peak hip adduction ( $p<0.001$ ;  $d =0.80$ ) and knee flexion ( $p=0.002$ ;  $d =0.50$ ) and external rotation ( $p=0.001$ ;  $d =0.50$ ) angles were observed at the greater drop height. Finally, initial contact hip ( $p=0.036$ ;  $d =0.33$ ) and ankle ( $p=0.043$ ;  $d =0.31$ ) flexion, hip adduction ( $p<0.001$ ;  $d =1.25$ ), and hip ( $p=0.025$ ;  $d =0.35$ ) and knee ( $p=0.002$ ;  $d =0.50$ ) external rotation at increased with drop height.

### Conclusions

Lower extremity joint kinematics and kinetics are altered during unilateral landings from different heights between men and women. Surprisingly, the modeled ACL loading was greater in the male, not female, participants when performing unilateral drop landings from different heights. These results are surprising when considering women incur ACL injuries at greater rates than men and the observed joint angles and moments present in the current investigation. Future research should seek to elucidate the mechanism(s) behind altered ACL loading between sexes during unilateral landings.

# Effects of ACL Reconstruction on *In Vivo* Quadriceps Contractile Behavior and Association with Knee Joint Biomechanics

## Summary

Our purpose was to quantify the effects of anterior cruciate ligament reconstruction (ACLR) on vastus lateralis (VL) fascicle length change behavior and the association thereof with gait biomechanics. Because active quadriceps muscles resist muscle-tendon unit (MTU) lengthening during weight acceptance, we hypothesized that ACLR limbs with known deficits in quadriceps force generation would exhibit more fascicle lengthening despite less MTU lengthening than contralateral and uninjured control limbs. We also hypothesized that fascicle length change in the ACLR limb would correlate with knee biomechanics during weight acceptance. As hypothesized, only the involved limb in individuals with ACLR exhibited VL lengthening during weight acceptance, which we interpret in the context of strength deficits and changes in series elastic tendon mechanical properties. Conversely, only the contralateral limb demonstrated associations between VL contractile behavior and knee biomechanics, perhaps to compensate after ACLR.

## Introduction

Insufficient quadriceps force production and altered knee joint biomechanics after ACLR may contribute to a heightened risk of osteoarthritis. Changes in walking biomechanics frequently manifest in early stance via smaller peak knee extensor moments (pKEM), and reduced knee flexion excursion for the ACLR limb compared to the contralateral and uninjured control limbs [1,2]. Despite widespread recognition that muscle force is governed not only by muscle activation and size but also by contractile state, no study to our knowledge has quantified *in vivo* quadriceps contractile behavior during walking in individuals with ACLR or examined correlations between *in vivo* quadriceps contractile behavior and joint biomechanics. We suspect that the altered gait biomechanics often associated with OA development after ACLR arise in part from an incomplete understanding of quadriceps muscle function in walking and changes thereof following ACLR.

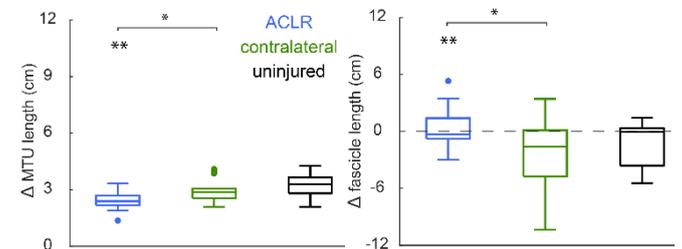

## Methods

We quantified bilateral VL contractile behavior (i.e., fascicle length and pennation) via cine B-mode ultrasound imaging [3] and gait biomechanics (i.e., vGRF, pKEM, and KFE) via standard gait analysis in 16 individuals with ACLR (age: 20.1±4.1 years, since ACLR: 7.4±1.2 months) who walked on an instrumented treadmill. We compared outcomes between limbs with paired samples t-tests and to outcomes collected from 11 uninjured control participants (age: 23.8±2.5 years)

with independent samples t-tests. Finally, we identified associations between measures of fascicle length and gait biomechanics using linear regressions.

## Results and Discussion

Despite 19% less VL MTU lengthening in the ACLR limb compared to the contralateral limb ( $p < 0.01$ ), the VL fascicle on the ACLR limb lengthened ( $0.23 \pm 2.13$  cm) whereas the contralateral limb fascicle shortened ( $-2.66 \pm 3.74$  cm,  $p < 0.01$ ) in manner similar to uninjured controls ( $-1.30 \pm 2.32$  cm,  $p = 0.05$ ). We may see more lengthening in ACLR limb fascicles due to a combination of insufficient strength, inhibition, and altered patellar tendon mechanics from graft removal. Ultimately, the eccentric action of the VL fascicles, unique to ACLR limbs, suggests that these muscles may succumb to the task demands of MTU lengthening during weight acceptance. VL length and length change behavior correlated with change in MTU length, change in KEM, and pKEM, but only in the contralateral limb ( $p \leq 0.04$ ). These contralateral limb correlations may allude to a greater influence of quadriceps muscle action in governing knee joint biomechanics, which may serve to compensate for ACLR limb deficiencies.

**Figure 1.** Change in VL MTU length (left) and VL fascicle length (right) between heel-strike and instant of pKEM.

## Conclusions

*In vivo* quadriceps muscle behavior may serve as a marker of recovery or a target for therapeutic intervention relevant to the risk of post-traumatic osteoarthritis in individuals with ACLR.

### Summary

This study applied optimization and unscented Kalman filter methods to an 18-DOF lower body model to convert synthetic inertial measurement unit (IMU) data into corresponding joint angles. Tracking errors produced by both methods were compared using overground and treadmill walking data. The optimization method was more accurate and robust, although it required more computation time.

### Introduction

IMUs could provide an attractive alternative to video motion capture systems for measuring walking in a non-laboratory setting. The two most common methods for converting IMU data into corresponding joint angle data are optimization and unscented Kalman filtering. While optimization methods are more flexible, unscented filtering methods are generally faster computationally. This study compares these two methods using noisy synthetic IMU data generated from actual video motion capture walking data.

### Methods

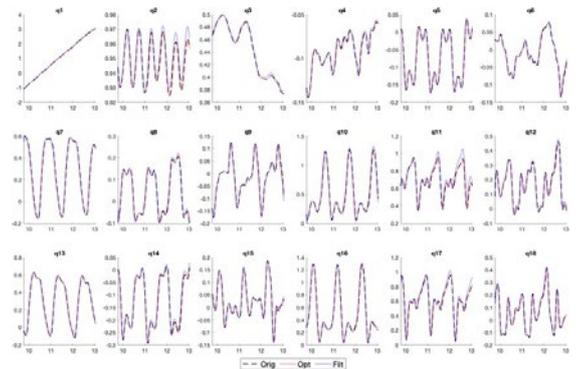

Experimental video motion capture and IMU data were collected from a single subject who performed overground and treadmill walking trials. For an initial static trial, three reflective markers were placed on each IMU consistent with IMU local coordinate systems. OpenSim model scaling [1,2] was performed to scale a generic 3D OpenSim model [3] and attach dynamic markers and IMUs to the pelvis (6 DOFs) and lower body segments (6 DOFs per leg). Next, OpenSim inverse kinematics was performed to calculate pelvis and lower body joint angles as well as corresponding synthetic IMU measurements. Finally, synthetic noise was added to the synthetic IMU data to emulate actual IMU data.

For one overground and one treadmill walking trial, pelvis and lower body joint angles were recovered from the noisy synthetic IMU data using a nonlinear least squares optimization method and a standard unscented filter method, both implemented in Matlab. For each time frame, the optimization method adjusted the kinematic model's joint positions, velocities, and accelerations to minimize errors between model and synthetic IMU data (including integrated IMU orientations, velocities, and positions) and between model and integrated joint positions and velocities. All numerical integration was performed using an implicit method.

### Results and Discussion

Overall, the optimization method was more accurate and robust than was the unscented filter method. While the unscented filter was only slightly less accurate for 4 seconds

of overground walking (Fig. 1), it completely diverged for 30 seconds of treadmill walking. In contrast, the optimization method tracked the correct joint positions well for the duration of the treadmill walking trial (average RMS errors of < 2 mm for translations and < 1 deg for rotations for last 3 seconds). Thus, the optimization method could entrain the kinematic model to the natural system dynamics, while the unscented filter method could not. The main drawback of the optimization method was increased computational cost, though no effort was made to improve it.

**Figure 1:** Optimization vs. filtering for overground walking.

Both methods required parameter tuning to achieve the best tracking of the original joint angles. The optimization method required identifying different cost function weights for position, velocity, and acceleration errors and was relatively insensitive to the selected values. In contrast, the unscented filter method required state and measurement covariance along with  $\alpha$ ,  $\beta$ , and  $\kappa$  algorithm parameter values and was more sensitive to the selected values.

### Conclusions

The optimization method produced more accurate and robust joint angle tracking than did the unscented filter method but at the cost of increased computation time. The next step will be to repeat the evaluation using actual IMU data that can be properly synchronized with the motion capture data.

# Eight-Week Individualized Gait Modification Intervention to Reduce Knee Adduction Moment: Preliminary Analysis of a Randomized Controlled Trial

Bryndan Lindsey<sup>1</sup>, Yakun Wang<sup>2</sup>, Scott Bruce<sup>2</sup>, Nelson Cortes<sup>1</sup>

<sup>1</sup> Sports Medicine Assessment, Research & Testing (SMART) Laboratory, George Mason University, Manassas VA

<sup>2</sup> Department of Statistics, George Mason University, Fairfax VA

Email: ncortes@gmu.edu

## Summary

Our preliminary analysis of a randomized controlled trial (RCT) investigating the effects of an individualized 8-week gait retraining intervention on KAM demonstrates that prior findings in quasi-experimental studies (often using healthy participants) are replicable using more rigorous study designs on the target population.

## Introduction

Increased first peak internal knee abduction moment (KAM) due to altered gait mechanics has been associated with increased knee osteoarthritis (KOA) severity [1]. Gait modifications using real-time biofeedback have shown to be effective in reducing KAM. Prior studies, however, have largely relied on single-session designs with healthy participants, limiting generalizability. Additionally, the majority of studies have not screened KOA patients in regards to which modification is most beneficial to reduce KAM, despite evidence of large variability in individual responses to different modifications [2]. Our purpose was to evaluate preliminary data from a RCT investigating the effect on KAM of an individualized 8-week gait modification intervention.

## Methods

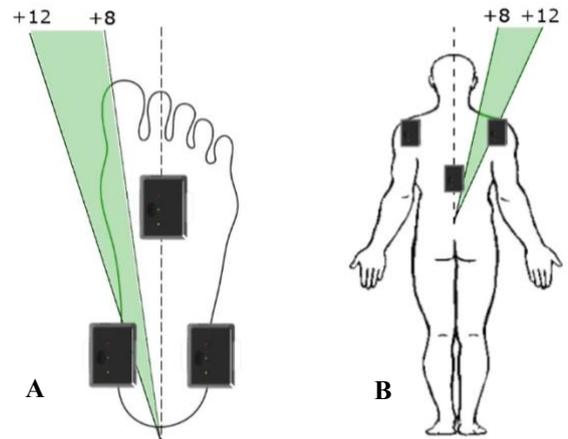

Eight patients with medial compartment KOA completed the intervention. Patients first performed a baseline screening session consisting of 10 normal, trunk lean, and toe-in walking trials. Patients were randomized into either the intervention group (where the modification used was that which most reduced KAM compared to normal walking) or control group. Those in the intervention group completed 20 minutes of training once-per-week for 8 weeks using a previously described wearable inertial measurement unit (IMU) system [3] (Figure 1). The protocol for the control group matched the intervention, however, with normal walking. KAM was collected at week 5, 1-week, and 1-month post-intervention where participants were asked to walk with their learned modification. A mixed effects linear regression model was developed to assess changes in KAM across sessions and groups while accounting for correlation due to repeated measurements from patients.

**Table 1:** Estimated change in KAM from baseline to posttests for intervention group using mixed effects linear regression.

Posttest	Estimate (SE)	P-value	95% CI
1	0.111 (0.070)	0.164	(-0.061,0.284)
2	0.057 (0.031)	0.114	(-0.019,0.133)
<b>3</b>	<b>0.086 (0.022)</b>	<b>0.008</b>	<b>(0.033, 0.139)</b>

## Results and Discussion

Of the patients randomly assigned to the intervention group, all three most reduced KAM using trunk lean gait. The remaining five were assigned to the control group. Estimated change in KAM from baseline for the intervention group (Table 1) showed a significant reduction in KAM during the final posttest ( $p < 0.01$ ). The control group (not shown) did not show any significant changes in KAM across sessions.

**Figure 1:** Gait modification schematic for (A) toe-in gait, and (B) trunk lean gait. Black nodes represent the placement of IMU nodes on the body. The nodes on the dashed lines computed joint kinematics in real-time while the others provided haptic feedback. If during training, a patient was not within their prescribed modification range ( $8^{\circ}$ - $12^{\circ}$  toe-in or trunk lean compared to baseline) they would be provided haptic feedback. If they were under the prescribed range during toe-in, the medial node would vibrate and vice versa. If they were under the prescribed range during trunk lean, the node on the side of the studied limb would vibrate and vice versa. Patients were instructed to attempt to walk so that they were provided no feedback.

## Conclusions

Our preliminary results provide strong support for prior quasi-experimental studies showing that gait modification strategies are effective to reduce KAM in both healthy and KOA samples. In addition, it is clear from the results of the baseline screening process that different patients will find certain modifications much superior to others. Future research should attempt to highlight if there are certain variables that indicate which modification a patient may respond best to.

# HOME-BASED FOOT-ANKLE EXERCISES PROGRAM ORIENTED BY A BOOKLET CHANGED POSITIVELY FOOT MOTION DURING GAIT IN PEOPLE WITH DIABETIC NEUROPATHY

Érica Q. Silva<sup>1</sup>, Jady L. Veríssimo<sup>1</sup>, Renan L. Monteiro<sup>1,2</sup>, Jane S.S.P. Ferreira<sup>1</sup>, Ronaldo H. Cruvivel-Júnior<sup>1</sup>, Marcos Duarte<sup>3</sup>, Isabel C.N. Sacco<sup>1</sup>

## Summary

We aimed at identifying the effect of a home-based foot-ankle exercises program oriented by a booklet in foot-ankle kinematics during gait in people with diabetes and neuropathy (DPN). Twenty participants were randomly allocated to usual care (control group [CG]) or usual care plus home-based foot-ankle exercises (intervention group [IG]) for 8 weeks. Preliminary results showed that IG increased hallux relative to forefoot (first metatarsal) range of motion (ROM) and decreased maximum forefoot relative to hindfoot (midfoot motion) dorsiflexion during gait. The home-based exercise programme showed preliminary positive changes in foot motion during gait of people with DPN.

## Introduction

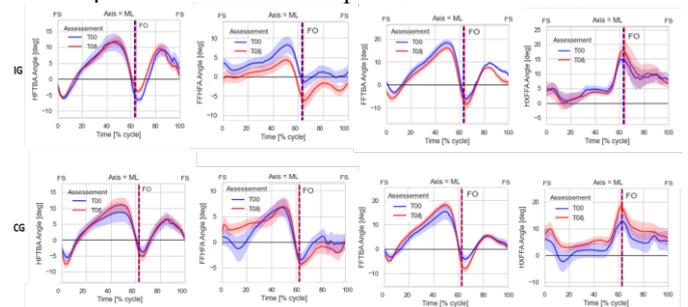

DPN leads to progressive losses in muscle strength, distal joints motion, sensibility, which can result in important changes in gait biomechanics[1,2]. Therapeutic foot-ankle exercises may be beneficial for people with DPN and were recommended for the first time in the most recent guidelines of the International Working Group on the Diabetic Foot[3]. However, it is not yet a worldwide strategy when prevention of ulcer formation is considered. A home-based program guided by a booklet can be an efficient preventive strategy for stimulating self-management, especially when physiotherapy is not regularly recommended for this population. Therefore, we sought to evaluate the effect of a foot-ankle exercises program oriented by a booklet in gait biomechanics in people with DPN through an randomized controlled trial.

## Methods

Twenty participants of both sexes with clinical diagnosis of type 1 or 2 diabetes and DPN were randomly allocated to usual care CG (55.3±8.9yrs) or usual care plus home-based foot-ankle exercises IG (58.1±3.6yrs) and assessed at baseline (T00) and Week 8 (T08) by 3D displacements of passive reflective markers tracked by 8 cameras at 100 Hz (VERO, Vicon). Plug-In Gait and Oxford Foot Model [4] setup protocols were used. Participants walked barefoot at a comfortable, self-selected speed on a walkway and 10 valid steps of each side were acquired. Digitisation and 3D reconstruction were performed in NEXUS software. Kinematic data were filtered using a zero-lag 2<sup>nd</sup>-order low-pass filter (6 Hz). Kinematics were computed with the open-source Python package pyCGM2 replicating the Vicon Plug-In Gait protocol and Plug-In of Oxford Foot Model. The variables calculated were ROM of first metatarsal, midfoot, rearfoot and tibia joints relative to the proximal segment. Comparisons between T00 and T08 within each group were performed by paired t-test to all variables (p<0.05).

## Results and Discussion

After 8 weeks, IG increased hallux relative to the forefoot ROM (first metatarsal joint) (p <0.001). A difference of 3.2 (-6.4 to 0.07) degrees was observed, suggesting an improvement in foot motion at a crucial gait phase when the first metatarsophalangeal joint is required for propulsion. IG showed a decrease in the maximum forefoot relative to hindfoot dorsiflexion (midfoot motion) (p=0.029). A difference of 5.0 (6.7 to 9.3) degrees was observed, suggesting an increase in the midfoot stiffness during push-off, favouring the midtarsal joint locking mechanism, resulting in a changeover from a flexible foot during weight acceptance to a rigid foot structure during propulsion. IG also presented a decrease in the maximum forefoot relative to tibia dorsiflexion (p<0.001) with a difference of 3.1 (1.95 to 4.15) degrees. The CG presented an increase in the hindfoot relative to tibia dorsiflexion ROM (p=0.027) of 3.7 (-6.9 to -0.5) degrees that can be explained by either a placebo effect or the supervision of usual care.

**Figure 1:** Ensemble averaged kinematics of the hindfoot (HFTBA), midfoot (FFHFA), tibia (FFTBA) and hallux (HXFFA) joints in degrees (deg) relative to the proximal segment. Blue colour indicates baseline assessment (T00), red colour indicates Week 8 assessment (T08). Error bars represent standard error. FS indicates foot strike, vertical lines (FO) indicate foot off event in the gait cycle.

## Conclusions

This is the first study to evaluate biomechanical outcomes specifically related to DPN losses using a specialised foot-exercises program guided by a booklet and it showed positive preliminary changes in hallux, forefoot and midfoot motion during gait.

### Summary

Clinicians are commonly using six-minute walk test (6MWT) to evaluate rehabilitation progress and needs in individual with lower-limb amputation (iLLA). In this study, we evaluated the intensity and spatiotemporal parameters of 6MWT using inertial sensors and heart rate sensor. Our findings showed that both workload and pain level increased over 6MWT. However, cadence and stance duration decreased and increased, respectively. Deterioration of spatiotemporal parameters could be due to physiological and pain-related fatigue.

### Introduction

The main goal of rehabilitation in iLLA is to improve mobility and lifestyle in iLLA [1]. Recently, wireless and light-weight inertial measurement units (IMUs) combined with heart rate (HR) sensor bring new inputs during the evaluation of 6MWT in iLLA [2]. Hence, clinicians were able to assess spatiotemporal parameters over 6MWT as well as workload among iLLA. In continuity of previous work, the objective of this study was to evaluate the intensity and spatiotemporal parameters over 6MWT in iLLA.

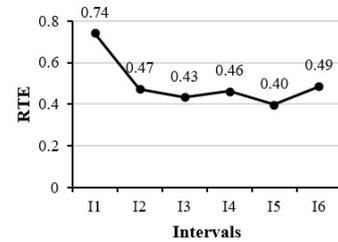

### Methods

Eleven unilateral iLLA (4 trans-femoral, 7 trans-tibial) participated in this study. The HR sensor (Polar® RS800CX™, Kempele, Finland, 1000 Hz) was placed below the chest muscles. Two synchronized IMUs (Physilog®4, Lausanne, Switzerland, 200 Hz) were attached on top of each shoe. Cadence and stance ratio were selected as spatiotemporal parameters. Pain level was estimated using a VAS score (0-10) before and after the 6MWT. The HR, cadence and stance ratio were classified in six intervals of one minute (I1-I6). Mean and variability (SD) of each interval were computed. The HR were normalized using the age-predicted maximal heart rates ( $HR_{max} = 220 - \text{age}$ ) to represent intensity of workload. Non-parametric repeated measures ANOVA (nparLD) test, with Bonferroni corrections were used to analyze mean and variability of HR performance and spatiotemporal parameters over 6MWT using R statistical software. A significant difference was set at a  $p$  level  $< .05$ .

### Results

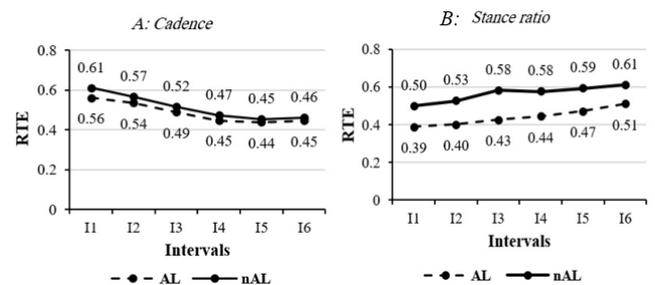

Mean of age and body mass index were  $57.91 \pm 6.22$  yrs and  $24.57 \pm 6.22$   $\text{kg}/\text{m}^2$ , respectively. Mean distance travelled during the 6MWT was  $321.93 \pm 128.04$  m. VAS score after 6MWT was significantly higher than before 6MWT ( $p = .016$ ). Our results showed that the mean of normalized HR gradually increased over 6MWT (I1:  $61.59 \pm 10.73$   $HR_{max}\%$ , I6:  $70.15 \pm 12.26$   $HR_{max}\%$ ) ( $p < .05$ ). Variability of HR during the

first interval of the 6MWT was significantly higher than others ( $p < .01$ ) (Figure 1).

**Figure 1:** Relative treatment effect (RTE) variability of HR.

Cadence in I1 (AL:  $100.16 \pm 20.18$ ; nAL:  $103.07 \pm 18.7$  steps/min) and I2 were higher than I3, I4, I5 and I6 (AL:  $96.76 \pm 21.93$ ; nAL:  $98.63 \pm 21.32$  steps/min) during 6MWT ( $p < .05$ ). Mean of stance ratio in I6 ( $63.39 \pm 3.27$  gait cycle%) and I5 were significantly longer than I4, I3, I2 and I1 ( $61.99 \pm 3.35$ ) in AL. Likewise, stance ratio in I5 ( $64.40 \pm 4.08$  gait cycle%) was longer than I1 ( $63.33 \pm 2.63$  gait cycle%) in nAL ( $p = .042$ ) (Figure 2).

**Figure 1:** Relative treatment effect (RTE), cadence and stance ratio. AL: amputated leg, nAL: non-amputated leg.

### Discussion and Conclusion

Variability of HR over the first interval of 6MWT was higher than over the others which can reflect high level of stress due to the test (white coat effect) [3]. Diminished HR variability after the first interval of 6MWT might reflect reduction of mental stress of clinic visit. Workload and the normalized mean of HR increased over 6MWT in iLLA. However, cadence decreased and stance ratio increased over 6MWT which can be due to physiological and pain-related fatigue [3].

### Acknowledgments

We would like to thank all the participants for their time.

# Foot Progression Angle Modifications that Maximally Reduce the Knee Adduction Moment do not Decrease Medial Knee Contact Force

## Summary

The knee adduction moment (KAM) is a surrogate metric for medial compartment knee loading, which is correlated with medial knee osteoarthritis (OA) progression. Gait modifications, like changing the foot progression angle (FPA), are often prescribed to maximally reduce the KAM. Selecting modifications in this manner does not reduce medial knee contact force (MCF), but MCF can be reduced by 6.4% ( $p < 0.001$ ) if it is used as the selection metric for an FPA modification.

## Introduction

Compressive joint loading is related to OA progression [1], but joint loads cannot be directly measured *in vivo* in a native knee, only estimated with musculoskeletal modeling. The KAM is used as a surrogate measure of joint loading [2]. Gait modifications, like changing the FPA, aim to decrease the KAM to slow the progression of medial knee OA [3]. It is understood that the KAM does not fully explain changes in MCF, yet it is the most common target for load-reducing knee OA interventions [4]. While KAM is easier to estimate, mechanobiology suggests that compressive force transmitted through the medial compartment may be a better metric of tissue-level strains that damage the cartilage microstructure [1]. The purpose of this study was to investigate how FPA modifications selected to reduce the KAM affect MCF. This work investigates three hypotheses: (1) FPA modifications selected to maximally reduce peak KAM (i.e., KAM-reducing modification) decrease peak MCF during initial training; (2) the KAM-reducing modification results in a persistent reduction in peak MCF after one year and (3) FPA modifications selected to maximally reduce peak MCF (i.e., MCF-reducing modification) will result in larger peak MCF reductions than the KAM-reducing modification.

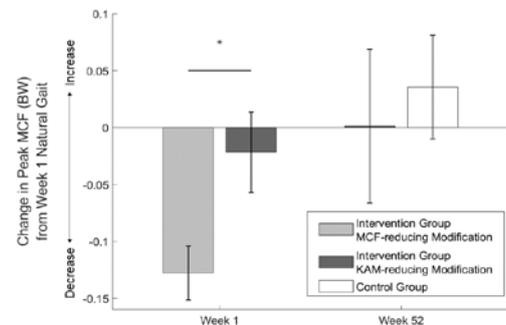

## Methods

Forty-nine individuals with radiographic and symptomatic medial knee OA participated in a 1-year gait retraining study. The intervention group ( $n=24$ ) was taught to walk with the KAM-reducing modification, an FPA modification ( $5^\circ$  or  $10^\circ$  toe-in or toe-out change) that maximally reduced their peak KAM, using biofeedback. The control group ( $n=25$ ) also received biofeedback to reinforce their natural FPA. Twenty steps were analyzed for the following trials: natural gait and KAM-reducing modifications at week 1, and the retrained KAM-reducing modification at week 52. MCF was estimated using OpenSim 4.0 with muscle forces estimated using a static optimization algorithm that minimizes the sum of squared muscle activations. Wilcoxon

signed rank and Mann Whitney U tests compare MCF ( $\alpha=0.05$ ) within and between subject groups, respectively.

## Results

Intervention subjects reduced their peak KAM by 12% with the KAM-reducing modification during week 1 but did not significantly reduce peak MCF (1.2%,  $p=0.33$ ). At week 52, there was no statistical difference in peak MCF between the KAM intervention group and control group ( $p=0.63$ ). Yet, an average 0.13 BW reduction in peak MCF could be achieved with an MCF-reducing modification, which was greater than ( $p=2.93 \times 10^{-4}$ ) the KAM-reducing modification (Figure 1).

**Figure 1:** Peak MCF changes from week 1 natural gait for the intervention (grey) and control group (white). At week 1, MCF-reducing modifications (light grey) reduce peak MCF more than the KAM-reducing modification (dark grey).

## Conclusions

FPA modifications that are selected to maximally reduce KAM do not decrease average peak MCF; however, average peak MCF was reduced by 6.4% ( $p=2.98 \times 10^{-4}$ ) when it was used as the gait modification selection metric. Future work is needed to identify the most effective targets for load-reducing interventions.

# Are medial and lateral tibiofemoral compressive forces different in uphill compared to level walking for patients following total knee arthroplasty?

Tanner Thorsen, Chen Wen, Songning Zhang

Biomechanics and Sports Medicine Lab, The University of Tennessee, Knoxville, Tennessee

Email: [tthorsen@vols.utk.edu](mailto:tthorsen@vols.utk.edu)

## Summary

The purpose of this research was to determine how knee joint compressive forces change during uphill walking as compared to level walking in both the replaced and non-replaced limbs of patients with total knee arthroplasty (TKA). TKA patients experience greater knee compressive force in their non-replaced limb during uphill walking.

## Introduction

Uphill walking is a necessary part of daily living that has also become popular in exercise and TKA rehabilitation. TKA patients exhibited lower knee extension moments than did healthy controls in both the replaced and non-replaced limbs and the replaced limb of TKA patients exhibited lower peak knee extension moment at 10° and 15° incline compared to the non-replaced limb [1].

Variables such as knee extension moment have been correlated to tibiofemoral compressive force in level walking, however, these variables do not directly indicate the magnitude or behavior of compressive forces [2]. Recent developments of musculoskeletal modeling have provided the ability to estimate total (TCF), medial (MCF), and lateral (LCF) knee joint compressive force [3]. The purpose of this research was to determine how tibiofemoral joint compressive forces change during 10° uphill walking compared to level walking of TKA patients.

## Methods

Twenty-five TKA patients (11 male 14 female, 68.6 ± 4.9 years, 22.1 ± 11.7 months since surgery) walked at self-selected pace at 0° (level walking) and 10° incline five times on a customized adjustable ramp system which was instrumented with two force platforms (1200 Hz, AMTI, Watertown, MA, USA). Three-dimensional (3D) kinematics (240 Hz, Vicon, Oxford, UK) and ground reaction force (GRF) were collected simultaneously.

An open-source musculoskeletal capable of resolving knee TCF, MCF, and LCF was used to perform the musculoskeletal simulations [3]. Static optimization and joint reaction analysis

were used in OpenSim to determine muscle activations and TCF, MCF, and LCF during level and uphill walking.

A 2x2 (slope: level and 10° × limb: replaced and non-replaced) repeated measures analysis of variance (ANOVA) was used to detect differences between slope and limb conditions and their interaction (SPSS). An  $\alpha$  level of 0.05 was set a priori and adjusted for post hoc comparisons such that the interaction  $\alpha < 0.0125$ .

## Results and Discussion

Peak loading-response TCF, MCF, and LCF were greater during uphill walking than level walking for the non-replaced limb (Table 1). During uphill walking peak loading-response TCF, MCF, and LCF were smaller in the replaced limb compared to the non-replaced limb. During level walking, the replaced and non-replaced limb experienced rather comparable joint loading, however the replaced limb experienced reduced joint loading in relationship to the non-replaced limb during uphill walking. Differences in joint loading between replaced and non-replaced limbs were not present during level walking, suggesting compensation from the replaced limb during the more difficult task. Furthermore, the distribution TCF (MCF vs. LCF) highly favors MCF at 86% and 87% of TCF for the replaced limb and non-replaced limbs, respectively. During uphill walking, the distribution of TCF shifts laterally such that MCF accounts for 75% and 74% of TCF for the replaced and non-replaced limbs, respectively.

## Conclusions

It is difficult to make direct conclusions about the benefit of uphill walking following TKA, as it promotes a more balanced loading (MCF vs. LCF) of the knee joint during stance, however these benefits come at the expense of increased loading at the non-replaced limb.

## Dynamic Gait Stability During Anteriorly Loaded Treadmill Walking

Caroline Simpkins<sup>1</sup>, Jiyun Ahn<sup>1</sup>, Meredith Wells<sup>1</sup>, Feng Yang<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Health, Georgia State University, Atlanta, GA, USA

Email: [claubacher1@student.gsu.edu](mailto:claubacher1@student.gsu.edu)

### Summary

This study examined the effects of anteriorly-loaded treadmill walking on dynamic stability in young adults. Participants were randomized into three groups: 0% or no load, 10% body weight (*bw*), 20% *bw*. Center of mass (COM) dynamic gait stability was found to be comparable across all groups at touchdown (TD) and liftoff (LO) during gait. To maintain stability during loaded walking, subjects leaned their trunk backward while keeping a similar step length.

### Introduction

Anterior load carriage during walking is common in activities of daily living and many occupations. Carrying a load in front of the body can affect gait patterns and increase the risk of falls [1]. Due to the advantages of using a treadmill, it has been broadly employed in previous work to investigate the effect of front load carriage on gait parameters while participants walk on a treadmill [2]. The variability of gait parameters has been used as an index of fall risk. Dynamic gait stability is another measurement of the human body's dynamic balance and the risk of falling during walking [3]. An examination of how front load carriage influences dynamic gait stability could provide novel insight into the impact of front load carriage on the risk of falls. However, it remains completely unknown how front load carriage impacts dynamic gait stability during treadmill walking. The purpose of this study was to inspect the effects of anteriorly-loaded treadmill walking on dynamic gait stability in healthy young adults. We hypothesized that front load carriage would affect dynamic gait stability during treadmill walking.

### Methods

Thirty healthy young adults ( $24.83 \pm 4.96$  years) were randomly allocated to three groups: 0% or no load (Group 1), 10% body weight (*bw*) (Group 2), 20% *bw* (Group 3). The load was assembled by filling sand bags with various weights into a fitness sandbag. Before loaded treadmill walking, participants walked on the treadmill unloaded for 10 minutes to warm up. Self-selected walking speed (in m/s) was also determined during the warm-up. After finishing three 30-sec treadmill trials at self-selected speed with either no load (Group 1) or the assigned load (Groups 2 and 3), participants completed three walking trials at a set treadmill belt speed of 1.2 m/s. This pre-set gait speed could remove confounding effects due to the uncontrolled speed. Groups 2 and 3 carried the sandbag against their abdomen using both hands in a symmetric posture maintaining load height with both elbows flexed about 90°.

Full-body kinematics were collected from 26 reflective markers on the body landmarks through a motion capture

system (Vicon, UK). Two more markers were attached at both sides of the sandbag. Marker paths were filtered. Two characteristic gait events (TD and LO) were identified based on foot kinematics. The body-load system's COM position was calculated from the filtered marker paths. The two components of the COM motion state (position and velocity) were calculated relative to the rear part of the base of support (or the lead heel) and normalized by foot length and the square root of the product of body height and gravitational acceleration, respectively. Dynamic gait stability at both events was calculated as the shortest distance from the COM motion state to the limit against backward balance loss [3]. Trunk angle (°, +: lean backward) at TD and LO in the sagittal plane and step length (/body height) were calculated from the marker paths. Dependent variables (dynamic stability at TD and LO, trunk angle at TD and LO, and step length) were compared between groups using one-way ANOVA. SPSS 25 (IBM) was used and  $\alpha$  level of 0.05 was applied.

### Results and Discussion

No significant differences were found between groups for dynamic stability at TD ( $p = 0.205$ ) and LO ( $p = 0.122$ , Table 1). Trunk angle showed significant group-related differences at TD and LO (both  $p < 0.001$ ). All groups took a similar step length ( $p = 0.344$ ).

	Group 1	Group 2	Group 3
Stability-TD	0.05±0.03	0.04±0.02	0.04±0.02
Stability-LO	0.22±0.04	0.16±0.10	0.19±0.02
Trunk angle-TD	-1.27±4.66	3.86±2.07	9.08±2.51
Trunk angle-LO	1.16±4.59	5.09±3.42	10.48±2.87
Step length	0.35±0.03	0.34±0.03	0.36±0.02

**Table 1:** Comparisons of outcome measures (mean ± SD).

The results reject our hypothesis. To maintain stability during loaded walking, subjects leaned their trunk backward in the loaded groups to maintain the body-load system COM's position relative to the base of support. As the gait speed is the same across groups, dynamic stability was not different between groups.

### Conclusions

Anterior load carriage of up to 20% *bw* may not alter dynamic gait stability in young adults during treadmill walking at a set-speed.

## Danger Ahead: Fatigued Obstacle Negotiation in an Unpredictable Environment

Joshua A. Vicente<sup>1</sup>, Nicole M. Stoehr<sup>1</sup>, Maria Ayala<sup>1</sup>, Michael Weise<sup>1</sup>,  
Sean M. Rogers, DAT<sup>1</sup>, Jacob W. Hinkel-Lipsker, PhD<sup>1</sup>

<sup>1</sup>Move-Learn Lab, Department of Kinesiology, California State University, Northridge, California, USA  
Email: movelearnlab@gmail.com

### Summary

This study investigated the impact of physical fatigue on an individual's ability to navigate randomized and unexpected obstacles during locomotion. Participants completed a series of obstacle negotiation trials in the dark, then underwent a fatiguing protocol, before completing another series of negotiation trials. Results revealed that participants had a significant decrease in leading toe and trailing toe clearance and a significant increase in leading heel clearance when fatigued. Additionally, participant fitness level significantly predicted where participant foot placement while approaching the obstacle. These results indicate that physical fatigue impacted participant's crossing mechanics. Implications from this study may be of interest to occupational work and safety associations to reduce workplace injuries for employees in physically demanding positions/fields.

### Introduction

A prominent cause of non-fatal work-related injuries is attributed to slips, trips, and falls [1]. While it is known that fatigue has a direct impact in navigating obstacle navigation, most of the literature surrounds the geriatric population and is not based around the working population [2]. Thus, the goal of this study is to explore the impact of physical fatigue on young, physically-fit individuals' ability to negotiate unpredictable obstacles. We hypothesized that participants would exhibit a riskier crossing behavior (e.g., lower foot clearance) when fatigued.

### Methods

Twenty-one participants were recruited and chosen for this study based on their respective cardiovascular (CV) fitness levels so that our results would reflect the potential outcomes of individuals with active, physically-demanding occupations. All participants were between 18 and 35 years of age, and were classified to have an above average level of cardiovascular fitness.

Participants were instructed to walk through a darkened pathway over a randomly placed hurdle that upon approach would be illuminated by a motion detection light. This setup was modelled to simulate an unpredictable workplace environment with limited to no visibility (Figure 1.).

To analyse participants' crossing mechanics, three-dimensional motion capture collected coordinate data and associated spatiotemporal measurements. Additionally, multiple linear regressions were performed to determine if any anthropometric or demographic variables predicted spatiotemporal negotiation mechanics.

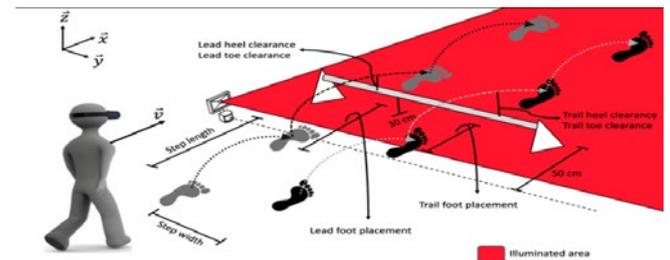

Figure 1: Layout of Obstacle Trial Attempt after Fatigue Protocol.

### Results and Discussion

Participants exhibited a significantly lower leading toe and trailing heel clearance. Participants also stepped closer to the obstacle prior to clearing it when fatigued, placing them at greater risk for foot contact and a subsequent likelihood of tripping. They also walked at a significantly faster gait velocity, which may have reduced the time available to them to coordinate motion over the obstacle, which may also be disadvantageous for obstacle negotiation. Finally, participant CV levels were a significant predictor of leading and trailing foot placement the step before negotiation, where those with lesser fitness stepped closer to the obstacle—a potentially riskier behavior as it provides them with less time to control the trajectory of their foot [3].

### Conclusions

Reductions to the participants' clearance margins suggest a diminished ability to coordinate the lower extremities, reflecting a riskier obstacle negotiation behavior when in a physically-fatigued state. With increased fatigue, an increase in work-related injuries like slips trips and falls could potentially occur in physically demanding occupations.

# Modeling Spatial Asymmetry in Visuomotor Coordination

Kolby Brink, Aaron Likens, and Nicholas Stergiou

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA

email: kolbybrink@unomaha.edu

Presentation Preference: Podium

## INTRODUCTION

Coordination is foundational to human movement<sup>1</sup>. One prominent model of coordination is the Haken-Kelso-Bunz (HKB) which predicts change in relative phase between two oscillators according to the following equation:

$$\dot{\phi} = \Delta\omega - a \sin(\phi) - 2b \sin(2\phi) - \sqrt{Q}\zeta_t,$$

where  $\Delta\omega$  quantifies differences in natural periods between the oscillators. The ratio,  $b/a$ , models the collective frequency of coordinated oscillation.  $\sqrt{Q}\zeta_t$  is a noise term with strength  $Q$ .  $\Delta\omega$  is an ‘imperfection parameter’ that predicts deviations in relative phase,  $\phi$ , due to timing differences in oscillators. Another possibility is that deviations of  $\phi$  might result from asymmetries in spatial alignment of oscillators, such as in visual motor coordination. We propose two possible mechanisms for modeling asymmetry based on a modified HKB model:

$$\dot{\phi} = \Delta\omega + \Delta s - a \sin(\phi - \eta) - 2b \sin(2\phi) - \sqrt{Q}\zeta_t$$

Two potential terms,  $\Delta s$  and  $\eta$ , can model the effects of spatial asymmetries of oscillators. Both predict shifts in mean relative phase,  $\bar{\phi}$ , away from stable fixed points. Only the  $\Delta s$  parameter predicts a shift in  $SD_{\bar{\phi}}$ , a decrease in the stability of coordination. This study was designed to distinguish which, if either, of those parameters best models spatial asymmetry.

## METHODS

10 healthy adults ( $26.4 \pm 6.87$  years, 7 males, 3 females) participated in this study. A 6-camera system (Optotrak, NDI) measured upper body movement at 100 Hz. The aim was to investigate the effects of reference frame alignment on the form and stability of visuomotor coordination. Participants coordinated their arm movements with a visually displayed sinusoidally oscillating stimulus ( $S_{Sine}$ ). Forearm movements

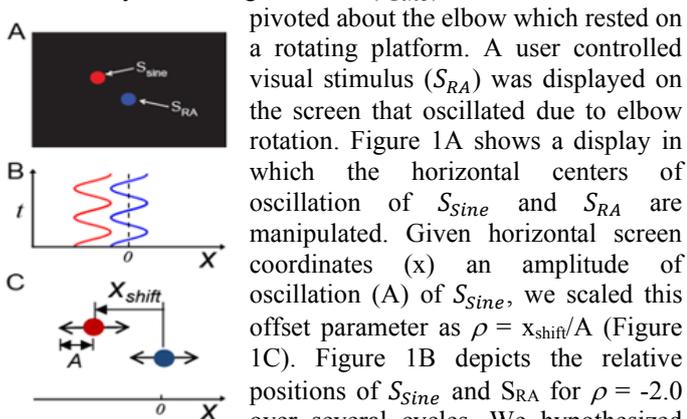

Figure 1. See Text

pivoted about the elbow which rested on a rotating platform. A user controlled visual stimulus ( $S_{RA}$ ) was displayed on the screen that oscillated due to elbow rotation. Figure 1A shows a display in which the horizontal centers of oscillation of  $S_{Sine}$  and  $S_{RA}$  are manipulated. Given horizontal screen coordinates ( $x$ ) an amplitude of oscillation ( $A$ ) of  $S_{Sine}$ , we scaled this offset parameter as  $\rho = x_{shift}/A$  (Figure 1C). Figure 1B depicts the relative positions of  $S_{Sine}$  and  $S_{RA}$  for  $\rho = -2.0$  over several cycles. We hypothesized that particular spatial offsets will be preferred. To test this hypothesis, we studied preferences for particular spatial arrangements of  $S_{Sine}$  and  $S_{RA}$  that arise from initial arrangements of  $\rho = -3, -2, -1, 0, 1, 2$  or  $3$ . Participants were free to move the location of  $S_{RA}$  as

long as they could comfortably perform anti-phase and in-phase coordination. Subjects performed 3 trials for each phase (in-phase, anti-phase)  $\times \rho$  pair, each lasting 60 seconds. 3 practice trials were given at  $\rho = 0$  to familiarize subjects with the task.

**Analysis Strategy.** We computed instantaneous relative phase between  $S_{Sine}$  and  $S_{RA}$  for all trials, along with circular means and standard deviations.<sup>2</sup> We then modeled  $\bar{\phi}$  and  $SD_{\bar{\phi}}$  as a function of  $\rho$  and phase (inphase/antiphase) in separate Bayesian multilevel models developed specifically for circular/directional dependent variables.<sup>3</sup>

## RESULTS AND DISCUSSION

Estimates in Table 1 replicate well known differences between required phases because the 95% credible intervals defined by LB and UB do not overlap. Modeling results in Table 2 show

**Table 1.** Estimated circular descriptive statistics for  $\bar{\phi}$  as a function of required phase. Estimates are in radians.

	Mean	Mode	SD	LB	UB
Anti-phase	-2.82	-2.87	0.13	-2.98	-2.59
In-phase	0.14	0.12	0.03	0.08	0.21

that most slope estimates indicate that a one unit change in  $\rho$  predicts a negative change in  $\bar{\phi}$  because credible intervals do not contain 0. Models relating  $\rho$  and  $SD_{\bar{\phi}}$  (not reported to due to space) found no evidence of such a relationship, implying that  $\Delta s$  may not be useful in modeling asymmetry effects.

**Table 2.** Slope estimates for  $\rho$  predicting  $\bar{\phi}$

Slopes	Mean	SD	Mode	LB	UB
$\beta_c$	-0.18	-0.22	0.23	-0.31	0.14
AS	-0.08	-0.08	0.15	-0.22	-0.02
SAM	-0.08	-0.09	0.06	-0.20	-0.02

Note:  $\beta_c$  = Slope at inflection point, AS = Average Slope, SAM = Slope at Grand Mean, LB/UB = Upper and lower bounds of 95 % credible interval from Bayesian estimates.

## CONCLUSIONS

Results suggest that, in the current context, spatial asymmetries may best be modeled via the  $\eta$  parameter in the modified HKB model. Future work will investigate the extent to which this modification transfers to other conditions of asymmetry.

Email: [lagoskinesiologo@gmail.com](mailto:lagoskinesiologo@gmail.com)

### Summary

The metabolic cost of transport (C) at variable speed, including gait transitions, has been determined through a series of experiments on a treadmill (Lab) and in the field (F). The Lab trials were replicated in the F by using an auditive feedback. The C in F was affected by a positive speed bias: the average speed was around 50% higher than in the Lab. Therefore the C adjusted for the real speed was lower in the F than in the Lab.

### Introduction

The metabolic cost of locomotion (C) at variable speed in real conditions has been poorly investigated [1]. Our experiments were designed to study the C during acceleration cycles around the walk-run (W-R) transition speeds, both on a treadmill (Lab) and in the field (F). One of our hypotheses was that the C in the F would be higher than in the Lab.

### Methods

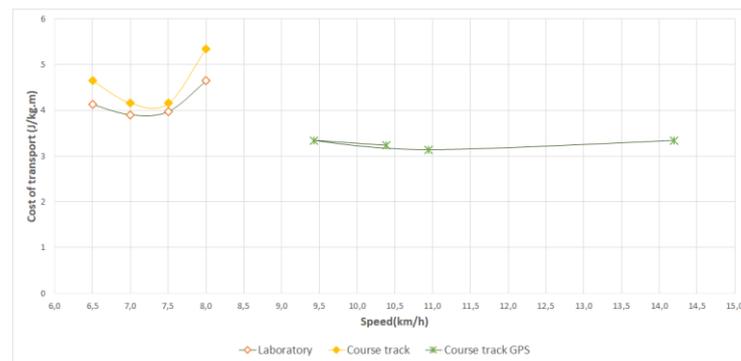

24 trained males signed an informed consent and participated in the investigation. The study was approved by the local Ethical Committee.

First, each subject was asked to perform three trials on a treadmill (T2100, GE Healthcare, USA), at variable speeds organized in two ascending and descending ramps, in order to determine the W-R transition speed (Ts). Then, a personalized ascending and descending speed ramp was designed, centered on the transition speed and ranged from Ts-20% to Ts+20%, each step lasting 5 s. Each ramp cycle lasted 50 s, and was repeated 5 times, for a total trial time of 250 s. Gas exchanges and heart rate(HR) were measured by a portable metabograph (K5, Cosmed, Italy). Only the last 50 s cycle was used to take the steady state oxygen uptake and carbon dioxide production. The step frequency (Sf) during the Lab trials was recorded, and used as audio guide for the F trials, which were performed on a regular course track in the Paysandú Sport Center. Speed progressions in F were controlled afterwards by analysing the GPS data of the K5 equipment.

### Results and Discussion

The C in the F at the same theoretical speed was higher than in the Lab (Table and Fig. 1). However the actual speed

detected by GPS was around 150% of the Lab speed. Therefore, the C in the F was lower, thus in a range of speed not comparable to the Lab. For this reason our hypothesis could not be proven.

**Figure 1:** Metabolic Cost of transport laboratory, course track and course track GPS.

The auditive feedback, based on the assumption that the same Sf would lead to the same speed, is, compared to other systems, simple and inexpensive [1, 3]. However it has proved unreliable in these complex trials. The subjects were able to maintain the Sf but at a larger, on average, stride length (SI) [2], suggesting different mechanical behaviours in Lab vs F. This difference explains the different C for unit distance.

### Conclusions

The speed control is a critical point in order to determine the C, because wrong assumptions could lead to misinterpretation of the results. Spatio-temporal and mechanical parameters should also be taken into account: it's one of our goals in the continuation of this project.

### Summary

Studying the parameters of the ground reaction force (GRF) during gait allows classifying them weight acceptance and impulse strategies during the vita cycle. In this study, we focused on comparing these variables between gait in children, adults, and older adults. We found differences between these parameters in different axes when comparing these strategies in children versus older people.

### Introduction

The clinical and biomechanical analysis of gait during the lifespan should be implemented to control alterations in daily life activities and the appearance of pathological processes in the elderly [1]. The study of the ground reaction forces is very important to provide an accurate description of the gait among age groups. This approach enables the collection of several parameters regarding gait biomechanics such as force-time characteristics, peaks of vertical and anterior-posterior ground reaction force components, spatiotemporal parameters, and impulses. These data can be used by researchers, physiotherapists, clinicians, or others interested in human movement as a tool to assess interventions, investigate the patient's walking pattern, diagnose gait disorders, compare different populations, among other applications. Larish et al. [2] described healthy gait patterns in older adults like walk velocity and its relationship with the economy of movement, as well as kinetic data, like the vertical and anterior-posterior ground reaction forces peak.

The purpose of this study was to compare gait ground reaction forces and derived parameters between children, young and older adults. We hypothesized that ground reaction forces and impulses would increase from children to young adults and decrease from young adults to older adults. Also, we hypothesized that the walking velocity would increase from children to young adults, and decrease from young adults to older adults, with the time parameters adapting to accommodate such alterations during the lifespan.

### Methods

Twenty-five children, thirty adults, and thirty-three older adults participated in this study. This investigation used a non-probability sampling process of intentional type, in which subjects were selected through a direct approach. Exclusion criteria were comprised of (i) a history of neuromusculoskeletal injuries, and (ii) have been submitted to an orthopedic/neurological surgery in the past two years that

could interfere with the participants ability to walk. Each participant performed five trials, walking at a self-selected pace, while wearing sports footwear, on a 6.0 m long by a 1.4 m wide walkway with 8 embedded force platforms (BTS Bioengineering, Milan, Italy). A Python 3 (Python Software Foundation; v3.8.1) script was developed to visually inspect and calculate the mean of the peaks of vertical forces and anteroposterior forces and their respective times across all steps. It also calculated the impulses using Simpson's rule to numerically integrate the area under the time-force curve. Normality assumptions were evaluated using the Shapiro-Wilk test. The intraclass correlation coefficient (ICC) was calculated to estimate the reliability of GRF parameters. A one-way analysis of co-variance (ANCOVA) was used to determine differences between groups in GRF parameters adjusted by gait velocity. Pairwise comparisons after ANCOVA were adjusted using Scheffé method. The magnitude of between group differences were also analyzed using Eta squared ( $\eta^2$ ) effect size. Results were considered significant at  $p \leq 0.05$ . All analyses were performed using STATA 15.0.

### Results and Discussion

A one-way analysis of variance revealed that gait velocity was significantly higher in children in comparison to older adults ( $p=0.031$ ). The one-way analysis of co-variance revealed that overall, gait velocity had a significant inverse effect in GRF parameters in all groups. The children group had a significantly higher first peak force (F1) and lower second peak force (F2) in comparison with adults and older adults. Time to peak forces (T1, T2, T3) were significantly lower in children in comparison with adults and older adults. Similarly, impulse of loading response and midstance and total impulse of the vertical GRF were significantly lower in children in comparison with adults and older adults.

### Conclusions

There are differences between the parameters of gait force, time and impulse, for the anteroposterior and vertical axes when comparing children and the elderly people.

**Summary** This study highlights the importance to consider the biomechanical consequences of gait modifications on the ankle and hip before considering a clinical application of gait retraining approaches.

**Introduction** Gait retraining as a non-invasive prospective approach to restore mechanical loading at the knee joint and slowing down knee osteoarthritis (OA) progression shows great promise [1]. However, the impact of gait modifications such as an increase in foot progression angle (FPA) or lateral trunk lean (LTL) on the ankle and hip is not yet well understood [1]. Thus, the goal of this study is to provide insight on the impact of FPA and LTL on the sagittal and frontal external moments at the ankle and hip in a cohort of healthy participants. We hypothesize that there is an optimum, for which an increase in FPA and/or LTL minimize the knee adduction moment (KAM) without increasing significantly the frontal and sagittal external moments at other surrounding joints during gait.

**Methods** A total of 23 healthy participants (age: 35.6±5.10y.o.; height: 1.73±0.09m; weight: 74.4±12.60kg, 10 women) were equipped with a 6 degrees of freedom marker set on both lower limbs and the pelvis following the International Society of Biomechanics standards [2, 3]. Marker trajectories were recorded at 100Hz using a motion capture system (9 cameras, Vicon motion system, Oxford, UK) and filtered using the predicted mean-squared error adaptive filter (Nexus software, version 2.6). Ground reaction forces were collected at 1000Hz for each lower limb using an instrumented treadmill with two embedded force plates (Bertec, Columbus, OH, USA).

Participants performed 12 walking trials in each condition (i.e., normal gait and with gait modifications [LTL at 5 or 10° and/or FPA at 10, 15 and 20°]). Self-selected comfortable gait speed kept constant throughout the experiment on the treadmill. Gait modifications were delivered through a visual feedback placed on a screen in front of the participant.

The kinematic and kinetic data were time-normalized to 101 samples from 0% (heel strike) to 100% (subsequent toe-off) to represent the stance phase of gait. The flexion and adduction external moments for the dominant lower limb joints were extracted, normalized to body weight and height (%BW·Ht) and averaged over eight gait cycles.

Statistical Parametric Mapping (SPM) was used to statistically compare the whole kinetic stance phase between walking conditions.

**Results and Discussion** A FPA of 10°, 15° and 20° significantly increased the hip sagittal moment in late stance ( $p < 0.001$ ) and the hip frontal moment in early, mid and late stance ( $p < 0.001$ ). An LTL of 5° and 10° significantly decreased the ankle sagittal moment in early stance ( $p <$

0.001) and increased it in mid-stance ( $p < 0.001$ ). It also significantly increased the hip sagittal moment in early and late stance ( $p < 0.001$ ). A combination of FPA and LTL significantly increased the ankle and hip sagittal moment mid-stance ( $p < 0.001$ ) and the hip frontal moment in early and late stance ( $p < 0.001$ ).

The hypothesis that an optimum where the KAM is minimized while the external moments at the ankle and hip are kept constant or decreased was not confirmed. While not all the gait modifications performed by the participants in this study reduced the KAM, they significantly increased the sagittal moment at the ankle and the frontal moment at the hip (Figure 1). Therefore, highlighting the importance of better understanding the impact of a gait modification on the neighboring joints.

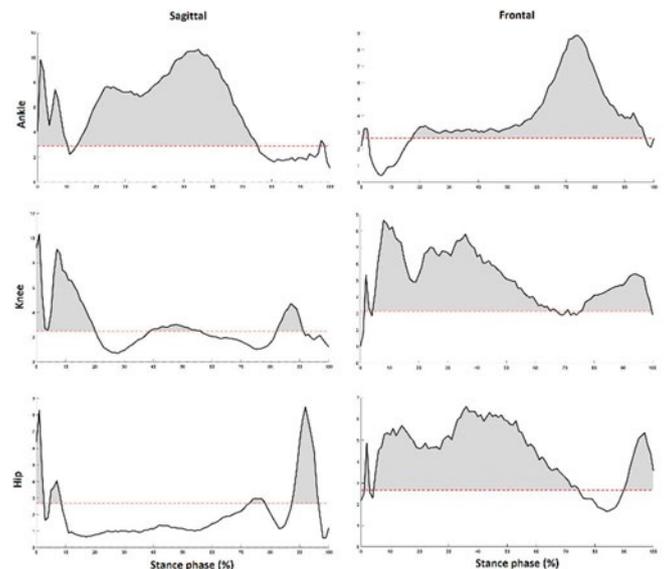

Figure 1: Statistical non-parametric mapping one-way repeated measures ANOVA conducted on the sagittal and frontal external moments at the ankle, knee and hip comparing the 12 walking conditions.

**Conclusions** This study highlights the importance to consider the biomechanical consequences of gait modifications on the ankle and hip before considering a clinical application of gait retraining approaches.

## Spinal Reflexes can Produce a Variety of Bipedal Gaits

<sup>1</sup>Biomechatronics and Human-Machine Control, Delft University of Technology, Delft, The Netherlands

Email: t.geijtenbeek@tudelft.nl

### Summary

Spinal reflexes are known to be important for legged locomotion, but their exact contribution and relation to other spinal circuits are poorly understood. We use predictive simulation from first principles to gain insight in the capabilities of spinal reflexes, using a biologically plausible neuromuscular controller that mimics proprioceptive reflex pathways as described in neuroscientific literature. After optimization, this relative simple control strategy was able to produce stable bipedal walking and running gaits that resemble real-world data, both for planar and 3D models. Our model is expected to have several clinical applications.

### Introduction

The way in which spinal circuitries contribute to human locomotion is a long-standing open research question. Neuromusculoskeletal simulations can be useful for unraveling these underlying mechanisms, as they allow systems-level studies with fine-grained control. However, existing simulation studies typically use a *finite state machine* to select feedback pathways and gains based on the active phase of the gait cycle (swing, stance, etc.) [1]. This is problematic, since there is no direct neurological evidence for such systems, while the hand-crafted states and transitions are domain-specific and do not generalize to other behaviors.

We developed a neuromuscular controller that solely mimics established spinal reflex pathways [2], and optimized its parameters for high-level gait objectives. Surprisingly, our simple network was able to produce a variety of walking and running gaits, and generalized to 3D models.

### Methods

**Neural network.** The input to our spinal control network consists of group Ia afferents from spindle sensors (modeled as a weighted combination of muscle length and velocity), group Ib afferents from Golgi tendon organs (muscle tendon force), and vestibular afferents that represent relative head position and velocity. Ia afferents connect directly to homonymous motoneurons (MN) and Ia inhibitory interneurons (IaIN), which reciprocally inhibit antagonist MNs. Ib afferents connect to Ib interneurons (IbIN), which connect either inhibitory or facilitatory to MN and other IbINs. Renshaw cells (RC) recurrently inhibit MNs and IaINs (see Figure 1, left). Neural excitation is modeled as a rectified weighted ( $k_{ij}$ ) sum of base  $b_i$  and its inputs  $\{X_I, \dots, X_n\}$ :

$$I_i(t) = \max(0, b_i + \sum[k_{ij}X_j(t - \Delta t_{ij})])$$

Neural delays  $\Delta t_{ij}$  are proportional to the length of the pathway, based on experimental data. Two-way connection delays for hip, knee and ankle muscles are 10ms, 20ms and 35ms respectively. One-way vestibular delay is 100ms.

**Optimization.** The crux is in finding the right weights  $k_{ij}$  and biases  $b_i$ . After finding suitable initial values, we optimized the parameters using single shooting in SCONE [3], based on target velocity, energy expenditure and joint load.

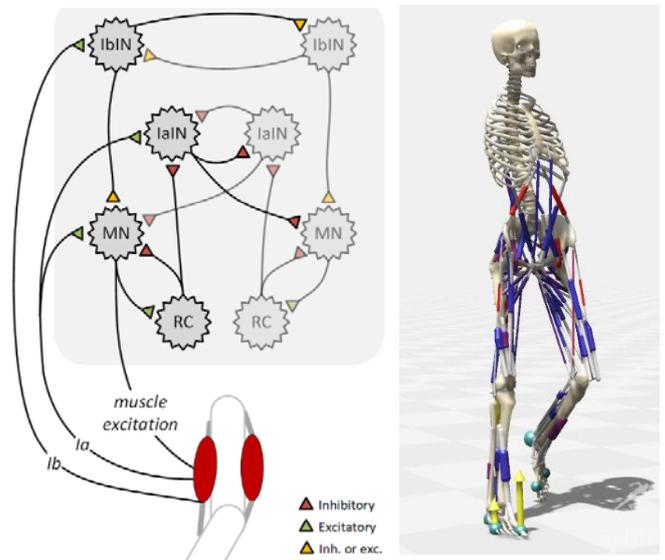

Figure 1: left: spinal control circuits, right: 3D simulation model

### Results and Discussion

After optimization, our neuromuscular controller could produce walking and running gaits that match real-world data. Results were on-par or better than control schemes with much more elaborate control, yet our control strategy generalizes better to running gaits, as well as 3D models. This enables a range of clinical applications and could help in the development of assistive devices. Our controller can potentially be augmented with additional interneurons and afferents to further increase its capabilities.

### Conclusions

Our results demonstrate proprioceptive reflexes to be a remarkably powerful musculoskeletal control primitive. Even though we know other circuits, such as central pattern generators, play an important role in gait, we might need to re-evaluate their relation and dependencies

## Summary

Young adults accommodate the increased energy expenditure, coordination, stance limb and hand discomfort associated with walking aids for non-weightbearing (NWB) ambulation, but it is unknown if adults over 50 years of age have such tolerance. The objective of this study was to determine how walking aid selection affects stance limb plantar force, walking speed, perceived exertion, and device preference in mature adults. Twenty-one participants walked 200 m unaided and NWB with three walking aids: crutches, walker, and wheeled knee walker (WKW). An in-shoe sensor measured plantar force, each walk was timed, perceived exertion (RPE) was reported using the BORG CR-10 scale, and device preference was self-identified. Using a WKW for NWB ambulation reduced stance foot plantar force, maintained unaided walking speed and perceived exertion, and was preferred to crutches or a walker.

## Introduction

Walking aids are prescribed to offload injured lower extremities. Little consideration has been given to the effect of device selection on stance foot loading and exertion in mature adults. Standard walking aids, such as crutches and walkers, cause axillary/hand pain and/or stance limb pain in 68% of users when used for NWB ambulation [1,2]. Understanding how diverse walking aids effect stance limb plantar force, walking speed, step frequency, and RPE will help guide clinical recommendations for patient use.

## Methods

This study was a prospective, randomized cross-over design. Participants were 50 years of age or older and in good overall health with no self-reported conditions that would affect walking. Walking aids were fitted to each participant. Participants choose their stance foot while the other was completely unloaded.

An insole force sensor (LoadSol®, Novel Inc., St. Paul MN) was fitted in the shoe of the stance foot to wirelessly record

plantar force at 100 Hz [3]. Participants then completed four NWB walking trials of 200 m, on a straight 50 m indoor path free of any obstructions with a randomized presentation of walking aid. Time to complete each walking trial was used to calculate self-selected walking speed. Participants stated their RPE and were given two minutes rest after each trial. Participants ranked walking aid preference. Individual steps were identified using a 50 N threshold from plantar force timeseries data. Steps occurring within 30-60 sec of each trial was reported as step frequency. One-way repeated measures ANOVAs were performed for each outcome variable with an a priori  $\alpha = 0.05$  and Bonferroni correction for multiple comparisons.

## Results and Discussion

Average plantar force was at least 75% lower when participants used a WKW when compared to other walking aids (Table 1). Self-selected walking speed did not differ between unaided walking or when using the WKW (Table 1). Step frequency was at least 27% higher in unaided walking but not different amongst walking aids (Table 1). RPE was 72% lower for unaided walking and 50% lower for WKW use when compared to crutches or a walker (Table 1). Participants overwhelmingly preferred the WKW over other walking aids as 20 of 21 participants stated they would use it as opposed to crutches or a walker.

## Conclusions

Reduced plantar forces, maintenance of self-selected walking speed, and a minimal increase to RPE may justify the prescription of the WKW over other walking aids for ambulation.

## Data Collection Settings Influence Total Body Angular Momentum: Effects of Walking Speed and Participant Sex

Jackson Lordall<sup>1</sup>, Alison Oates<sup>1</sup>, Joel Lanovaz<sup>1</sup>  
<sup>1</sup>University of Saskatchewan, Saskatoon, SK, CA  
 E-mail: [Jackson.Lordall@usask.ca](mailto:Jackson.Lordall@usask.ca)

### Summary

The study explored the influence of setting on total body angular momentum during walking at different speeds in male and female young adults. Settings impacted ranges of total body angular momentum while walking at slow and self-selected speeds, with the greatest ranges in a laboratory setting and the smallest ranges in an outdoor setting. There were larger ranges of total body angular momentum at slow speeds and smaller ranges at self-selected and fast speeds. Total body angular momentum in the frontal plane was greater for males, independent of setting and speed condition.

### Introduction

Recent developments in wearable sensor technology allow complex measures of behaviour to be explored outside of a laboratory setting. Total body angular momentum (H) during walking is highly regulated to maintain stability [1-3]. An increase in the range of H suggests reduced control of angular motion about the total body centre of mass [1]. The objective of the current study was to explore how H is affected by setting when walking at different speeds in male and female young adults.

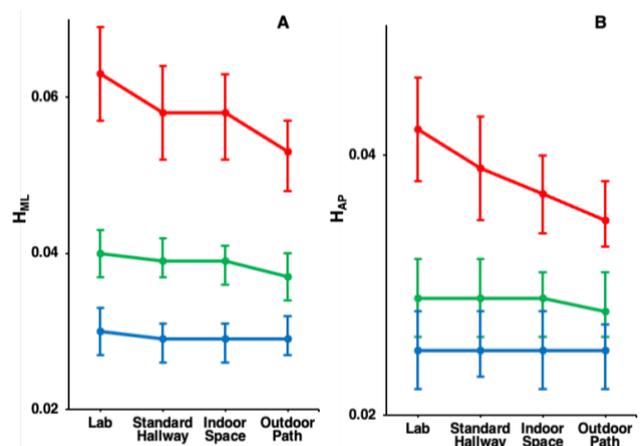

### Methods

Healthy young adults walked in four different settings: laboratory (10m); standard hallway (20m); large indoor open space (20m); and outdoors along an open pathway (20m). Participants walked at three different speeds (slow, self-selected, and fast) following standardized verbal instructions. The order of settings and walking speed conditions were block-randomized. Participants wore an inertial-based full body kinematic data collection system (Xsens Awinda, Culver City, CA, fs=60Hz). The range for anterior-posterior (AP) and medial-lateral (ML) H over a stride ( $H_{AP}$  and  $H_{ML}$ ) were computed with a 16-segment model [4] using data from the middle strides of each trial (~440 strides/participant). H data were normalized to participant height, walking speed, and mass [2,3]. A 4 x 3 x 2 (setting x walking speed x participant sex) RM ANOVA was conducted for each dependent variable. Significant interaction effects were investigated using multiple RM ANOVAs with adjusted pairwise comparisons. Violations of sphericity were corrected using the Greenhouse-Geiser correction and significance was set at  $\alpha = 0.05$ .

### Results and Discussion

A total of 14 males (age = 23±4yrs; height = 181±7cm; mass = 79±1kg) and 15 females (age = 22±4yrs; height = 170±7cm; mass = 70±2kg) participated. Outlier analysis excluded data for one female. Significant setting x speed interactions for  $H_{AP}$  ( $F(3.358, 87.296) = 13.496, p < .001$ ) and  $H_{ML}$  ( $F(2.523, 65.603) = 11.033, p < .001$ ) were found (Figure 1). Values for  $H_{AP}$  and  $H_{ML}$  were significantly larger in the slow condition, regardless of setting. For the self-

selected condition,  $H_{AP}$  was greater in the lab compared to the large indoor area and outdoor setting, and in the hallway compared to outdoors. For the slow condition,  $H_{AP}$  was greater in the lab compared to the hallway, large indoor area, and outdoors; and greater in the hallway and large indoor area compared to outdoors. For the slow condition,  $H_{ML}$  was greater in the lab compared to the large indoor area and outdoors, and in the hallway compared to outdoors. No setting effects were found for the fast condition. There was a significant main effect of sex for  $H_{ML}$  (male =  $.034 \pm .008$ , female =  $.028 \pm .007$ ,  $F(1, 26) = 5.937, p = .022$ ).

**Figure 1:** Mean H data (+/- 95%CI, A:  $H_{ML}$ , B:  $H_{AP}$ ) in different settings at different walking speeds (slow, self-selected, fast).

Data suggest that ranges of H increase as walking speed decreases, aligning with previous research [3]. Settings had a greater influence on H in the slow condition, suggesting that having individuals walk at different speeds can provide insight on mechanisms of locomotor control. Setting influenced AP and ML angular momentum at slow walking speeds and in the AP direction at self-selected speeds, suggesting that H during walking in laboratory settings may not be reflective of H during walking in indoor and outdoor non-laboratory settings.  $H_{ML}$  was greater for males, independent of settings and speed condition, which could be partly due to greater ML trunk ranges of motion in young adult males [5]; however, further exploration is required to explain these sex-based differences.

### Conclusions

H was influenced by settings during walking at slow and self-selected speeds, with larger ranges of H in a laboratory setting.  $H_{ML}$  was greater for males which could be related to sex-based differences in locomotor control [5].

## Adaptations in mechanical limb power and metabolic energy cost after chronic growth-period limb loading

Katugam, K<sup>1</sup>, Johnson, T<sup>1</sup>, Dechene, I<sup>1</sup>, Cox, SM<sup>1,2</sup>, Piazza, SJ<sup>1</sup>, Rubenson, J<sup>1</sup>.

<sup>2</sup>Department of Ecology and Evolutionary Biology, University of California, Irvine

Email: kavya@psu.edu

### Summary

How locomotor mechanics and energetics are affected by long-term alterations to external loading during growth remains largely unknown. Here we test whether a reduction in mechanical limb work contributes to a lower cost of carrying externally-applied limb mass after chronic loading. We find that animals subjected to increased limb loading across their growth period do not adapt their mass-specific mechanical power during limb swing to achieve a lower walking metabolic power.

### Introduction

Humans and other animals adapt to expend the least amount of energy to complete a movement task, both over acute [1,2] and evolutionary timeframes [3]. Whether adaptations in locomotor economy occur in response to altered life history (e.g. environmental fluctuations, or training in humans) remains less clear. Furthermore, the mechanical underpinning to developmental adaptations in locomotor economy have not been well explored.

Here we test the hypothesis that a reduction in mechanical limb work contributes to the lower cost of carrying externally-applied limb mass after chronic loading. Specifically, we hypothesize that (1) limb-loaded animals (LL) locomote with added mass using less mechanical power (Watts/kg) than control (CON) animals, (2) the increase in mechanical power between unweighted and weighted conditions will be smaller for LL animals than CON animals, and finally (3) if mechanical power is a strong determinant of the metabolic plasticity.

### Methods

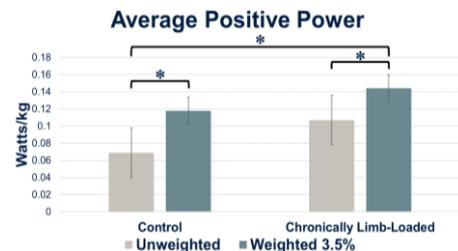

To study the effect of load stimulus on locomotor mechanics and energetics, we applied a mass equal to 3.5% body mass unilaterally to the lower limb of a group of guinea fowl continuously from 1-16 weeks of age (limb-loaded group, LL; n = 6). We raised a second group of birds in the same conditions but with no external limb loading (CON group; n = 6). At 16 weeks of age, we measured the metabolic power of walking on a treadmill at 0.5 m/s in both unilaterally-loaded and non-loaded conditions. The mass-specific power of walking of unilateral limb loading was 26% greater in the CON group compared to the LL group (p = 0.03). The power of walking in the habitual condition (limb loaded in LL; unloaded in CON) was the same for both groups, despite the LL group moving substantially more limb mass.

Birds limb joints and body segments were marked and video recorded (Point Grey, Grasshopper 3, Richmond, BC) walking for 20-second bouts at 0.5 m/s, both loaded and

unloaded. An inverse dynamic formulation was used to compute instantaneous joint power during the swing-phase. Work (joules/kg) was computed per animal per load condition by integrating each instantaneous joint power curve and summing across all joints. Positive mechanical power (watts/kg) was computed by dividing the positive work of the swing phase by the stride time. Five strides were used to generate averages per animal per load condition.

### Results and Discussion

Average total swing-phase positive power for LL animals when compared to CON animals was 55% greater for the unweighted condition (p = 0.15), and 22% greater for the weighted condition (p = 0.067). Average total swing-phase positive power of the habitual conditions for each group (unweighted for CON, 3.5% weighted for LL) were significantly different, with LL habitual power being 109% greater than CON habitual (p = 0.01).

**Figure 1:** Average positive power (watts/kg) computed across 5 swing phases per group per condition.

### Conclusions

Contrary to our hypothesis, animals subjected to increased limb loading across their growth period do not adapt their mass-specific mechanical power during limb swing to achieve a lower metabolic power. Surprisingly, LL animals exhibit comparatively greater mechanical power, despite their lower metabolic power. The lower mechanical power in CON may represent an offloading strategy, but one that incurs a higher metabolic cost. Future directions for this work include analyses of limb mechanics of the contralateral limb, as well as adaptations to muscle architecture/physiology.

## Summary

Using the arms to assist the legs during treadmill walking provides both mechanical and metabolic benefits. Our stepping kinematic analyses reveal little to no changes in walking balance, suggesting that linking the arms and legs may be useful for gait rehabilitation.

## Introduction

Coordinating the active use of the arms with the motion of the legs shows promise for gait rehabilitation [1]. In recent work, we developed a rope-pulley system that links the arms and legs during treadmill walking [2; Fig. 1]. We discovered that the arms harnessed energy from the treadmill via the rope connection which provided an assistive force to the body. This significantly reduced the need for propulsion and the net metabolic power required to walk. However, we observed greater arm swing ranges with rapid transitions and greater collision forces, which may have disrupted the control of balance from step-to-step. Disrupting a patient's ability to maintain balance could increase fear of falling, hinder walking recovery and/or lead to a direct fall. Therefore, understanding if and to what extent balance control was compromised would help determine if this type of assistive approach could feasibly translate to clinical users. As indicators of balance, we quantified step width, step length, step time, and variability. We hypothesized that these indicators of balance control would remain the same when walking normally and when walking with the arm-leg assistive device.

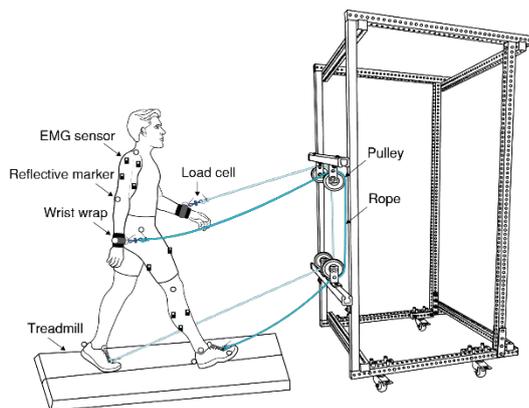

Figure 1: Arm-leg rope pulley system.

## Methods

Eight young, healthy subjects (3 women, 5 men) participated in the study. Subjects performed two randomized walking trials: (1) Normal and (2) Assisted (walking with the arm-leg pulley system) on a treadmill at 1.25 m/s. A twelve-camera motion capture system recorded the 3-D positions of reflective

body markers (100 Hz) during the last 3 min of each 7 min trial. We calculated foot placement from the left and right heel marker positions and used 288 steps as the minimum number of steps for all subjects. We calculated average and standard deviation values for all step parameters. We then normalized step width and length by leg length (% LL), and step time by  $\sqrt{LL/g}$ . Paired sample *t*-test, or the non-parametric Related Samples Wilcoxon Signed Rank test, were performed.

## Results and Discussion

When compared to normal walking, we found that linking the arms and legs during assisted walking revealed no significant differences in step length and step time ( $p > 0.05$ ). However, subjects increased their step width by 31% ( $p = 0.012$ , Fig. 2). Despite adjustments in step width, the variability of step width and step length did not differ between conditions ( $p > 0.05$ ). Step time variability, however, increased by 39% compared to normal walking ( $p = 0.008$ , Fig. 2).

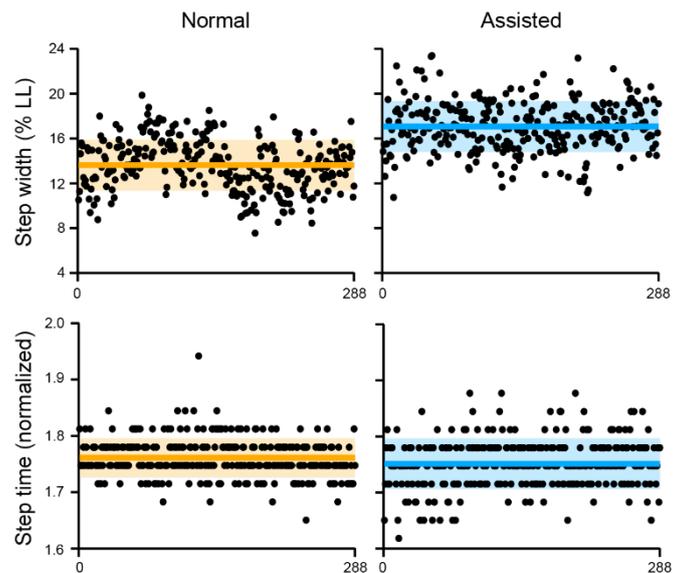

Figure 2: Representative data for both conditions ( $n = 1$ ). Average and SD values shown as solid lines and shaded regions, respectively.

## Conclusions

Our step-to-step kinematic analyses reveal minimal disruptions to balance control when linking the arms and legs during walking. Our future work aims to test this assistive device in patients recovering from a spinal cord injury.

## Lower-limb impact loading and bone stimulus in children during a week-long protocol

Danilo S. Catelli<sup>1</sup>, Sasha Carsen<sup>2</sup> and Mario Lamontagne<sup>1</sup>

<sup>1</sup> Human Movement Biomechanics Laboratory, School of Human Kinetics, University of Ottawa, Canada

<sup>2</sup> Children's Hospital of Eastern Ontario, Ottawa, Canada

Email: danilo.catelli@uottawa.ca

### Summary

Step counting and chart logs are insufficient for quantifying activity types/levels/intensity in the pediatric population. Wireless inertial sensor units were able to differentiate activity intensity based on step impact levels between very and less active children. This study demonstrates the potential of a week-long protocol to self-monitor step intensity activity and to compare lower-limb impact loads, impact symmetry and bone stimulus in active and less-active children.

### Introduction

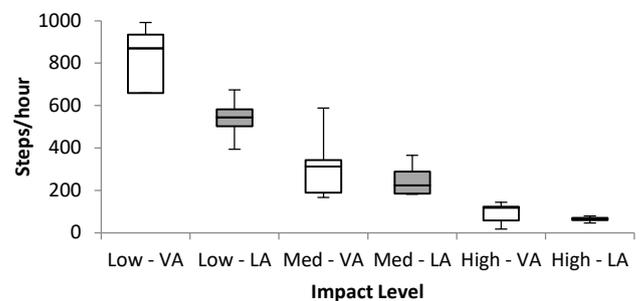

Excessive physical activity and loading of the proximal femoral growth plate are considered determinants to the development of cam-type hip morphology [1,2]. Physical activity monitoring based on step counting, only, gives limited information about activity intensity or limb loading. Impact loading and load symmetry of the lower-limbs provide supplementary metrics about limb overload, that can be used to monitor bone load stimulus [3], and to the development of cam-type hip morphology. Specific physical activities and intensity may be linked to several forms of pediatric injury and development. Step counting and patient/family logs are insufficient for accurately quantifying and comparing activity types/levels/intensity in the pediatric population. The purpose of this study is to (1) demonstrate the potential of a week-long protocol data outcome to self-monitor step intensity activity in children; and to (2) compare lower-limb impact loads, impact symmetry and bone stimulus in active and less-active children.

### Methods

Nine healthy children, five considered very active (VA, over 1,000 steps/h, 1F/4M, 10±3 years old, BMI 14±2 kg/m<sup>2</sup>), and four less-active (LA, less than 1,000 steps/h, 1F/3M, 10±3 years old, BMI 16±4 kg/m<sup>2</sup>) were monitored for 6 to 12h/day for five consecutive days. Two wireless inertial sensor units (IMU) sensors (Blue Trident, IMeasureU, NZ) recorded and computed the participant's physical activity intensity. The sensors were strapped just above the malleolus on both legs. The data were collected and pre-processed using STEP software (IMeasureU, NZ) to obtain the step count and acceleration normalized by gravity (g) of each step, and exported in Matlab (MathWorks, USA) to further analysis. All variables were time-normalized per hour. Step Impact (SI) was classified by low (below 5g), medium (6 to 20g) and high (over 21g) accelerations. Impact load (IL) was calculated based on the sum of each intensity created from every SI. Symmetry indexes were computed for the low, medium and high impact steps. Bone stimulus was computed per day [3].

### Results and Discussion

VA averaged 44% greater number of steps/hour (1235±286) than LA (853±159). Within the total number of steps, the proportional SI for the VA group was 68±11% (823±156 steps/h) in the low, 25±9% (320±168 steps/h) in the medium, and 7±4% (92±53 steps/h) in the high levels; compared to 63±7% (540±115 steps/h), 29±7% (249±86 steps/h) and 7±0% (64±14 steps/h) of the LA, respectively. Symmetry indexes were very similar between the groups for low (VA:1±0%, LA: 2±1%), medium (VA:3±1%, LA: 4±4%) and high impacts (VA:5±4%, LA: 5±1%). VA averaged 58% greater IL per minute (76±30 n<sub>step</sub>\*g/min) than LA (51±13 n<sub>step</sub>\*g/min), but similar bone stimulus per day (VA:260±29, LA:253±11).

**Figure 1:** Average and standard deviation of steps per hour performed by the very active (VA, white) and less active (LA, gray) participants, separated by step impact levels (low, medium and high).

### Conclusions

Wireless inertial sensor technology was able to differentiate activity intensity based on step impact levels between VA and LA children. The VA children performed more steps/hour in all SI levels, and as well as the LA, with very similar proportion among the three impact levels. The higher standard deviation found in medium and high impact levels for the VA group, can be an evidence that not all children within that group reached the step count during sports activities, but perhaps prolonged low-impact daily activities (e.g. walking to the school). The VA children showed 58% higher IL/hour when compared to LA, but the similar bone stimulus outcomes (due to its saturation over time) [3], can be indicative that this type of metric creates a limitation for prolonged data collections. This type of protocol illustrates a more precise indicator of activity level and intensity than step count alone. Likewise, this type of protocol allows minimal or no physical interaction between researchers and volunteers, and can offer an opportunity to collect motion data during periods when people are carrying out physical distancing measures.

# Novel Clamp Protocol Examines Cause-Effect Relations Between Propulsive Force, Walking Speed, and Cost of Transport

<sup>1</sup>Joint Dept. of BME, UNC Chapel Hill and NC State University, USA <sup>2</sup>Division of Physical Therapy, UNC Chapel Hill, USA  
Email: rickypim@live.unc.edu

## Summary

This study sought to examine cause-effect relations between peak propulsive force ( $F_P$ ), walking speed, and metabolic cost of transport in young adults. In different experimental trials, we clamped walking speed or peak  $F_P$  using targeted biofeedback and a self-pace treadmill controller. We show in part that walking with larger/smaller  $F_P$  yields faster/slower walking speeds. These cause-effect relations may inform the time course of gait changes due to age and disease and build confidence that interventions designed to increase peak  $F_P$  may translate to improved walking speed.

## Introduction

Walking speed serves as a simple surrogate for human health status and ambulatory function. The selection of walking speed in healthy young adults is often attributed to minimizing the metabolic cost of transport (CoT). However, declines in walking speed due to age or disease are frequently accompanied by smaller propulsive forces ( $F_P$ ) during push-off. Thus,  $F_P$  is considered a biomechanical determinant of walking speed. However, no study to our knowledge has established empirical cause-and-effect relations between  $F_P$ , walking speed, and CoT, even in healthy young adults. Our purpose was to: (1) investigate if  $F_P$  governs the selection of walking speed using real-time targeted biofeedback and self-pacing treadmill control, and (2) quantify how metabolic energy cost shapes the relation between  $F_P$  and walking speed. We ultimately aim to better understand the time course of gait changes due to age or disease and to inform targeted interventions.

## Methods

Ten young unimpaired adults have thus far participated (5F/5M; age:  $25.2 \pm 5.8$  years, typical overground walking speed:  $1.40 \pm 0.10$  m/s, typical  $F_P$ :  $21.5 \pm 2.4$  %BW). We first determined participants' typical overground walking speed (4 passes of 30 m). Next, participants completed five 5-minute trials on a dual-belt instrumented treadmill at a fixed speed.

We recorded participants' average peak  $F_P$  at their typical speed as well as at  $\pm 10\%$  and  $\pm 20\%$  of that speed in randomized order (speed clamp). Participants then walked for 5 minutes each on the same treadmill in a self-paced mode while responding to a visual biofeedback paradigm to target their average peak  $F_P$  from each of the fixed-speed trials ( $F_P$  clamp). The self-paced mode adjusted speed in real-time based on subjects' anterior-posterior position on the treadmill. We measured rates of oxygen consumption and carbon dioxide production, which were averaged over the final 2 minutes of each trial to calculate net metabolic CoT using standard procedures. We averaged speed and  $F_P$  over the same time period. A two-way repeated measures ANOVA analyzed differences in walking speed,  $F_P$ , and CoT between clamp types (fixed-speed vs.  $F_P$  targeting) and condition intensity.

## Results and Discussion

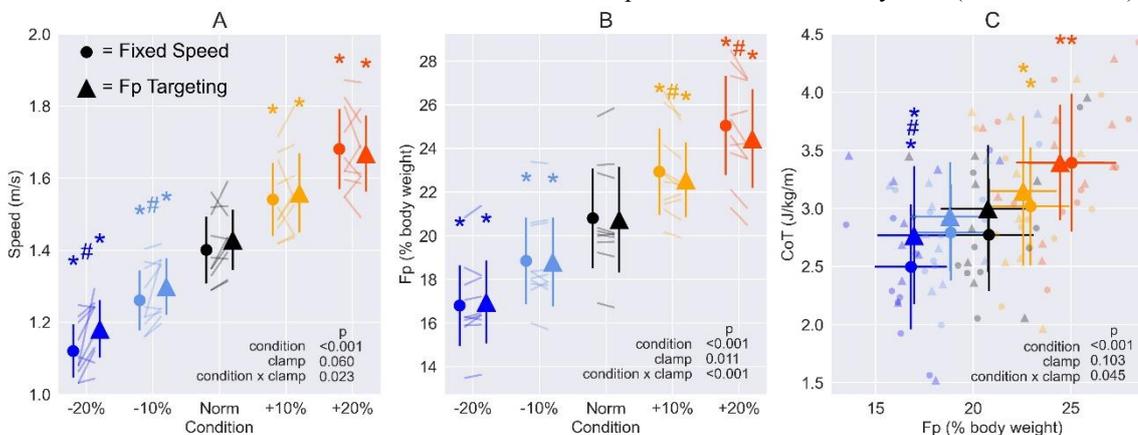

Subjects increased and decreased  $F_P$  and CoT in response to faster and slower walking speed and increased and decreased walking speed and CoT in response to larger and smaller  $F_P$ , respectively ( $p$ -values  $< 0.05$ , Figure 1). Significant condition  $\times$  clamp interaction effects revealed that walking speed and CoT were less sensitive to the  $F_P$  clamp versus the speed clamp when decreasing condition intensity. In other words, participants selected faster speeds at a higher CoT for those conditions despite identical  $F_P$ . Additionally,  $F_P$  was less sensitive to the  $F_P$  clamp when increasing condition intensity; we were surprised to find that participants walked at the same speed and with the same CoT despite lower  $F_P$ .

## Conclusions

We provide evidence that walking with larger/smaller  $F_P$  yields faster/slower walking speeds paralleled by changes in CoT in young adults. However, these cause-effect relations are more complex than previously appreciated and are not always governed by minimizing metabolic cost of transport.

### Summary

The human foot is stiff enough to withstand ground forces and not bend severely when walking and running. The foot's medial longitudinal arch and transverse tarsal arch are key contributors to this bending stiffness. The transverse arch is hypothesized to stiffen the foot by coupling sagittal plane midfoot bending with the stretching of intermetatarsal tissues. This cross-axis coupling hypothesis has so far only been tested in cadaveric feet. However, active muscle contraction is known to influence the stiffness contribution of the longitudinal arch, and may similarly affect transverse arch function. We tested this hypothesis *in vivo* by increasing intermetatarsal stiffness at the forefoot and measured the resulting change in the foot's bending stiffness in standing human volunteers. We find that the cross-coupling hypothesis carries over *in vivo*, and suggest strategies for foot stiffness augmentation in clinical and athletic settings.

### Introduction

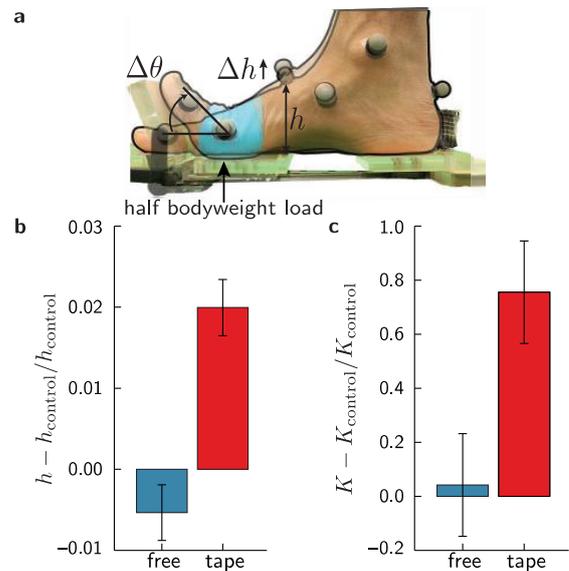

The cross-axis coupling hypothesis arising from the foot's transverse tarsal arch was recently tested in static loading experiments on cadaveric feet [1]. Surgically incising the intermetatarsal tissues led to a significant loss of foot bending stiffness [1], suggesting a coupling between midfoot bending stiffness in the sagittal plane and transverse intermetatarsal stiffness. While cadaveric studies identify the contribution of passive tissues to the baseline stiffness of the foot, muscle activity is known to modulate around it [2]. Such modulation is well understood in the context of the longitudinal arch, but muscles with insertions in the transverse arch could similarly influence its stiffness contribution. This motivates an *in vivo* test of the cross-axis coupling hypothesis. We wrapped elastic tape around the forefoot to increase intermetatarsal stiffness and measured the resulting change in foot stiffness to assess the extent of the cross-axis coupling. If the hypothesis holds *in vivo*, we expect foot stiffness to increase upon taping.

### Methods

We used two methods to measure the change in foot stiffness. First, the height of the midfoot above ground  $h$  when supporting half bodyweight on the forefoot provided an indirect midfoot stiffness measure. Second, we used the windlass mechanism of the foot to deliver a perturbative midfoot torque by externally dorsiflexing the toes by  $\Delta\theta$  and measured the change in midfoot height  $\Delta h$ . The ratio  $\Delta h/\Delta\theta$  is inversely proportional to the midfoot stiffness  $K$ . All measurements were made in standing human subjects under three conditions (Figure 1a): (i) *free* - with no tape, (ii) *tape* - with the forefoot tightly wrapped, and (iii) *control* - with loosely wrapped tape. Subjects received live feedback to maintain consistent half bodyweight load under the ball of the foot. Free and taped stiffness measures were normalized by the control condition, and compared using a one-way ANOVA and pairwise comparisons between conditions.

### Results and Discussion

Forefoot taping led to an increase in both measures of foot stiffness. Midfoot height with the forefoot tape was significantly greater than the control condition (mean  $\pm$  std. error =  $2.0\% \pm 0.4\%$ ,  $p < 0.0001$ ), but not in the free condition ( $-0.5\% \pm 0.3$ ,  $p = 0.12$ ) (Figure 1b). The stiffness  $K$  found using the perturbative torque was significantly greater in the taped condition than the control ( $76\% \pm 19\%$ ,  $p = 0.0002$ ), but not in the free condition ( $4\% \pm 19\%$ ,  $p = 0.82$ ) (Figure 1c). These results show that cross-axis coupling between midfoot stiffness and transverse intermetatarsal stiffness is present *in vivo*. Therefore, the muscle activity involved in forefoot bodyweight support does not disrupt this coupling. The finding and the methodology to experimentally alter midfoot stiffness paves the way for future studies to investigate how the transverse tarsal arch and the cross-axis coupling it introduces could influence dynamical foot stiffness modulation during locomotion. Our non-invasive foot taping protocol may find application in the management of disorders that cause a loss of foot stiffness, and in the augmentation of foot stiffness in athletic settings.

**Figure 1: Foot stiffness change because of forefoot taping.** a. A foot in the taped condition, showing the measured midfoot height  $h$ , and the change in height  $\Delta h$  upon dorsiflexion of the toes by  $\Delta\theta$ . Bar plots of b, the midfoot height and c, the stiffness estimated using the perturbative midfoot load in the free and taped conditions relative to control. Whiskers show standard error of the mean (n=7).

### Conclusions

Cross-axis coupling due to the transverse arch significantly contributes to *in vivo* foot stiffness.

## Movement decreases muscle and tendon stiffness compared to torque and angle matched isometric conditions

### Summary

While muscle and tendon govern ankle impedance, it remains unknown how the muscle and tendon contribute to the decrease in ankle impedance during movement compared to postural conditions. This is largely due to a lack of *in vivo* measurement techniques for quantifying muscle and tendon impedance during movement. We recently developed a novel measurement technique that simultaneously quantifies muscle, tendon, and ankle impedance. This study uses our technique to determine how muscle and tendon govern ankle impedance between posture and movement. We observed that the decrease in ankle impedance during movement is mainly driven by decreased muscle impedance with a small, unexpected decrease in tendon impedance. Unlike postural conditions where ankle impedance is primarily governed by the tendon, during movement, muscle and tendon impedance were similar. These data provide the first *in vivo* measurements on how muscle and tendon govern ankle impedance between posture and movement.

### Introduction

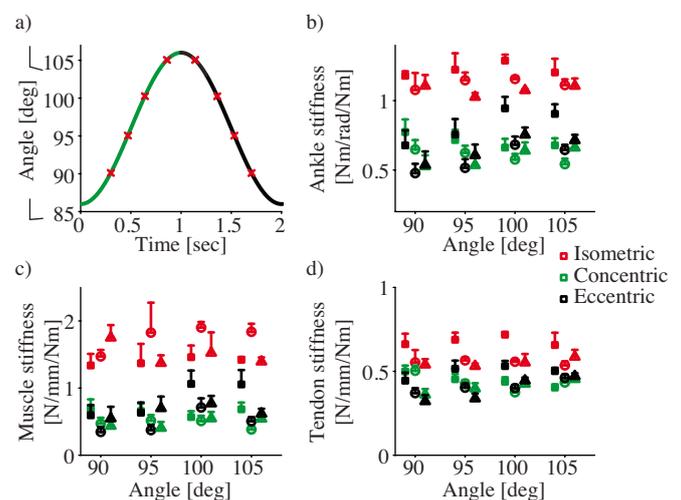

Ankle impedance during movement is decreased compared to postural conditions [1]. However, it is unknown how changes in the muscle or tendon, the structures that govern ankle impedance, drive this decrease. This gap is largely due to a lack of *in vivo* measurement techniques to quantify muscle and tendon impedance during movement. We recently developed a novel *in vivo* measurement technique using ultrasound to address this overall gap [2]. Using this technique, this ongoing study aims to determine how the contribution from the muscle and tendon to ankle impedance differs between posture and movement. Previous *in situ* muscle impedance measurements suggest that muscle impedance varies not only between posture and movement but also within a movement between concentric and eccentric contractions [3]. In contrast, tendon impedance scales with force and, to our knowledge, does not vary between force-matched postural and movement conditions. Thus, we hypothesize that the decrease in ankle impedance during movement is due to decreased muscle impedance.

### Methods

Three young adults were seated with their right foot rigidly secured to a rotary motor and 6-degree-of-freedom load cell. The motor controlled the position of the ankle while subjects produced voluntary plantarflexion torque at 15% of their maximum. The motor moved the subject's ankle through a 20-degree sinusoidal motion resulting in periods of eccentric and concentric contractions. Four isometric conditions were also tested (Figure 1a) within the same range as the imposed movements. Small stochastic perturbations were superimposed on the large sinusoidal movement and isometric conditions to quantify ankle impedance [2]. Muscle and tendon displacement was measured using B-mode ultrasound to track the medial gastrocnemius muscle-tendon junction. We estimated ankle, muscle, and tendon impedance from the collected data [2]. Here we present the stiffness component of these impedances.

### Results and Discussion

Ankle and muscle stiffness decreased by an average of 42% and 62%, respectively, during movement relative to isometric conditions ( $p < 0.001$  for both; Figure 1b & c). More surprisingly, we also found that tendon stiffness decreased by an average of 27% during movement ( $p < 0.001$ ; Figure 1d). No difference was observed between concentric and eccentric contractions for ankle, muscle, or tendon stiffness. The muscle was 2.6x stiffer than the tendon during postural conditions but only 1.4x stiffer during movement. Since the muscle and tendon are connected in series, the stiffness of the ankle is dominated by the most compliant component. These results indicate that the tendon dominated ankle mechanics in the tested isometric conditions, but muscle and tendon contributed more evenly during movement.

**Figure 1:** (a) During the movement condition, ankle angle was varied to produce concentric (green) and eccentric (black) contractions. Isometric contractions at matched angles were performed (red x's). Comparisons between ankle (b), muscle (c), and tendon (d) stiffness during the concentric, eccentric, and isometric contractions. Different symbols represent different subjects, and subjects are offset for ease of viewing.

### Conclusions

Applying our novel technique, we demonstrate that the contribution from the muscle and tendon to ankle impedance differs between posture and movement. Prior to this work, muscle and tendon impedance could only be estimated. These data provide the first *in vivo* reference on how muscle and tendon govern ankle impedance during movement.

### Summary

The patella extends the moment arm of the knee extensor mechanism, but it is less clear how its motion contributes to variation in the moment arm during stance. In this study, we used a lower-limb musculoskeletal model with a twelve degrees-of-freedom knee to simulate patella kinematics in walking and running. We compared variation in the moment arm to the variation in the moment caused by the knee extensors. We hypothesized that the knee extensor moment would increase with moment arm length. However, we found that the knee extensor moment increased with a decrease in moment arm in both walking and running. Future research will investigate muscle force contributions to knee velocity with variation in moment arm.

### Introduction

The patella contributes to knee extension by increasing the knee extension moment arm and altering its mechanical contribution throughout the gait cycle [1]. The moment caused by the knee extensors can be calculated by multiplying the force from knee extensor muscles acting on the tibia with the knee extensor moment arm. Reducing the mechanical advantage by decreasing the extension moment arm may reduce the muscle shortening requirement during concentric contraction and may benefit joint velocity [2]. Moment arm advantages have been studied at the ankle [2], but there remains a lack of understanding of moment arm contributions at the knee in walking and running, due to the difficulty of measuring *in vivo* motion of the patella paired with muscle and ligament forces.

Musculoskeletal modelling is an approach that can be used to investigate *in vivo* tibiofemoral and patellofemoral mechanics [3]. Optimization algorithms are used to solve for secondary kinematics of the tibiofemoral joint and six degrees-of-freedom patellofemoral joint kinematics, as well as muscle and ligament forces. The objective of this study was to determine relationship of knee extensor moment production to moment arm length in walking and running. We hypothesized that the knee extensor moment would increase with an increase in moment arm.

### Methods

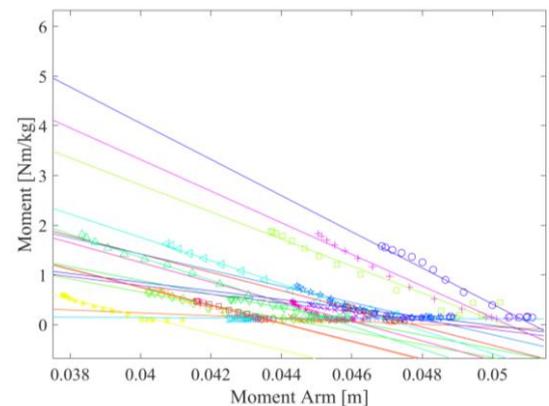

Mean bone and cartilage geometry was calculated from a previously collected dataset of fourteen healthy knee MRIs [4]. Optical motion capture and GRF data were recorded for walking and running trials from ten participants. We incorporated kinematics and mean geometries into a validated, lower-limb musculoskeletal model with muscles, ligaments, and a twelve degrees-of-freedom knee joint. We sectioned gait depending on if the knee was flexing or extending and calculated the rotation axis of the knee as the change in pose of the tibia from the first frame of each section to the last frame of the same section. Knee extension

moment arms were calculated using a geometric method during stance [5].

We represented the knee extensor moment by the product of patellar ligament force normalised to body weight and moment arm. F-tests determined if the correlation between moment and moment arm length were non-zero with an alpha of 0.05 for each trial and section of stance. We performed linear regressions of each trial and section to determine the trend of the relationships. T-tests determined if the means of the slopes were non-zero.

### Results and Discussion

Correlations between moment and moment arm length were all non-zero ( $p < 0.004$ ) (Figure 1). The slopes of the sections and trials were non-zero ( $p < 0.001$ ). There average slope for walking (-103.3 N/kg) and running (-298.8 N/kg) trials were both negative. These trends represent a decrease in moment arm with an increase in knee extensor moment in both walking and running. Higher forces in running allowed the peak running moment to be 112% larger than the peak walking moment walking and running had similar ranges of moment arm.

**Figure 1:** Linear regressions of correlations between moment and moment arm for the first section of stance in walking and running.

### Conclusions

Contrary to our hypothesis, the knee extensor moment increased with a decrease in moment arm in both walking and running. Further research is required to determine how the increased force in running relates to muscle force-velocity properties and its contribution to knee extension velocity, though moment arms were similar in walking and running during stance.

## Simulation-Based Exploration of the Anterior Drawer Test in Juvenile Patient Populations

Alexandria Mallinos<sup>1</sup>, Brian Davis, Ph.D<sup>1</sup>, Kerwyn Jones, MD<sup>2</sup>

<sup>1</sup>Cleveland State University, Cleveland, OH, USA, <sup>2</sup>Akron Children's Hospital, Akron, OH, USA

Email: a.mallinos@viks.csuohio.edu

### Summary

Every year, there will be more than 200,000 ACL tears in the US alone. In this study, the goal was to develop baseline knee models that accurately predict anterior tibial displacement when undergoing an anterior drawer test and provide a starting point for further knee model investigations. The models were able to predict tibial displacement measurements that are statistically similar to those obtained in clinical settings.

### Introduction

Knee arthrometers have been used to evaluate the structural integrity of the anterior cruciate ligament (ACL). The purpose of this study was to establish baseline specimen-specific computational juvenile knee models that accurately predict the anterior drawer test (ADT). This study utilized data on normal ACL laxity measurements obtained using knee arthrometers [1-3]. These data were used to compare the anterior translation of the finite element representations (FER) of the knee joints under anterior loads of 67, 89, and 133 N.

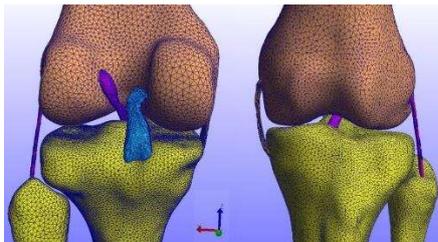

Figure 1: Sagittal plane view of the finite element model.

### Methods

A total of 22 CT images of juvenile knees were utilized. The patients selected had no ACL pathologies and no bony deformations (ages: 9-18, males: n=16, females: n=6). 3D Slicer was used to convert the CT images into a three-dimensional representation of the bony anatomy. The bony anatomy was uploaded into FEBio to construct each tibiofemoral joint (Fig.1). The bones were defined as rigid bodies while the ligaments were modeled as incompressible transversely isotropic Mooney-Rivlin. The material properties of each bone and ligament were obtained from the Open Knee User's Guide and the ligament stl files were utilized for each model [4]. To replicate the ADT, the femur was fixed in all degrees of freedom while the tibia-fibula was only allowed anterior-posterior translation (y-axis). An anteriorly directed force was applied to the tibia-fibula at 67, 89, and 133 N.

### Results and Discussion

The FER of the juvenile knees provides a realistic depiction of the ADT data obtained using knee arthrometers. The model predicted tibial displacement fell within the range of the experimental data (Fig. 2). The computer simulated models exhibited similar behavior to the experimental data by

increasing in anterior tibial displacement with each loading force level: 4.4 mm, 5.4 mm, and 7.3 mm. A two-sample t-test ( $\alpha=0.05$ ) was used to analyze the differences between the experimental and predicted data for each force level. The calculated p-values (0.27, 0.49, 0.15) were all greater than  $\alpha$  which concludes that there are no significant differences between the experimental and simulated ADT.

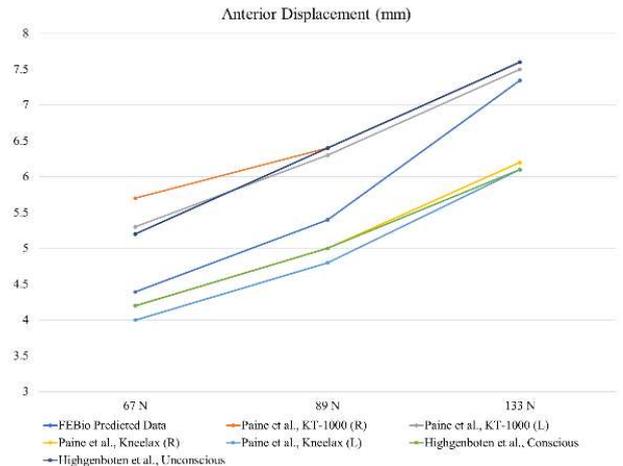

Figure 2: Graphical representation of the FEBio predicted anterior displacement versus the experimental data published in the literature using a knee arthrometer.

Simulations run at 67 and 89 N fell within the midrange of the clinical studies. This is a novel and important advancement because it provides a solid foundation at which to assess the in vivo biomechanics of the knee and its ligaments. At 133 N, the mean ADT is skewed towards the higher end of the experimental range. A possible factor as to why this occurs at higher forces can be due to natural physiological barriers such as the muscles and skin that prevent excessive anterior tibial translation and are not represented in the models.

### Conclusions

Despite the limitations of this study, the FER were able to accurately simulate the ADT, predicting tibial displacement that is representative of the clinical data available in the literature.

## Lower Extremity Biomechanical Demands of a Bend and Pick-Up Task in Healthy, Older Adults

Email: jaredmoo@usc.edu

### Summary

In order to improve/maintain health-related quality of life in older adults, it is important develop adherent exercise programs and examine the physical demands they engender. Golf is a multimodal activity that provides multiple fitness benefits for older adults [1]. An activity commonly overlooked is the bending task to tee or mark a ball (MTB). The purpose of this pilot work was to investigate the lower extremity (LE) demands of this task and compare the results to common exercises for older adults, such as bodyweight squatting. Our results demonstrated similar or greater LE demands during the MTB task compared to bodyweight squatting.

### Introduction

Aging is associated with decreased muscle mass and a corresponding drop in muscular strength, which decreases functional capacity and increases fall risk [2]. Golf is a multimodal exercise activity that encompasses multiple aspects of fitness including: aerobic training through walking, high-velocity swings, squatting, balance and cognitive challenges, and social interaction. One aspect of golf that is commonly overlooked is the repeated squatting maneuver to tee and pick up a ball. The purpose of this pilot study was to quantify the sagittal plane lower extremity mechanical demands of this task and to compare these demands to those associated with squatting activities in older adults.

### Methods

Fifteen healthy, right-handed, older adults whom did not currently golf were enrolled in a 10-wk, 2x/wk, golf program with fitness testing before and after the intervention. During follow-up testing, participants were asked to perform a ‘mark the ball’ (MTB) task, during which they placed a marker behind a ball before picking the ball up to return to an upright position. Lower extremity sagittal-plane internal net joint moments were calculated from kinematic and kinetic data using a lower extremity marker-based 11-camera Qualisys motion capture system (Qualisys, Sweden) and Visual3D software (C-motion Inc, USA). The participants stood with each foot on a forceplate (AMTI, USA) while they completed 3 trials of the MTB task. Peak moments were averaged across trials for the right and left limbs at the ankle, knee, and hip. Support moments were also calculated [3]. Differences between moments in the left and right limbs were evaluated using Hedge’s g effect sizes [4].

### Results and Discussion

Participants completed 283/300 (94%) sessions and there were no adverse events (AE’s) during the program. Table 1 displays average peak net extensor/plantarflexor moments presented as mean±SD with Hedge’s g effect sizes for differences between limbs. There was a smaller net joint moment about the left knee with a moderate effect size that coincided with greater left hip

loading with a large effect size during the MTB task. There was no difference in the support-moment between limbs. All participants were right-handed which may have led to higher demands on the left hip while marking the ball with their right hand.

Moment (Nm/kg)	Left	Right	Hedge’s g
Ankle	0.61±0.10	0.60±0.09	0.10
Knee	0.47±0.26	0.67±0.43	0.55
Hip	1.28±0.17	0.96±0.29	1.30
Support	2.27±0.38	2.13±0.52	0.30

**Table 1:** Average peak net extensor/plantarflexor moments during MTB task and Hedges g effects sizes for differences between limbs.

The MTB task mimics a squatting task and is done repeatedly over the course of play. Our participants performed this task an average of 24 times during 9 holes of golf. Comparing the lower extremity joint demands of this task to squatting in similar age healthy older adults, the MTB task creates similar or greater joint moments compared to bodyweight squatting and chair squatting [5]. Thus, MTB appears to provide a sufficient demand that could improve lower extremity strength. These types of demands should be investigated alongside more common analyses of the golf swing and traditional exercises. The differences shown in knee and hip loading between limbs should be acknowledged and considered when determining exercises appropriate for individuals with knee or hip osteoarthritis, which is an increasing risk in older adults. The results from this study show that the goal of the task being performed should be considered as the demand may shift between joints depending on that goal.

### Conclusions

This work is important in helping to determine safe and adherent exercise programs that also supply the necessary demands to influence strength improvements in older adults. Older adults also have other needs in an exercise program, such as social interaction, that can help to promote adherence. Golf is a multimodal exercise activity that encompasses multiple aspects of fitness that includes an MTB activity that mimics the loading of bodyweight squats in older adults shown here. This activity is performed multiple times throughout golf play and is interspersed within other physically demanding activities such as swings, balance control, and walking over uneven terrain.

## Validation of a non-invasive intra-abdominal pressure measurement tool in living and cadaveric specimen

N. Jacobson<sup>1</sup>, M. Driscoll<sup>1</sup>

<sup>1</sup>McGill University, Montreal, Canada

Email: [mark.driscoll@mcgill.ca](mailto:mark.driscoll@mcgill.ca)

### Summary

Prolonged increase in intra-abdominal pressure (IAP) is a life-threatening condition occurring in between 20 and 50% of intensive care unit patients. IAP is typically measured using urinary bladder pressure (UBP): an invasive, disputed method of measurement. Given the dangers associated with increased IAP, and the invasive nature of popularized measurement methods, it is the effort of this research to validate a novel, non-invasive tool for IAP measurement. In a cohort of 14 participants, IAP was measured with the novel device and compared to published ideal values at four body positions: supine, inclined, sitting and standing. Pearson correlation ( $r$ ) between tested and literature based ideal IAPs revealed high correlation between results with  $r$  of 0.982 ( $p < 0.0001$ ). Further, direct IAP measurements via UBP were compared in 4 cadavers to the novel device. These tests presented  $r$  values of 0.129 ( $n = 21$ ). Positive results indicate the need for further research on the novel device, particularly in larger and wide-spread samples.

### Introduction

Intra-abdominal pressure (IAP) is the pressure contained in the abdominal compartment [1]. High IAP is a life-threatening condition, typically diagnosed in intensive care units by urinary bladder pressure (UBP) measurement [2, 3]. Previous research has indicated the feasibility of a novel, non-invasive suction technique for measuring IAP [4]. Therefore, it is the objective of this study to validate said novel system for IAP measurement against existing popularized methods, namely, UBP.

### Methods

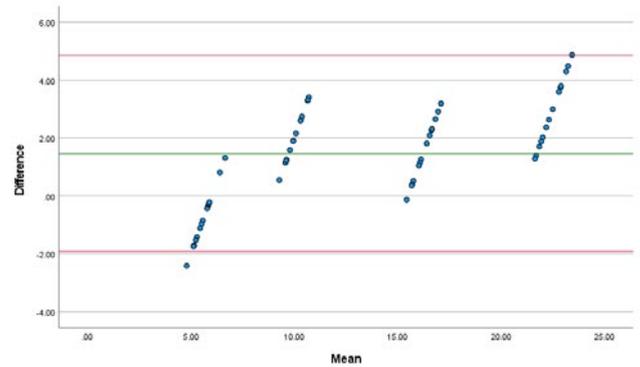

The IAP of four fresh cadavers (1 male, 3 female) was measured using the popularized method of UBP, as suggested by the World Society on Abdominal Compartment Syndrome (WSACS), alongside the novel device [2]. Measurements were taken with cadavers in supine and inclined positions, 5 cm subxiphoid. The correlation between the two measurement tools was evaluated with Pearson's correlation ( $r$ ), where  $r$  greater than 0.7 is deemed "high" correlation [5].

In addition, 14 living participants (7 male, 7 female) were tested with the novel device, 5 cm subxiphoid, in supine, inclined, sitting, and standing positions. Participants were tested without abdominal activation and at end-exhalation. Measured IAPs were compared to "ideal" IAP values, as suggested in literature.

### Results and Discussion

Pearson correlation between ideal IAP values from literature and living participants was 0.982 ( $p < 0.0001$ ).

Results are illustrated by the given Bland-Altman plot given in Figure 1.

**Figure 1:** Bland-Altman plot comparing "ideal" data versus the novel device. Clusters indicate (from left to right) supine, inclined, sitting and standing positions.

Pearson correlation between UBP and the novel device on cadaveric specimen was 0.129 ( $p < 0.6$ ) ( $n = 21$ ), indicating negligible correlation, though with insufficient data. The average (standard deviation) absolute error between measured and actual results was 3.1 (2.8) mmHg.

### Conclusions

A novel, non-invasive IAP measurement system was evaluated against "ideal" literature values, as well as benchmark cadaveric UBP measurements. Results demonstrated high correlation between measurement sets in living participants, and negligible correlation in cadaveric specimen. Negligible results may be attributed to uncertainty in the experimental setup of control measurements. Therefore, though promising in its results, it is recommended to consider a wider sample of varying BMI and baseline IAP in future research.

# Development of a Novel Tibiofemoral Dynamic Unloading Knee Brace with Air Bladder Insert and Wearable Control Box

Email: rzgao@uwaterloo.ca

## Summary

A proof of concept dynamic unloading brace for managing medial tibiofemoral osteoarthritis was tested against force-sensitive resistors to verify its unloading pressure applied to the lateral knee. The dynamic knee brace was created by combining an off-the-shelf varus/valgus brace (Medi Soft OA light) with a soft air bladder insert powered by a wearable control box. Preliminary testing proved that two 60-gram pumps fluidically connected in parallel achieved clinically relevant unloading pressures within 250 ms of inflation, allowing for dynamic unloading during every step.

## Introduction

Commercially available unloading braces for managing medial tibiofemoral osteoarthritis (OA) are all passive. The biggest issue with unloader knee braces is poor adherence due to discomfort and bulkiness [1,2]. However, discomfort due to constant unloading force remains problematic. Thus, we added dynamic unloading capabilities to a brace. The novelty of this technology involves applying an unloading pressure during only the stance phase of gait and removing this pressure during the swing phase. A soft air bladder powered by a wearable control box replaces the knee brace's original cushion at the hinge. The soft air bladder's inflation and deflation are triggered by a feedback control using a pair of inertial measurement units. This proof of concept study focused on observing the unloading pressures experienced on the medial knee during activation of the soft air bladder.

## Methods

A prototype of the unloader brace was fitted on the right knee of a healthy male (age 25 years, Body Mass Index 23.7). The control box's internal components were placed on a table (Figure 1(a)). A Tekscan force-sensitive resistor array sensor was placed between the skin-contact fabric and soft air bladder on the lateral knee. Pressure maps indicating the location and magnitude were captured during standing at the following time points: the brace donned passively, 250 ms after inflation and 15 ms after deflation of the soft air bladder.

## Results and Discussion

In the passive condition (i.e. when wearing the inactivated brace), the pressure observed on the medial knee was 374 mbar. In the inflated condition, the pressure observed was 436 mbar. In the deflated condition, the pressure observed was 218 mbar (Figure 1(b)).

15 ms of deflation was chosen for dynamic unloading during every step to not over-deflate and still achieve clinically relevant unloading pressure during the stance phase. Lastly, the minimum unloading pressure level should be tolerable by the user during the swing phase.

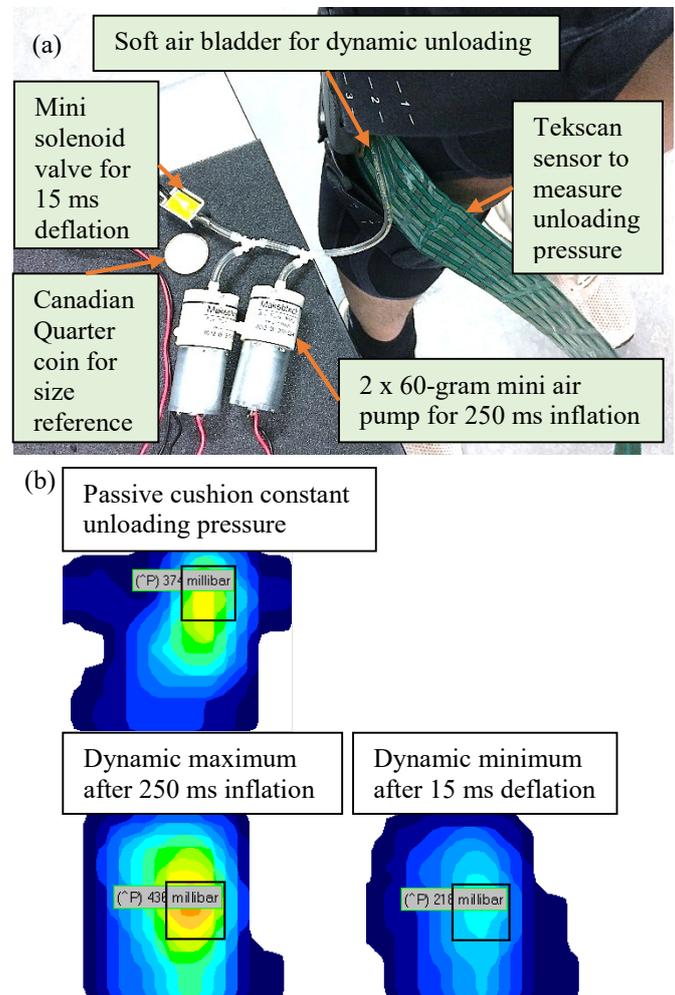

Figure 1: (a) Testing setup. (b) Testing results.

## Conclusions

This proof of concept showed that a dynamic knee brace with clinically relevant unloading pressure and timing during each step with a truly wearable control box is possible. Future work will involve incorporating IMUs for feedback control of the timing for actuating the unloading pressures.

<sup>3</sup>Department of Orthopaedic Surgery, Beth Israel Deaconess Medical Center, Boston, MA

Email: pmwill@bu.edu

## Summary

We describe a novel method of biomechanical testing of proximal humerus locking plate fixation using a previously validated shoulder testing system mimicking passive shoulder abduction. We report normative glenohumeral joint reactive forces and compare interfragmentary gap displacement between bicortical and unicortical locking screw fixation during cyclic abduction loading.

## Introduction

Proximal humerus fractures present a challenge to treating orthopedic surgeons due to osteopenia, fracture comminution, and inadequate fixation. Fractures commonly fail in varus malalignment with head screw cut out. [1] Previous biomechanical cadaveric studies have evaluated locking plate fixation through axial and torsional loading of the proximal humerus. [2] The goal of this study was to use a novel biomechanical shoulder testing system mimicking physiologic passive glenohumeral abduction to test strength of proximal humerus fixation.

## Methods

### Specimen Preparation and Fixation

Four fresh-frozen cadaveric shoulders were used. A dectopectoral approach exposed the proximal humerus. Proximal humerus locking plates were used with five 3.5 mm locking screws in the humeral head and three 3.5mm non-locking cortical shaft screws. For condition one, screws 2 mm short of the subchondral bone were placed, achieving unicortical purchase only. For condition two, screws were placed minimally penetrating through the subchondral bone, achieving bicortical fixation. Fluoroscopy confirmed screw placement. A surgical neck osteotomy with a 5 mm gap was made. The scapula and humerus were potted in 2-part epoxy (Smooth-Cast 300q and PMG Smooth-on Inc., Macungie, PA) and loaded onto the biomechanical testing device.

### Biomechanical Device and Testing

Specimens were tested using a previously validated 7 degree of freedom cadaveric shoulder testing system. [3] Two hundred abduction cycles, from 45 to 90° of glenohumeral abduction per condition were passively applied per specimen. Interfragmentary gap motion was measured using the position of two electromagnetic sensors (240Hz, Liberty, Polhemus, Rochester, VT) rigidly affixed to the proximal humerus and humeral shaft. The maximum gap displacement during testing was taken as the maximum change in position between sensors. A 6DoF load cell (Mini58 IP65/IP68, ATI, Apex, NC) beneath the scapula was used to measure joint reactive force during motion. Statistical analysis was performed in MATLAB.

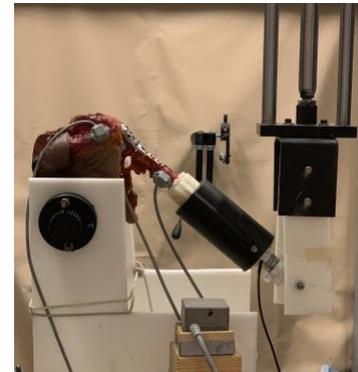

Figure 1: Biomechanical Shoulder Testing System

## Results and Discussion

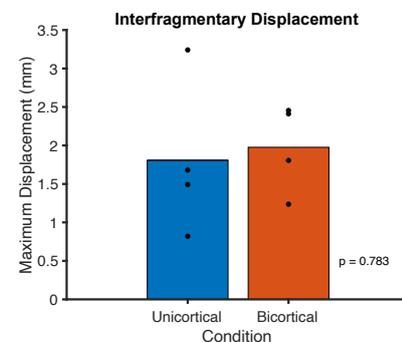

Figure 2: Maximum Interfragmentary displacement over 200 passive scapular plane abduction cycles.

There was no statistically significant difference in maximum interfragmentary gap displacement between the two conditions (Figure 1). The mean (SD) joint reactive force measured across specimens under the two conditions was 37.84 (3.0) N.

## Conclusions

We describe a novel method of testing proximal humerus fixation in fresh frozen cadavers, using a previously validated testing system, simulating physiologic loading of the proximal humerus. We provide normative joint reactive force data for reference in future testing of proximal humerus fixation.

## To filter, or not to filter force plate data for jump height determination?

Brendan L. Pinto, Jack P. Callaghan

Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada

Email: blpinto@uwaterloo.ca

### Summary

Previous evidence has recommended against low pass filtering force plate data when calculating jump height. However, this evidence used unfiltered force plate data as the criterion. The purpose of this investigation was to examine the effect of low pass filtering on jump height calculated from force plate data, using a kinematic criterion. Contrary to previous evidence, low pass filtering with a low cut-off frequency appears to improve the estimation of jump height.

### Introduction

Previous evidence has advised against low pass filtering force plate data when calculating jump height [1, 2]. Filtering can alter the frequency content of the signal and is suspected to be the highest source of error when compared to other analysis procedures in determining jump height. However, these investigations used unfiltered force plate data as the criterion. The effects of low pass filtering on jump height calculated from force plate data, were evaluated using a kinematic criterion that directly measures the whole-body vertical displacement that the force plate calculation aimed to estimate.

### Methods

Thirty-four counter-movement jumps from 12 participants (6 female; mean  $\pm$  SD age  $24 \pm 4$  years; mass  $73.4 \pm 17.6$  kg; height  $1.74 \pm 0.08$  m) were each single pass (SP) and dual pass (DP) filtered, with cut-off frequencies of 100, 50 and 5 Hz. Unfiltered and filtered data from each jump were used to calculate jump height using the take-off velocity summed with take-off displacement method [3].

A single marker on the third lumbar vertebrae was used to record vertical displacement. This captured the displacement of the torso while limiting the influence of limb, ribcage and pelvis posture. This criterion matched the assumption of point mass made by the force plate calculation and was thus more appropriate than estimating centre of mass (COM) using a rigid link model (the force plate calculation does not account for changes in COM due to body posture redistribution during flight).

Paired differences between the criterion and jump heights calculated from the unfiltered and six filtered force plate signals, were analyzed using a linear mixed effects model. If the ANOVA from this model indicated a significant main effect of filter condition ( $\alpha=0.05$ ), pairwise comparisons of the estimated marginal means (EMM) were conducted with a Tukey adjustment ( $\alpha=0.05$ ).

### Results and Discussion

The 5 Hz SP data had the lowest paired difference with the criterion, followed by the 5 Hz DP filtered data. Both conditions were significantly different from each other (pairwise comparison  $p<0.001$ ) and all other conditions (pairwise comparison  $p<0.001$ ), whereas the other filter conditions did not differ from each other (pairwise comparison  $p>0.997$ ). It is possible that filtering with a low cut-off frequency, models the second order nature of the biomechanical system to improve the biofidelity lost when calculating jump height from the force plate assuming point mass.

**Table 1:** EMM and 95% confidence limits (CL) of the paired jump height difference for each condition relative to the criterion.

Filter Condition	EMM (cm)	Lower 95% CL	Upper 95% CL
Unfiltered	-1.86	-2.38	-1.34
100 Hz SP	-1.85	-2.37	-1.34
50 Hz SP	-1.84	-2.36	-1.32
5 Hz SP	-0.82	-1.34	-0.30
100 Hz DP	-1.86	-2.38	-1.34
50 Hz DP	-1.86	-2.38	-1.34
5 Hz DP	-1.30	-1.82	-0.78

### Conclusions

Contrary to previous evidence, low pass filtering with a low cut-off frequency improves the calculation of jump height from force plate data. Future investigation should elucidate this effect and if there is a biomechanical purpose to filtering the force time signal, as this may also inform the analysis of other force plate outcome measures.

## Timing of gait events affect time-continuous analysis outcomes

Eric C. Honert<sup>1</sup>, Todd C. Pataky<sup>2</sup>

<sup>1</sup>Human Performance Lab, Faculty of Kinesiology, University of Calgary, Calgary, Alberta, Canada

<sup>2</sup>Department of Human Health Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan

Email: eric.honert@ucalgary.ca

### Summary

Time continuous analyses, such as statistical parametric mapping (SPM), have been increasingly used in biomechanics research. Currently, it is not known how sensitive time-continuous analyses are to timing variability that occur in gait data. We evaluated this sensitivity by examining the frequency of significant SPM outcomes for lower limb joint powers between two walking speeds for 40 different stride definitions, based on repeatable lower limb gait events. Our findings demonstrate that gait interventions (e.g. changes in walking speed) can induce temporal shifts in gait events, which can in turn affect time-continuous outcomes. Understanding that time-continuous analyses are sensitive to the timing of gait events may enable researchers to better understand the outcomes and limitations of these methodologies that inform injury prevention, device development and basic understanding of biomechanics.

### Introduction

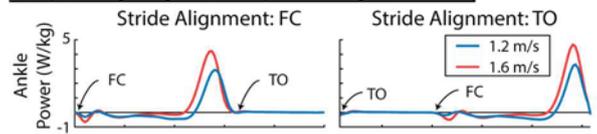

It has become increasingly common to utilize time-continuous analyses (e.g. SPM, principal component analysis) to examine biomechanical data. One methodological consideration for time continuous algorithms is curve registration [1]. It is common practice in gait analysis to linearly register curves based on a single event such as foot contact. This linear alignment allows for inherent timing variability of gait events [2]. However, it is not known how timing variability of gait events affects time-continuous analysis outcomes.

### Methods

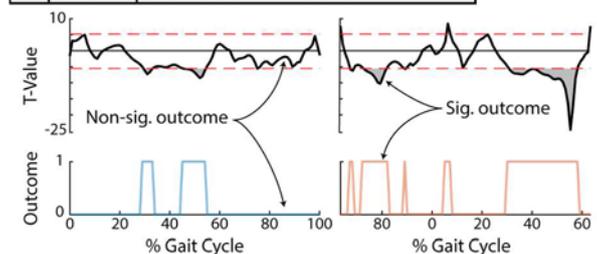

Ten subjects from [3] were reprocessed to understand how gait event timing variability affects SPM outcomes. For conciseness, data from only 1.2 and 1.6 m/s during level ground walking are reported. Lower limb joint powers were segmented and aligned based on 40 different gait events (Fig. 1: Step 1). We use the term ‘stride definition’ to refer to a gait event-based definition of stride. Repeatable gait events were determined from lower limb joint and segment kinematics, joint kinetics as well as ground reaction forces. For each subject and stride definition, 10 strides were analyzed. SPM paired t-tests compared the subject-averaged curves for each stride definition between the two walking speeds using `spm1d` ( $\alpha=0.05$ , [www.spm1d.org](http://www.spm1d.org)). For each SPM test, we recorded whether there was or was not statistical significance with a binary outcome of “1” or “0”, respectively, at each time point (Fig. 1: Step 2). This binary outcome for each stride definition was time-shifted to temporally align the outcomes (Fig. 1: Step 3). These shifted outcomes were finally averaged together across all 40 stride definitions to provide the frequency of statistical outcomes (Fig. 1: Step 4).

### Results and Discussion

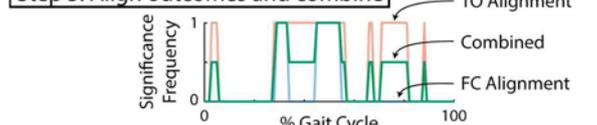

#### Step 1: Align signal on repeatable gait feature

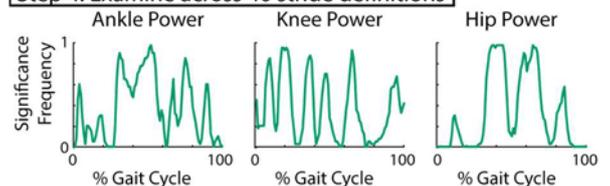

#### Step 2: Compute SPM t-test and outcomes

#### Step 3: Align outcomes and combine

#### Step 4: Examine across 40 stride definitions

**Figure 1:** Determining frequency of statistical outcomes for joint powers with data aligned by foot contact (FC) and toe-off (TO) and with data aligned by 40 different gait events.

Statistical outcomes from joint powers were sensitive to stride definitions defined throughout the gait cycle (Fig. 1, Step 4). This sensitivity arose due to variable timing of gait events in the data. In the future, researchers should consider performing multiple SPM tests with alternative event-based stride definitions to quantify this timing variability and sensitivity.

### Conclusions

Investigators are encouraged to test alternative event-based stride definitions to ensure robust conclusions from time-continuous analyses.

## Analysing the impact of sensor placement on the quality of sEMG signals on the human forearm

Schimmer J.<sup>1</sup>, Ganguly A.<sup>1</sup>, Mombaur K.<sup>2</sup>

<sup>1</sup>Optimization, Robotics and Biomechanics, Institute of Computer Engineering, Heidelberg University, Heidelberg

<sup>2</sup>Chair in Human-Centred Robotics & Machine Intelligence, University of Waterloo, Waterloo

Email: schimmer@stud.uni-heidelberg.de

### Summary

Surface electromyography (sEMG) is increasingly used in next-generation wearable assistive devices to facilitate user in-loop controls and replace state machine controllers such as exoskeletons and prosthetics. Conventionally, muscle bellies are chosen as sEMG affixation sites to ensure high quality recordings. However, the muscle bellies are not always accessible, often due to the design of wearable assistive devices and hence, alternative sites are sought to record reliable sEMG signals. In this study, 5 muscles in the forearm region of 10 subjects were chosen which are responsible for wrist flexion and extension as well as ulnar and radial deviation. sEMG signals were recorded from the muscle belly, 1cm proximal and distal to the muscle belly of each muscle, respectively. The study demonstrates that some alternative sites indeed offer reliable sEMG signals, but it does not intend to replace the conventional sEMG practice.

### Introduction

The majority of upper limb replacements are so-called passive prosthesis [1]. In order to develop these wearable assistive technologies, primary data from myoelectric as well as kinetic measurements have to be recorded. sEMG signals are conventionally measured from the muscle belly but this study indicates that reliable sEMG recordings can be derived on sites away from the muscle belly.

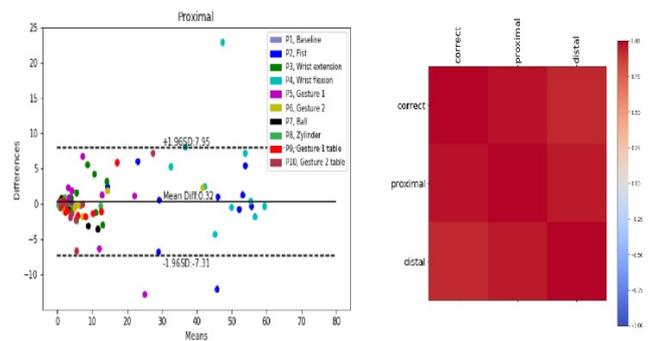

### Methods

The arm of each subject was palpated for 5 muscles, FCR, FCU, ED, and AN in order to locate appropriate sites to place the sEMG electrodes. Electrodes were placed on those muscle bellies, 1 cm distal and 1 cm proximal to it. The subjects carried out 10 different tasks, including resting and Maximal voluntary isometric contraction used to normalise the obtained data. The mean amplitude of each period was used for further evaluation.

For every muscle placement one ANOVA per period was carried out, including all 10 subjects and all 3 different electrode placements resulting in 10 F-values per muscle. To investigate correlation between measurements the Pearson correlation coefficient (PCC) was calculated for the conventional and distal placement as well for conventional and proximal placement of each muscle. Finally to further compare the placements Bland-Altman Plots (BAP) were computed.

### Results and Discussion

No ANOVAs show a significant difference between the placements. This has been a prerequisite for further investigation of correlation and similarity which makes it possible to interpret similarity of the placements. However the different affixation sites showed a high correlation with PCCs > 0.90. Whereas, the BAPs indicated that some placements yield equal results while others failed to pass this test. An exemplary set of results is given for the FCU in Figure 1.

**Figure 1:** Bland-Altman Plot and PCC for Flexor carpi ulnaris .

### Conclusions

Most of the tested muscles showed reliable similarity in at least one of the alternative placement sites. Even placements which failed to fulfil the conditions of the BAP acquired high correlation and might be useful for prosthesis development. This study shows that alternative sEMG sites can be used when muscle belly of the target muscle in question may not be easy to access. This is often found in wearable devices being driven by EMG.

### Acknowledgments

## Stochastic Resonance and Heaviness Perception of an Ocluded Object

Alli Grunkemeyer<sup>1</sup>, Aaron D. Likens<sup>1</sup>

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA

Email: [agrunkemeyer@unomaha.edu](mailto:agrunkemeyer@unomaha.edu)

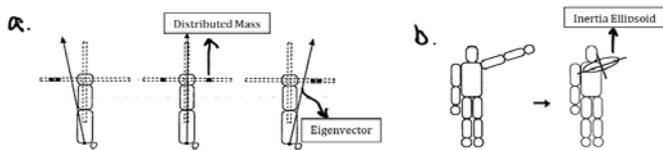

### Summary

We are investigating a novel means to enhance haptic perception of wielded objects. Specifically, we are interested in the effect of low amplitude vibratory noise, when applied to a limb, when perceiving the weight of an occluded wielded object. This research project, if successful, would contribute new theoretical knowledge about the role and structure of neuromuscular noise in the perception of wielded objects. Stochastic resonance is a newly introduced phenomenon and when applied to perception it can advance the theoretical literature in this topic and apply it to human movement variability.

### Introduction

Heaviness perception is the ability to use haptic feedback from effortful touch to determine the weight of a wielded object [1]. The perception of an object being wielded does not rely solely on the object's mass, but muscular effort as well. When an object is wielded, torques and moments of inertia are produced. The inertia tensor contains those moments and provides information about how mass is distributed in a rigid body. The corresponding eigenvalues and eigenvectors of the inertia tensor have been related to an object's perceived magnitudes (e.g., weight) and directions (e.g., orientation with respect to hand), respectively (**Figure 1a**) [2]. The inertia tensor can be visualized as an ellipsoid, as seen in **Figure 1b**, which is produced in effect from the constraints related to the position of the limb. In this study, we will manipulate the eigenvectors associated with an object in relation to the limb.

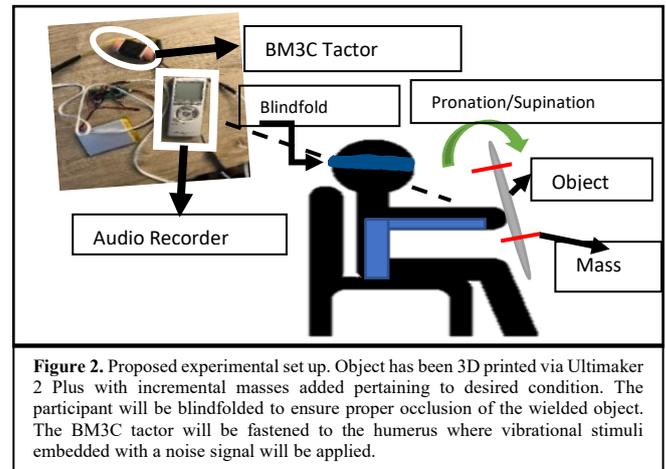

Recent studies have also provided evidence that adding noise to a weak stimulus can enhance a person's ability to detect it [2]. Introducing a subthreshold (vibrational) stimulus embedded with noise may, in some cases, improve sensations gained from limb movements [1]. We hypothesize that adding vibrotactile noise of various forms will improve accuracy in perceiving heaviness of a wielded object (**Figure 2**).

**Figure 1.** (a) Effect of varying mass loads on eigenvectors. (b) Inertia ellipsoid of upper limb.

### Methods

Ten adults (18-45 years of age) will be seated for the duration of the trial with a BM3C tactor fastened to the humerus of the subject as seen in **Figure 2**.

Vibrational stimuli will be introduced via the tactor with different signals of colored noise, or signals produced by stochastic processes varying in power spectral slope. Noise (3) × mass (6) combinations will be presented. Each condition of noise and mass will be introduced randomly. Subjects will rate the heaviness of the object by stating their perceived proportion of mass added on a scale of 1-10.

### Expected Results and Discussion

The study will be introduced as a 3x6 repeated measures design with the first factor being noise, along with the second factor, mass. Mass will be added in increments of 20% all the way up to a max 100% mass increase. Based on previous literature as well as what we know about the various impacts of coloured noise on biological systems, it is expected that with the addition of pink noise to the system, the accuracy of heaviness perception will be the greatest compared to white noise and the control group as the mass increases.

### Conclusions

Introducing a noise as a subthreshold vibration is hypothesized to improve the heaviness accuracy of a given wielded object. Pink noise is expected to display the highest level of accuracy considering the exploratory patterns conveying fractal properties the subjects will exert. These fractal properties are common in most biological systems, therefore producing a more accurate identification of weight.

# SEX DIFFERENCES AND FATIGUING MOVEMENT EFFECTS ON TASK-SPECIFIC STABILITY

Hasanbarani F.<sup>1</sup>, Yang C.<sup>1</sup>, Bailey C.A.<sup>1</sup>, Slopecki M.<sup>1</sup>, Côté J.N.<sup>1</sup>

<sup>1</sup> Department of Kinesiology and Physical Education, McGill University, Montreal, QC H2W 1S4, Canada

Email: [fariba.hasanbarani@mcgill.ca](mailto:fariba.hasanbarani@mcgill.ca)

## Summary

There are several internal factors that affect task-specific stability. However, the sex-specific effects of fatigue on the stability of arm kinematics during a repetitive pointing task (RPT) remain unidentified. We quantified the stability (variability) of an RPT using the Un-Controlled Manifold (UCM) approach. Participants performed the RPT while arm and trunk kinematics was captured by a 3D system in both fatigue and non-fatigue conditions. Results showed good and bad variability more in women compared to men after fatigue, which may reflect an underlying mechanism of sex differences in musculoskeletal disorders.

## Introduction

According to the principle of abundance, a living system uses all elemental variables (EVs) to produce movement, which leads to variability in EVs to keep performance-related variables stable and accomplish a task. Synergy and Motor Equivalence concepts in the UCM framework have been developed to explain the motor control processes that may underlie task-specific stability. The motor equivalence analysis quantifies the amount of deviation in the space of elemental variables that occurs in two directions; one that preserves the performance variable (good variance, ME), and the other one that affects it (bad variance, nME). Synergy index ( $\Delta V > 0$ ) and inequality of  $ME > nME$  represent stability (more good variability) in performing a task. Although previous studies showed an increase of synergy after fatigue [1], this approach has never been used to study the sex-specific multi-joint adaptations in tasks with multiple upper limb joints. We aimed to study the effects of fatigue and sex differences on an RPT's stability using the Motor equivalence model in UCM's framework.

## Methods

Healthy adults ( $n = 26$ , 13F; age:  $35.3 \pm 10.6$  yrs.) performed an RPT by moving their dominant arm between a proximal target and a distal target in a standing position (Fig 1) until near fatigue (Borg CR10 rating 8/10). Tridimensional kinematics of pelvis, trunk, upper arm, forearm, and hand

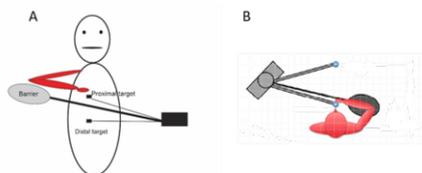

Figure 1: Experimental setup

segments were captured by high-resolution cameras (Vicon) every minute.  $\Delta V$  and ME and nME (Equation 1) were computed in MATLAB using the specific equations [2, 3].

$$\text{Eq1: } nME = \frac{\sum_{j=0}^n |nME_j|}{\sqrt{n \times DoF_{PV}}} \quad ME = \frac{\sum_{j=0}^n |ME_j|}{\sqrt{n \times DoF_{EV-PV}}}$$

In SPSS, a mixed-effect analysis of variance with the factors of Sex (woman vs. man) \* Phase (early vs. middle vs. late) \* Condition (NF vs. FT) on Component (ME vs. nME) and synergy index ( $\Delta V_z$ ) were used with  $P \leq 0.05$ .

## Results and Discussion

Results showed  $\Delta V > 0$  and  $ME > nME$  for women and men, reflecting the EV synergies stabilizing the end-point coordinate in Non-Fatigue and Fatigue conditions. Moreover, the movement phase during which the sex differences occurred changed with fatigue, suggesting different time-dependent compensatory mechanisms (Fig 2).

The effect of Condition \* Sex ( $p = .01$ ) and Bonferroni comparisons showed higher ME (by  $0.19 \pm 0.1$  rad) and nME (by  $0.15 \pm 0.09$  rad) in women related to men after fatigue, which reflect more good variability and bad variability in women compared to men.

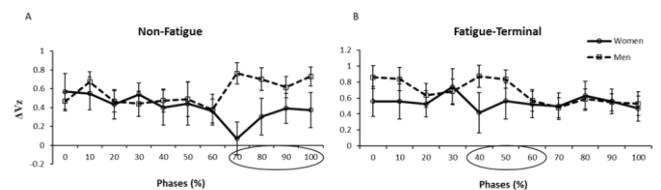

Figure 2:  $\Delta V$  in NF and FT conditions for both women and men. The significant differences are shown with Circles.

## Conclusions

Despite showing comparable endurance, women fulfilled the task similar to men; nevertheless, they showed an increase in the bad variability, which could explain the mechanisms underlying sex differences in musculoskeletal disorders.

## Acknowledgments

We thank Dr. Mark Latash for data analysis suggestions and Kim Emery for her assistance with data collection.

## Movement Preferences of the Wrist and Forearm Combined During Activities of Daily Living

Scott Tew<sup>1</sup>, Will Anderton<sup>1</sup>, Spencer Ferguson<sup>1</sup>, Joshua Hernandez<sup>1</sup>, Steven K. Charles<sup>1,2</sup>

<sup>1</sup>Mechanical Engineering and <sup>2</sup>Neuroscience, Brigham Young University, Provo, UT, USA

### Summary

We characterized the combined behavior of the wrist and forearm during activities of daily living. Subjects spent 50% of their time in the central 20% of their functional range of motion, and movement speed dropped off exponentially. Interestingly, subjects often merged the dart-thrower's motion (DTM) with a twist from pronation to supination (similar to a hand-to-mouth movement). Given its importance in many activities (e.g. eating and grooming), the prevalence of this action is not surprising. However, it suggests that the importance of the DTM may not lie in itself, but rather in combining with pronation-supination to bring objects toward the head.

### Introduction

Although the wrist and forearm function together during activities of daily living (ADL), few studies have investigated the *combined* kinematics of wrist flexion-extension (FE), wrist radial-ulnar deviation (RUD), and forearm pronation-supination (PS). In addition, most past studies investigating the kinematics of these three degrees of freedom (DOF) have focused on the functional range of motion (fROM) needed to perform activities of daily living, or else on the impact of fractures, neurological disorders, surgical procedures, or orthotic devices on the maximum range of motion (mROM) in these DOF. However, the behavior of the wrist and forearm *within* the fROM has received relatively little attention. Here we characterized natural wrist and forearm behavior throughout the entire space spanned by PS, FE, and RUD.

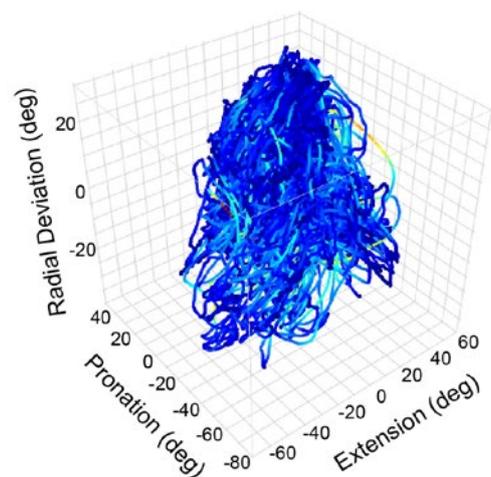

### Methods

Ten young, healthy participants (5 male, 5 female) were instrumented bilaterally with electromagnetic motion capture sensors (trakSTAR by Ascension Technologies, Burlington, VT) on the acromion, distal upper arm, distal forearm, and back of the hand. Each participant performed 24 ADL, with 5 repetitions per ADL, for a total of 120 actions. Most ADL were selected from past studies to allow comparison. Sensor data were converted into joint angles, resulting in joint configuration (FE, RUD, PS) over time for each of the 120 actions of each subject. From joint configurations we extracted the following movement preferences: mean configuration, distribution of configurations, path direction, distribution of speed (combined across all three DOF), and common configurations at different speeds.

### Results and Discussion

Combining the kinematic data resulted in three-dimensional data clouds (Figure 1), from which we extracted movement preferences in each of the three projection planes (FE-RUD, FE-PS, PS-RUD). *Mean configuration (centroid) and mROM:* The mean configuration, averaged across all ADL and subjects, was  $12^\circ \pm 20^\circ$  of extension,  $3^\circ \pm 12^\circ$  of ulnar deviation,

and  $16^\circ \pm 27^\circ$  of pronation (mean  $\pm$  STD). Centroids of motion were not aligned ( $p < 0.001$ ) with the anatomical origin in any of the three DOF. *Distribution of configurations:* The distribution of joint configurations was not uniform for any projection ( $p < 0.0001$ ) but roughly mimicked the shapes of mROM in each projection plane. *Path direction:* The directions of movement were not uniformly distributed ( $p < 0.001$ ) among any of the DOF. For example, in the FE-RUD plane, movements in the direction of the dart-thrower's motion (DTM) were about three times more common than movements perpendicular to that direction. *Speed:* The distribution of movement speed was well-fit by an exponential with a decay constant of 62.9 deg/s, indicating that 25%, 50%, and 75% of the velocities were under 18, 44, and 87 deg/s, respectively. *Common configurations at different speeds:* At low speeds, the configuration was roughly uniformly distributed in direction. However, at higher speeds, certain movement directions became more common. Specifically, the most common movement directions at high speeds were the DTM with a twist from pronation to supination.

**Figure 1:** Wrist and forearm joint configuration over time during ADL. Hotter colors indicate higher movement speeds.

### Conclusions

From the measures analyzed, it is evident that wrist and forearm behavior during ADL favors certain movement configurations, directions, and speeds. One preference was of particular interest: at high speeds, the most common movement combined the DTM with PS. This pattern is what is required to pick up an object in front of one's body (pronation and extension, with some radial deviation) and place it close to the head (supination and flexion, with some ulnar deviation). We hypothesize that the importance of the DTM may not lie in itself, but rather in its role with PS of bringing objects toward the head.

## Information in EMG within and between pedal cycles

### Summary

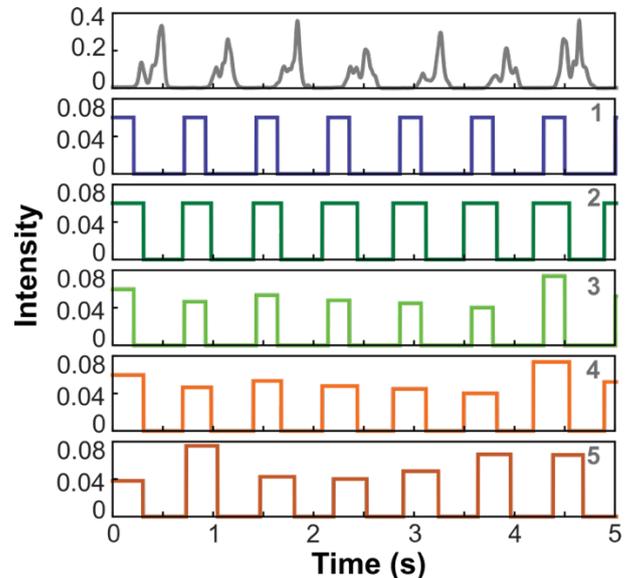

EMG signals contain small fluctuations between data points across time. Although small fluctuations were historically attributed to motor system noise, recent work found the order of these fluctuations contains information relevant to motor control. In a cyclic task, EMG can fluctuate within a burst of excitation, between the excitation and quiescent periods of a cycle, and across multiple cycles. It is unknown how these sources of variation affect the measurement of structure in EMG. We used pedaling to explore the order of fluctuations or 'structure' in EMG that occurs both within and between cycles. We constructed square wave signals that lack fluctuations within an excitation burst and fluctuations across multiple pedal cycles and compared the structure of these signals to that of experimental EMG intensities using Entropic Half Life (EnHL) analysis. We found that the EnHL is primarily affected by variation between the excitation and quiescent periods of a cycle.

### Introduction

Small fluctuations within EMG collected during gait are thought to reveal information about underlying motor control [1, 2]. This has been assessed using Entropic Half-Life (EnHL) analysis during cycling, which quantifies the timescale at which regularity in a signal decays [3]. At present, we do not know how variation within and between cycles in the EMG signal affects the EnHL. In this study we use measured and constructed EMG signals to explore structure within and between pedal cycles.

### Methods

In order to determine the sources of variation that are responsible for the rate of decay of structure in an EMG signal, we compared measured with constructed EMG signals where we altered the sources of variation in the signals. We collected EMG from nine participants and six muscles of the lower limb during cycling at a constant cadence and resistance. EMG signals were resolved into intensities, where the intensity is a close approximation to the power in the EMG. We determined the duration of each excitation burst and rest period, as well as the average intensity of each burst. Using these burst and rest durations and average intensities, we constructed five square waves that lacked variation within a burst of excitation (Figure 1). Square waves 2-4 possessed variation in time, intensity, or both between multiple cycles. Square wave 1 lacked variation between multiple cycles. To construct square wave 5, we randomized the order of each cycle in square wave 4 to remove information related to the order of multiple cycles but maintain a random variation between cycles. We analyzed the EnHL of all square waves and compared these to the EnHL of the EMG intensities.

**Figure 1:** Measured and constructed EMG signals from the vastus medialis of a representative participant. From top to bottom: EMG intensity, and square waves 1-5.

### Results

The EnHL of square wave 1 (with constant burst and rest parameters) was longer than all other analyzed signals. All square waves with variable burst and rest durations or variable intensity had similar EnHL values to the EMG intensities. The EnHL of the square wave with randomized cycle order was similar to the EnHL of the square wave with preserved cycle order (square waves 5 and 4, respectively).

### Discussion and Conclusions

Although the EMG intensities contained variation within a burst of excitation, these variations did not contribute to the EnHL. This is shown through the similar EnHL between the square waves and the EMG intensities. Variation across multiple cycles contributed to the EnHL, as the EnHL of square wave 1 was longer than all other signals. However, the order of this variation did not contribute to the EnHL as the EnHL was unaffected when cycle order was randomized. The EnHL was thus primarily influenced by variation in the burst and rest durations and the average EMG intensities.

## Ultrasound estimates of muscle quality: correcting for the confounding effect of subcutaneous fat.

<sup>1</sup>Biomechanics Laboratory, Federal University of Santa Catarina, Florianopolis, Brazil

<sup>2</sup> School of Biological Sciences, Federal University of Santa Catarina, Florianopolis, Brazil

Email: [heiliane.fontana@ufsc.br](mailto:heiliane.fontana@ufsc.br)

### Summary

Subcutaneous fat is a major confounding factor when comparing echo intensity (EI) of skeletal muscle sonograms. We used exogenous fat to analyze the confounding effect of fat thickness on muscle echo intensity. Equations for improved accuracy in estimates of muscle quality in obese/overweight are provided.

### Introduction

EI of skeletal muscle sonograms has been used as an estimate of muscle quality in individuals with various phenotypes. Until now, most studies that correct ultrasound-based estimates of muscle quality for the confounding effect of subcutaneous fat have counted on the equations developed by Young et al. [1].

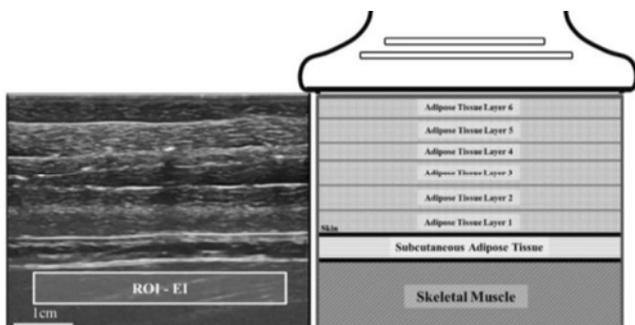

However, their experiment consisted in changing fat thickness by applying different levels of pressure with the ultrasound (US) probe on the skin, which is expected to lead to changes in tissue parameters that may influence the speed of US wave propagation, producing changes in EI that do not represent the effect of subcutaneous fat thickness [2].

In this study, we aim to provide an unbiased estimate of the effect of subcutaneous fat thickness on EI scores. Fat thickness was modified by adding exogenous fat layers over the skin, and the resulting change in EI was analyzed. This experimental approach allowed us to mimic the effects of increasing fat thickness (attenuation and changes in ROI relative position) on EI estimates of muscle quality.

### Methods

Ten healthy subjects (age 28.0±5.6 years, height 1.70±0.11 m and body mass 67.8±11.9 kg) participated in this study.

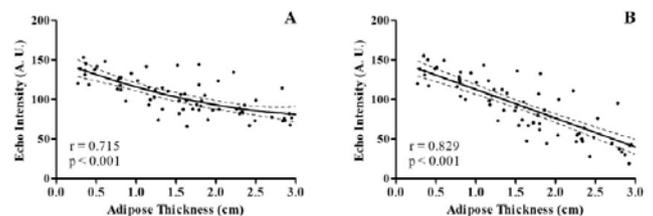

Sonograms were taken from the tibialis anterior mid-belly with the ultrasound probe longitudinally aligned with the muscle and perpendicular to the skin. (Figure 1).

**Figure 1:** The average of three independent B-mode sonograms (40-mm depth and 60-dB gain) for each condition (no fat and for 6 additional exogenous layers) was used in the analysis.

### Results and Discussion

A significant effect of adipose thickness (AT) was observed on EI ( $p < 0.001$ , Figure 2).

**Figure 2:** EI scores decrease as fat thickness increases. This confounding effect on EI differs between sonograms with focus fixed at 1 cm (A) and with focus adjusted to the ROI (B).

Correcting equations (with standard errors) for sonograms without (i) and with (ii) focus adjustment are presented:

$$(i) EI_{corrected} = EI_{measured} - 5.0054 \cdot AT^2 + 38.30836 \cdot AT$$

$$(ii) EI_{corrected} = EI_{measured} + 39.2297 \cdot AT$$

The confounding effect of subcutaneous fat thickness on EI estimates of muscle quality leads to an underestimation of the negative impact of obesity/overweight on muscle health [3,4] and may lead to erroneous conclusions regarding chronic exercise induced changes in muscle quality and differences in muscle quality between men and women or between muscles and muscle regions [5,6]. The slope of the relationship between subcutaneous fat thickness and EI observed by [1] with tissue compression differs substantially from the one observed in our study (Figure 2A). Differences may be explained by the nature of the experiment conducted by [1], which does not allow for the quantification of the independent effect of fat thickness, and also by the limited range of fat thickness tested in their experiment.

### Conclusions

US estimates of muscle quality should be corrected for the confounding effect of subcutaneous fat and the correction should take into account whether focus is adjusted to the muscle region of interest or not. To our knowledge, this is the first study to systematically analyze the confounding effect of fat thickness as an independent factor and the provided equations can be used for improved accuracy in estimates of muscle quality in obese/overweight subjects/patients.

# Probabilistic DTI tractography demonstrates better consistency with ultrasound estimates of muscle fascicle lengths in comparison to deterministic methods

Divya Joshi<sup>1,2</sup>, Amy Adkins<sup>1,2</sup>, Wendy Murray<sup>1,2,3</sup>, Julius P.A. Dewald<sup>1,2,3</sup>, Carson Ingo<sup>2,4</sup>

 Email: divyajoshi@u.northwestern.edu

## Summary

We establish, for the first time, feasibility of probabilistic DTI tractography in skeletal muscles, as compared to the deterministic methods prevalent in literature. Probabilistic methods estimated fascicle lengths more consistent with ultrasound measurements and produced more variability, which suggests heterogeneity previously only identified in cadaveric measurements.

## Introduction

Musculoskeletal structure has traditionally been investigated using cadaveric specimens, while *in vivo* measurements are made with ultrasound (US). More recently, magnetic resonance (MR) based diffusion tensor imaging (DTI) has emerged as a promising approach that can non-invasively capture skeletal muscle architecture while overcoming limitations posed by ultrasonic and cadaveric methods.

In order to estimate muscle fascicle length properties, DTI can be implemented by using either deterministic tractography, which computes a binary fiber direction at each voxel, or probabilistic tractography, which produces a probability distribution of fiber direction at each voxel [1]. While it has been shown that probabilistic tracking more reliably reconstructs crossing fibers within a voxel, the two methods have yet to be compared for musculoskeletal tractography. Due to the computational burden of probabilistic methods, previous literature in skeletal muscle DTI has predominantly used deterministic algorithms [2]. Here, we explore the differences seen when using both methods and compare the results to previously obtained ultrasound measurements.

## Methods

Diffusion-weighted images of both upper arms were acquired in two male, age-matched individuals using a spin-echo echo planar imaging sequence (voxel resolution=1.25x1.25x5 mm<sup>3</sup>, diffusion gradient b=450 s/mm<sup>2</sup>, 12 directions with 3 averages). High resolution T1 anatomical images were also obtained to guide the identification and segmentation of the biceps brachii muscle and its inner tendon.

Deterministic and probabilistic tractography was initiated from the same segmented seedmask of the biceps brachii muscles. Deterministic tractography was run using DSI Studio with the following parameters: angular threshold=10°, step size=0.5 mm, and minimum length=20 mm. Probabilistic tractography was run using FSL with the following parameters: maximum fibers per voxel=2, burnin period=1000, and step size=0.5 mm. Probabilistic tractography had a 400-fold greater expenditure of time than deterministic tractography. Resulting tracts from both

algorithms were constrained using anatomical boundaries and fit to polynomial curves, from which fascicle lengths were measured and compared to previously reported US results [3].

## Results and Discussion

Both tractography methods were able to capture fascicles across the entire muscle region, resulting in an order of magnitude more fascicles than were captured using ultrasound, which can only estimate superficially located fibers (Figure 1) due to limited field of view inherent to US. Both DTI methods produced shorter fascicles than ultrasound. Probabilistic methods yielded an average of 57.6% longer median fascicles, which were more consistent with ultrasound measurements, than deterministic methods.

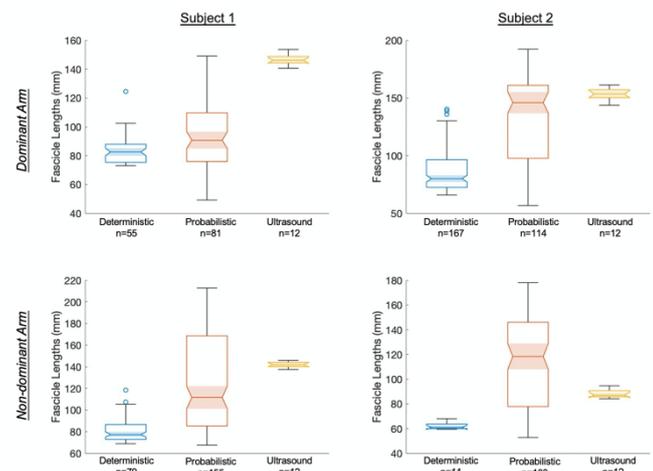

Figure 1: Fascicle length measured by deterministic and probabilistic tractography, and 2D ultrasound [3].

## Conclusions

Probabilistic tractography can estimate an increased number of fascicle length measurements, which are closer to previously reported results. Additionally, it has potential to capture a more heterogeneous sample of fascicles, which has previously only been explored via cadaveric methods [2].

# Open vs closed articular architecture of the forearm for an analysis of muscle recruitment during throwing motions

Claire Livet<sup>1</sup>, Théo Rouvier<sup>2</sup>, Charles Pontonnier<sup>1</sup>, Georges Dumont<sup>1</sup>

<sup>1</sup>Univ Rennes, Inria, CNRS, IRISA – UMR 6074, F-35000 Rennes, France

<sup>2</sup>Institut de Biomécanique Humaine Georges Charpak, Arts et Métiers ParisTech

Email: claire.livet@ens-rennes.fr

## Summary

The osteoarticular architecture of the forearm can be modeled by an open or a closed-loop. This study aims to compare the impact of the chosen architecture on the muscle activity for overhead throwing motions. Preliminary results show similar muscle behaviors with both models.

## Introduction

Musculoskeletal modeling can analyze human motion from kinematics to muscle activity. The impact of modeling on the kinematic reconstruction of the motion has been studied [1]. This pilot study aims at comparing activations estimated with a full-body musculoskeletal model presenting an open-loop (OLM) [2] or a closed-loop (CLM) [3] model at the forearm during overhead throwing motions.

## Methods

The OLM is based on [4] for the lower limb and [2] for the upper limb. Muscle activations are estimated by the following static optimization under the respect of dynamic equations [5]:

$$\min_a \sum_{i=1}^m a_i^2$$

$$\text{s. t. } \begin{cases} 0 \leq a_i \leq 1, \forall i \in \llbracket 1, m \rrbracket \\ H(q)\dot{q} + C(q, \dot{q}) = R(q)F_{max} \odot a \end{cases}$$

The muscle force model is  $F_m = F_{max}a$ , with  $a$  the muscle activations.  $q$  are the degrees of freedom,  $H(q)$  is the mass matrix,  $C(q, \dot{q})$  is the Coriolis matrix and the effect of external forces,  $R(q)$  is the moment arm matrix from [6].

The CLM is based on [4] for the lower limb and [3] for the upper limb. The forearm contains a closed loop modeled by constraints  $h(q) = 0$ , contributing to dynamic equations via its Jacobian  $K$  and Lagrange multipliers  $\lambda$  [7]. The muscle recruitment problem is now:

$$\min_{a, \lambda} \sum_{i=1}^m a_i^2$$

$$\text{s. t. } \begin{cases} 0 \leq a_i \leq 1, \forall i \in \llbracket 1, m \rrbracket \\ H(q)\dot{q} + C(q, \dot{q}) = R(q)F_{max}(q) \odot a + K^T \lambda \end{cases}$$

The study was implemented in CusToM [9], an open-source Matlab toolbox for musculoskeletal modeling. Geometrical and inertial parameters were extracted from [10] and scaled to the subject (1m74, 64kg) using the CusToM scaling routine. The raw data for 18 throwing trials were taken from [11].

Measured EMGs and activations computed from OLM and CLM were compared with phase error metrics [8].

## Results and Discussion

OLM and CLM had similar results while compared to EMG measurements (Figure 1). This was confirmed by the OLM and CLM comparison, with phase errors under 25%.

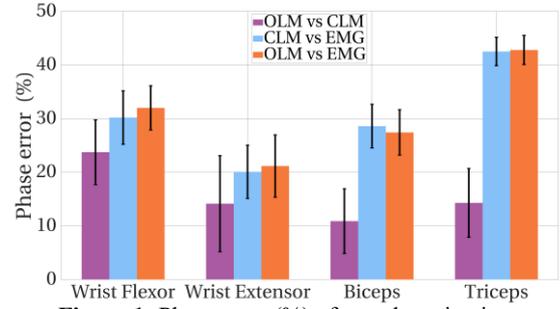

Figure 1: Phase error (%) of muscle activations

OLM and CLM were expected to have similar behaviors. However, adding constraints in the dynamic equations may impact the muscle recruitment to give a better match with measurements. We can see that constraints did not have a strong impact on these specific motions and that none of OLM or CLM fairly match EMG data. This could be explained by the small number of solids in the CLM and the relatively low level of solicitation related to this motion.

## Conclusion

Finally, it seems that CLM did not bring any improvement compared to OLM for studying throwing motion. A similar study should be done for a larger cohort to validate these preliminary results. The same comparison could be done for shoulder models, using more complex constraints.

### Summary

Inverse dynamics is widely used to quantify the joint torque and work during walking, assuming rigid segments. But many body tissues are not rigid, and soft tissue deformations are expected to passively dissipate some energy. New analysis techniques quantify that dissipation, but with few direct tests of their validity during walking. We therefore evaluated soft tissue work analysis, by artificially adding non-rigid dissipatory elements to the body—flexible air pumps—for which the amount of dissipation was quantified independently. We performed soft tissue work analysis for normal walking and walking with artificial dissipation, and evaluated the accuracy of the dissipation estimate. We found that the soft tissue work calculated from the artificial soft tissue conditions was much larger than that calculated from normal walking, and was close to the values obtained from independent mechanical characterization. We also found the observed dissipation to be well quantified by distal foot power. We conclude that soft tissue work can be accurately quantified during walking, particularly if associated with the foot.

### Introduction

Inverse dynamics analysis uses dynamic equilibrium between rigid bodies to quantify joint torques, based on measured kinematic variables and ground reaction forces. The body is not entirely rigid, as indicated by observations of net positive joint work [1], even though there is negligible net work done over a stride of periodic walking. A previously proposed analysis quantifies the work of soft tissue deformations [1], using the discrepancy between summed joint work and change in total mechanical energy (including body center of mass and peripheral motions). Here, we quantitatively test this analysis by introducing an experimental manipulation of artificial soft tissues mounted under the feet that dissipates a known amount of energy. We tested whether the soft tissue analysis could quantify the artificial energy dissipation, to determine its validity for human walking.

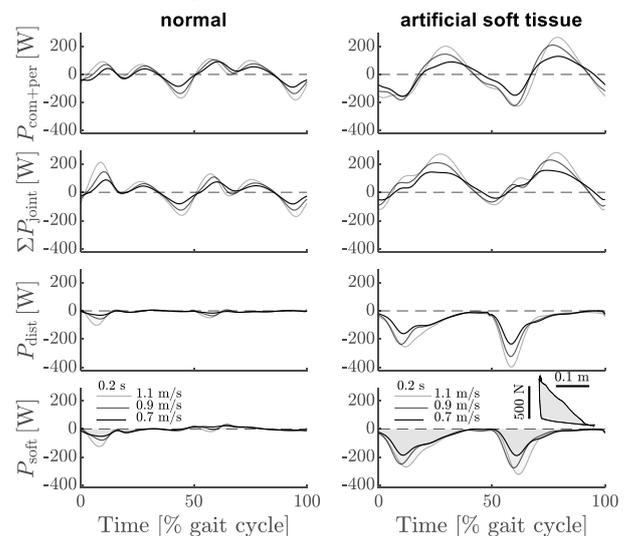

### Methods

We performed inverse dynamics and soft tissue work analysis for walking with and without artificial soft tissues. The manipulation was a flexible air pump attached to the bottom of each shoe. One human subject walked in both conditions on an instrumented treadmill at three speeds (0.7 – 1.1 m/s), while kinematic data of the feet, shanks, thighs and trunk were recorded [2], along with ground reaction forces. (The test focused on a mechanical perturbation and analysis, and not on variation between human subjects.) Inverse dynamics analysis was performed on about 50 seconds of data for each trial [1]. From these results, total mechanical power, sum of joint power, distal foot power, and soft tissue power were calculated [1,2]. Total mechanical power was quantified as the sum of center of mass power (using ground reaction forces and including soft

tissue motion) and peripheral power (from motion relative to the center of mass), from which subtracting summed joint power yielded soft tissue power. Distal foot power was quantified as the 6-DOF joint power between ground and foot [2]. For each of these variables, net work was calculated by integration with respect to time.

### Results and Discussion

We found that walking with artificial soft tissue resulted in substantially more soft tissue dissipation (94, 102, 111 J/stride for both feet) than normal walking (8, 9, 13 J/stride), for all three speeds (Figure 1). The amount of additional energy dissipated during one step with the artificial soft tissue (about 40 J) was close to that observed during a single compression of the air pump (39 J), quantified in a separate experiment. This dissipation largely agreed with net distal foot work, which was 10, 12 and 16 J/stride for normal walking and 101, 112 and 119 J/stride for walking with artificial soft tissue.

**Figure 1:** Total mechanical power, sum of joint power, distal foot power and soft tissue power as a function of normalized stride time. Data is average over strides (starting left heel strike). Each line corresponds to a trial at a different speed, as indicated by the legend, which also serves as scale bar for the time axis. The inset (bottom right) shows one work loop for a separate decompression cycle of the air pump, in the vertical dimension. Shaded areas indicate net work done.

### Conclusions

The additional energy dissipation of an artificial soft tissue is well quantified by both soft tissue work analysis and distal foot power. Whereas distal foot power should be applicable to deformation of the foot, soft tissue analysis should quantify the energy dissipated in deformations throughout the body.

## Can Electrically Induced Contractions Replicate Walking in Microgravity?

### Summary

Neuromuscular Electrical Stimulation (NMES) is an electrical pulse that elicits muscular contractions, which can potentially reduce bone loss in astronauts. External Force output of the Vastus Medialis, Vastus Lateralis, and Hamstring muscle group from NMES-induced isometric contractions of the knee were measured (n=1), and applied to biomechanical knee and hip models to estimate the internal forces. The muscle and joint reaction forces were then applied to a finite element analysis (FEA) of the femur to produce a strain model. The peak trabecular tensile and compressive strains were 1391 and -2095 microstrain ( $\mu\epsilon$ ) respectively. Peak cortical tensile and compressive strains were 715 and -890  $\mu\epsilon$  respectively, which is comparable to estimated peak  $\mu\epsilon$  during walking. Therefore, it is possible that a daily application of NMES can replicate the daily strain stimulus one would experience with recommended daily walking doses ( $\approx 5,000$  steps).

### Introduction

Astronauts in microgravity experience muscle and bone loss and are required to exercise daily. For future long duration missions, alternative methods are being investigated to reduce mass and logistical requirements. Neuromuscular Electrical Stimulation (NMES) is a technique that sends electrical pulses via skin electrodes to elicit an involuntary muscular contraction. NMES has previously been applied to reduce bone loss in spinal cord injury patients [1], and therefore is a potential method to reduce bone loss in astronauts [2]. Bone is thought to respond to its daily strain stimulus, which is determined by the peak strain experienced and total loading cycles [3]. Strain experienced on the femur from walking has previously been estimated by both finite element analysis (FEA) [4] and *in-vivo* studies [5]. In addition, studies have estimated the total number of daily steps required to maintain bone density at healthy levels ( $\approx 5000$ ) [6]. In order to determine potential effective of a NMES regimen for use with astronauts, a FEA strain model of the femur during isometric NMES contractions against a fixed resistance was created.

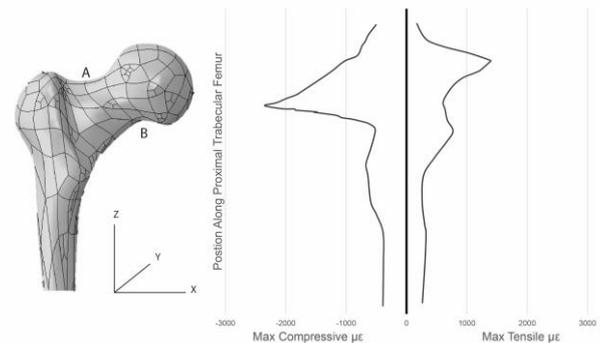

### Methods

Isometric contraction force of the Vastus Medialis (VM), Vastus Lateralis (VL), and Bicep Femoris/Semitendios muscles of one subject were measured while seated with the knee at 90°. For each muscle, the amplitude of the NMES pulse was increased to a subjective, maximum tolerable level. The internal muscle and reaction forces were estimated using simple knee and hip biomechanical models, and the forces were applied to a Finite Element Analysis (FEA) of the femur. A 4<sup>th</sup> generation Standard Femur Model [7], which is composed of a cortical shell and a distal and proximal cancellous components, was used with the Abaqus CAE software. A linear tetrahedron element mesh of approximately

uniform size (1.2mm) was implemented with literature derived bone mechanical properties and muscle origin points.

### Results and Discussion

Figure 1 displays the peak principal strains ( $\mu\epsilon$ ) along the z axis of the proximal trabecular femur. The overall peak tensile and compressive strains were 1391 and -2095 ( $\mu\epsilon$ ).

**Figure 1:** The trabecular peak principal strains ( $\mu\epsilon$ ) along nodal paths within x-z plane that bisected the model y axis. The peak tensile and compressive strains were at points A and B.

Peak principal tensile and compressive strains measured on the cortical surface of the femoral neck were 715 and -890  $\mu\epsilon$  and occurred superficial to the trabecular peaks. These results are comparable to those observed *in vivo* (1198, -393  $\mu\epsilon$ ) and FEA (752, -859  $\mu\epsilon$ ) walking studies [4,5].

### Conclusions

This study demonstrated that isometric contractions from NMES can produce peak bone strains akin to walking. If 5,000 daily steps (2,500 per leg) is able to maintain bone health on Earth [6], a NMES regimen of similar repetitions could possibly be used to reduce bone loss in astronauts in microgravity. The addition of another cross hip joint muscle, the rectus femorus, in leui of the VM and VL could further increase the strain, potentially reducing the required number of repetitions, increasing practicality. Future research aims include 1) repeating the analysis for subjects of varying leg size, strength, and gender, as individuals can have a wide range of responsiveness and tolerance to NMES, and 2) performing co-contractions of the knee extensors and flexors to create isometric contractions without a fixed resistance to replicate microgravity conditions.

## Foot Joint Stiffness Effects on Maximum Vertical Jumps

Daniel J. Davis, John H. Challis

Biomechanics Laboratory, The Pennsylvania State University, Pennsylvania, United States

Email: [djd426@psu.edu](mailto:djd426@psu.edu)

### Summary

Shoe and foot stiffness may play a role in athletic performance. The present investigation used a musculoskeletal model of maximum vertical jumping to clarify mechanisms of potential performance enhancement. Overall, increased passive midtarsal joint stiffness and increased toe flexor strength had little effect, whereas increased shoe longitudinal bending stiffness increased jump height by over 1.5%.

### Introduction

The longitudinal bending stiffness (LBS) of athletic footwear has received considerable attention with regards to running and jumping performance. Stefanyshyn & Nigg (2000) reported increased jump heights with stiffer shoes, proposing that less negative work at the metatarsophalangeal (MTP) joint was at least in part responsible. Recently, investigators have reported that the muscles of the foot can alter the stiffness of the foot's joints [2], which could perhaps also be beneficial for vertical jump performance. The purpose of the present analysis was then to determine the mechanisms by which model shoe and foot joint stiffness changes influence maximum vertical jump performance.

### Methods

A two-dimensional direct dynamics model with 11 muscles/muscle groups (gluteus maximus, vasti, rectus femoris, hamstrings, gastrocnemius, soleus, tibialis posterior, peroneus brevis/longus, flexor digitorum/hallucis longus) was created in OpenSim (v4.0). Muscle excitation time-histories were optimized to maximize jump height and were the same across model variations. The effects of shoe LBS were determined by altering passive MTP joint dorsiflexion stiffness values to approximate flexible (baseline) and stiff shoe conditions. Passive joint moments were used to enforce biologically relevant ranges of motion and stiffnesses [3], with systematic variations from baseline midtarsal joint stiffness used to examine its influence on jump performance. Lastly, the extrinsic toe flexor's maximum isometric forces were increased from baseline to model the effects of strengthening these muscles.

### Results and Discussion

Modelling an increase in shoe LBS had the largest effect on jump performance, increasing jump height by nearly a centimeter between the baseline and most stiff shoe conditions. This was accompanied by 5.4 Nm (21.7%) greater peak MTP joint moment and about 16% less negative work between conditions. Increasing shoe LBS also increased the proportion of vertical ground reaction force on the model's toe segment, effectively increasing the plantarflexion moment arm (Table 1).

The least stiff midtarsal joint condition reduced vertical jump height compared to the baseline condition by 2 mm but jump height did not differ between baseline and the most stiff midtarsal joint conditions. Peak joint moments were about 5 Nm different between the least stiff and baseline conditions, and the midtarsal joint extended 2.5 degrees more in the least stiff condition compared to the baseline condition (Table 1).

Increasing the maximum isometric force capacity of the model's toe flexor muscles by 20% increased vertical jump height by 2 mm. The proportion of the vertical ground reaction force on the toe segment was increased, albeit to a lesser extent than in the increased shoe LBS condition (Table 1). MTP joint negative work was reduced by 4% compared to the baseline condition.

### Conclusions

Foot joint stiffness and muscle strength changes influenced maximum vertical jump performance much less than externally supplementing MTP joint stiffness. Passive foot joint properties and foot muscle strength therefore likely contribute less to maximum jump performance than footwear choices.

Email: lschroel@vols.utk.edu

### Summary

ACL injuries are the most common medically disqualifying injury in female youth soccer. Alterations in biomechanical and neuromuscular control have been identified throughout the maturation process, potentially affecting ACL loading ( $F_{ACL}$ ). However, it is unknown how ACL loads change throughout maturation. Fifty-nine adolescent female soccer players, classified into prepubescent, pubescent, and post-pubescent, completed unanticipated cutting trials. Musculoskeletal modeling was used to estimate  $F_{ACL}$ , and peak  $F_{ACL}$  was compared between groups. No significant differences in peak  $F_{ACL}$  between groups were present.

### Introduction

Age significantly affects anterior cruciate ligament (ACL) injury rates in female soccer, with players 15 years or older exhibiting an almost twofold increased injury rate compared to younger players. Sex disparities in ACL injury rates increase after the onset of adolescence, suggesting the rapid musculoskeletal changes that occur significantly contribute to ACL injury rates. Musculoskeletal modeling allows researchers to estimate ACL loading ( $F_{ACL}$ ), providing insight into how kinematic and neuromuscular changes affect ACL loading through the maturation process. Understanding these changes throughout maturation could aid in improving ACL injury prevention programs. Therefore, the purpose of this study was to compare estimated ACL loading between maturation groups in young female soccer players. It was hypothesized that the more mature females would exhibit greater  $F_{ACL}$  compared to less mature females.

### Methods

Motion capture data from 59 adolescent female soccer players completing unanticipated cutting trials (CUT) off the dominant leg were used. Participants were classified into three maturation groups based on their predicted adult stature percentage [1]: prepubertal (PRE:  $n = 17$ , age:  $10.3 \pm 0.6$  yrs, ht:  $1.38 \pm 0.07$  m, mass:  $34.23 \pm 4.49$  kg), pubertal (PUB:  $n = 20$ , age:  $11.8 \pm 0.9$  yrs, ht:  $1.52 \pm 0.07$  m, mass:  $43.64 \pm 6.50$  kg), and post-pubertal (POST:  $n = 22$ , age:  $15.1 \pm 1.6$  yrs, ht:  $1.62 \pm 0.06$  m, mass:  $54.54 \pm 10.40$  kg).

Musculoskeletal simulations of the CUT trials were conducted in OpenSim (v3.3, <http://simtk.org>). Inverse

kinematics and inverse dynamics were used to calculate joint angles and moments from a subject-specific scaled musculoskeletal model [2]. Joint torques were decomposed into net muscle forces using static optimization. A Joint Reaction Analysis was used to obtain anteroposterior knee joint reaction forces, using muscle forces from static optimization as inputs. Finally, a previously established data-driven model was utilized to estimate  $F_{ACL}$ , using the anteroposterior knee reaction force and knee flexion angle [3].

Peak  $F_{ACL}$  during stance phase was identified. To see how mass affects  $F_{ACL}$ , two separate one-way ANOVAs were performed on peak  $F_{ACL}$  between the three maturation groups, one using the raw  $F_{ACL}$  and the other using  $F_{ACL}$  normalized to body weight (SPSS,  $\alpha = 0.05$ ).

### Results and Discussion

Both raw and normalized peak  $F_{ACL}$  and standard deviations for the three maturation groups are presented in Table 1. Our hypothesis was not supported. There were no significant differences in both raw  $F_{ACL}$ :  $F(2,56) = 2.684$ ,  $p = 0.077$ ,  $\eta^2_p = 0.087$ , and normalized  $F_{ACL}$ :  $F(2,56) = 2.511$ ,  $p = 0.090$ ,  $\eta^2_p = 0.082$ . However, a medium  $\eta^2_p$  effect size was detected in both analyses. Raw  $F_{ACL}$  increased from PRE to PUB in a way that reflected body mass increases, but changes in raw  $F_{ACL}$  from PUB to POST were small and did not reflect the increase in body mass between groups, possibly implying a movement strategy to reduce ACL loading in the POST group.

### Conclusions

Our results revealed no significant differences in estimated raw and normalized  $F_{ACL}$  between maturation groups during unanticipated cutting in young female soccer players. Future analyses should consider examining movement strategies between groups, as well as adjusting the model to better reflect age and sex of the participant by altering body segment mass and inertial parameters, as well as muscular parameters.

## Dynamic foot model to study the syndesmotic variation during the rotation of the ankle

Maria Ruiz<sup>1</sup>, Rostam S. Kojouri<sup>1</sup>, Sorin Siegler<sup>1</sup>

<sup>1</sup>Biomechanics Lab, Department of Mechanical Engineering, Drexel University, Philadelphia, PA

Email: [mr3393@drexel.edu](mailto:mr3393@drexel.edu)

### Summary

A dynamic computational model of the foot, which includes the full tibia and fibula bones, the ankle joint and the midfoot bones up to the metatarsals, is used to study the effect of ankle rotation in the proximal and distal tibiofibular syndesmotic joints. Dorsiflexion/plantarflexion and external/internal rotations are simulated, and the predictions of the model are checked with previous published data as a validation method.

### Introduction

The syndesmotic joint ensures the stability of the ankle. An excessive widening of the distal fibula from the tibia, might lead to joint sprains or injured ligaments. Yet, syndesmotic flexibility is crucial to allow for proper rotation of the foot. Due to the importance of this joint, several studies have been carried out to understand its properties.

In this project, a 3D subject specific model of the foot and ankle is used to study the syndesmotic width variation as the ankle rotates. The relationship between the proximal fibula and tibia is also analyzed, since it is closely related to the syndesmosis of the ankle. Measuring the syndesmotic opening on CT scans is limited to 2D images; using markers on skin during gait is not very reliable either, since the slightest of displacements from these markers may lead to incorrect monitoring of the joint motion. As opposed to these, the computational model provides high precision in 3D for all sorts of situations. This analysis also serves as a validation for the model by matching its predictions to previously published data.

### Methods

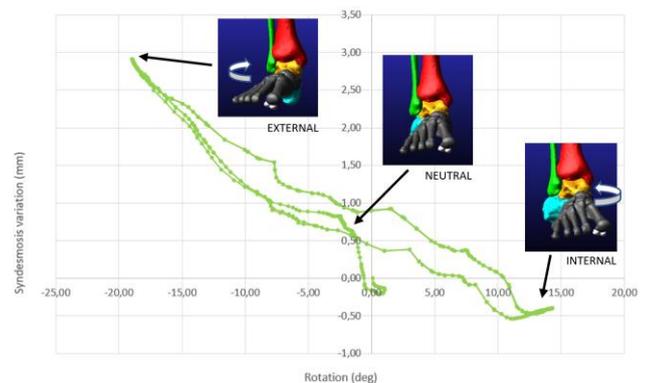

While the original computational model kept the fibula and tibia completely fixed [1], the fibula is released for all 6 degrees of freedom in this project, which allows for the analysis of the syndesmotic joint. Apart from the ankle ligaments the model had, the proximal and distal tibiofibular ligaments, as well as the interosseus membrane, had to be included to connect the fibula to the tibia. The midfoot bones were another addition to the computational model since they can have an effect in the behavior of the ankle during certain activities. All the ligaments were assumed to act as tension-only springs, with individual non-linear strain properties. Contact between the bones is assumed to be frictionless and no penetration is allowed. The articulating bone surfaces have also been offset to compensate for cartilage.

The computational model is set to rotate passively in dorsiflexion/plantarflexion and external/internal rotation. These two rotations have been proven to have the largest effect on the syndesmosis. For that, the simulation will be set

up with the tibia completely fixed, while the other bones are free to move in any directions as controlled by the ligaments and the contact mechanics. An axial load of half body weight is applied upwards to serve as ground force reaction. At the same time, a rotational moment is applied to the foot for each of the two directions. Thus, matching the experimental set-up of cadaveric studies that were published in the past, where variations in syndesmosis in the proximal and distal sides were recorded [2,3].

### Results and Discussion

As the foot is made to go through a moment of 10Nm for dorsiflexion/plantarflexion, its rotation ranges 40°. It can be seen during the simulation, that when the foot goes into dorsiflexion, a coupling of slight external rotation is produced, which pushes the fibula 1.3mm away from the tibia. When a moment is applied in external/internal rotation, the foot rotates 34°, and the syndesmosis widens up to 2mm. The foot internally rotated barely affects the position of the fibula, while in external position, the talus pushes the fibula from the tibia, thus increasing the syndesmotic width (Figure 1). This particular test is very commonly carried out during clinical procedures to test typical syndesmotic injuries.

**Figure 1:** Syndesmotic width variation during external/internal rotation of the foot.

### Conclusions

This computational model of the foot and ankle proved to be very powerful to further understand the biomechanics of the foot under different conditions. Besides, the data from the simulations match the same patterns to previous published results, which increases the reliability of the model.

## Verification of a Method to Examine the Effects of a Knee Brace on Joint Loading and Muscle Activity

Ryan C.J. Baxter<sup>1</sup>, Scott C.E. Brandon<sup>2</sup>, Janet L. Ronsky<sup>1</sup>

<sup>1</sup>Schulich School of Engineering, University of Calgary, Calgary, AB, Canada

<sup>2</sup>School of Engineering, University of Guelph, Guelph, ON, Canada

Email: ryan.baxter2@ucalgary.ca

### Summary

Knee braces are commonly prescribed for knee osteoarthritis (OA) to reduce pain and improve user function. The Levitation brace from Spring Loaded Technology (SLT) was designed to reduce forces in all compartments of the knee by lowering quadriceps muscle activity, a predictor of knee joint contact force. Here we verify a 3-D musculoskeletal (MSK) modelling method to evaluate the effect of the Levitation brace on knee joint loading and quadriceps muscle activity during gait for the first time. We verify that knee extension moment and quadriceps activity are reduced when the brace is applied versus when the brace is not, as expected. Further model development is required in order to assess potential differences in compartmentalized knee joint contact forces.

### Introduction

Musculoskeletal (MSK) computer modelling approaches are commonly used to estimate knee joint contact forces from measured biomechanical data [1]. A wide variety of methods and models can be applied for solving joint contact forces under different conditions, making verification an important step in determining the effectiveness of these models [2].

Knee braces are prescribed for knee OA, a debilitating MSK disease, as assistive devices to reduce pain and improve function for the user. The SLT Levitation knee brace was designed to reduce forces in all three compartments of the knee, by lowering the tensile quadriceps muscle forces that compress the knee joint [3]. This is achieved using a silicon liquid spring to store energy during knee flexion and return energy to assist in knee extension. A previous 2-D modelling study shows reduced quadriceps and knee contact forces with the Levitation brace [4], but 3D knee contact forces have yet to be assessed. The objective of this study is to verify a 3-D MSK modelling method to examine the effects of the Levitation brace on knee joint loading and quadriceps muscle activity. By applying an external moment to the knee, the brace is expected to reduce knee contact forces, knee extension moment and quadriceps activity, which are the measures used to verify the model performance. The results will provide valuable insight to inform design modifications.

### Methods

*In-vivo* walking data collected for a single participant for the second “Grand Challenge” MSK modelling competition was used as the raw input data [3]. Kinematic data from marker trajectories and ground reaction force (GRF) data was collected and used to inform a generic MSK model, using OpenSim [1]. The model, comprised of 18 segments and 92 muscle-tendon actuators, was scaled using static trial data. The model was augmented to include an expression-based coordinate force at the knee joint to represent the Levitation knee brace (data provided by SLT). Two conditions were

analyzed: brace ‘on’ and brace ‘off’, to verify that the model predicts decreases in knee measures with the brace external moment applied. Inverse kinematics (IK) were determined with the gait data. IK results and GRF data were filtered (dual-pass, 2<sup>nd</sup>-order Butterworth filter, 6 Hz and 12 Hz cutoff frequencies, respectively) to calculate inverse dynamics. Residual reduction was applied and internal knee extension moments were determined and compared between bracing conditions. Muscle forces during walking were solved using static optimization techniques. Quadriceps muscle forces were compared between braced and unbraced conditions in order to verify that the brace decreased muscle force output. Knee joint contact forces calculated using joint reaction analysis were compared to evaluate differences with bracing.

### Results and Discussion

Applying the simulated brace resulted in reduced knee extension moment up to 33% (Fig.1) and quadriceps muscle activity between 4-17% compared to the unbraced condition, verifying the successful implementation of the brace modelling method. Knee contact forces showed no substantial differences between conditions, which was not surprising given the low flexion angles associated with walking and brace angular force profile. Future work will focus on analyzing movements involving greater knee flexion ranges and developing a more sophisticated model.

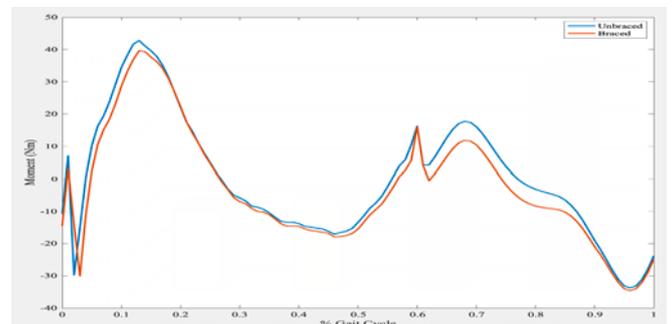

Figure 1: Knee extension moment across gait cycle.

### Conclusions

The modelling method incorporating the Levitation brace was successfully verified producing results to evaluate differences between simulated braced and unbraced conditions for knee joint loading and muscle activity. Further research is required to assess potential knee joint contact force reductions with this brace in greater ranges of knee flexion/extension.

## Effect of Muscular Fatigue on ACL Loading in Healthy and ACL-Reconstructed Females

Shelby Peel<sup>1,2</sup>, Jake Melaro<sup>1</sup>, Jeff Reinbolt<sup>1</sup>, Songning Zhang<sup>1</sup>, Liesel Schneider<sup>1</sup>, John Sorochan<sup>1</sup>, Joshua Weinhandl<sup>1</sup>

<sup>1</sup>University of Tennessee, Knoxville, TN, USA, <sup>2</sup>High Point University, High Point, NC, USA

Email: [speel@genevaUSA.org](mailto:speel@genevaUSA.org)

### Summary

Females are 16 times more likely to sustain a second anterior cruciate ligament (ACL) injury compared to their healthy female counterparts. Many of these females return to sport after ACL-reconstruction (ACL-R). Muscular fatigue is a hypothesized risk factor for female athletes. Previous studies suggest both fatigue and previous ACL-R can independently influence ACL loading ( $F_{ACL}$ ). Seven healthy and four ACL-R females completed five anticipated cutting trials pre- and post- a fatigue protocol. Musculoskeletal modeling was used to estimate  $F_{ACL}$  pre- and post-fatigue. No significant differences were found in  $F_{ACL}$  between groups or fatigue.

### Introduction

Up to 83% of ACL-R athletes return to their pre-injury sport, however 10 to 30% may sustain a secondary ACL injury. Re-injury of the ACL-R leg is multifactorial, such as altered lower extremity mechanics and altered muscle activity. However, lesser understood factors, such as muscular fatigue, could play a role in ACL reinjury. Previous research has shown that fatigue can influence lower extremity ACL-injury risk mechanics in both healthy and ACL-R females. However, it is unknown if fatigue can influence  $F_{ACL}$ . Therefore, the purpose of this study was to investigate the effects of fatigue on  $F_{ACL}$  pre- and post- during a laboratory-based fatigue protocol in healthy and ACL-R females.

### Methods

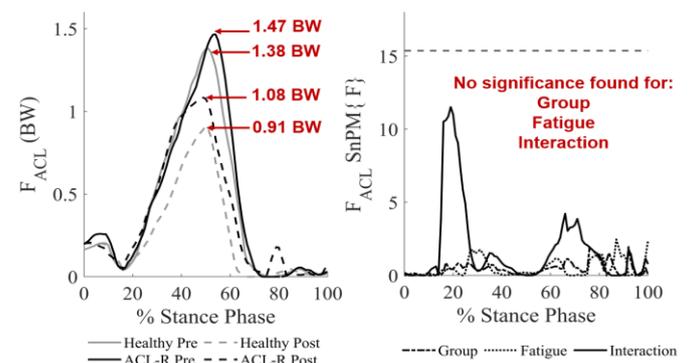

Seven healthy ( $23.0 \pm 2.6$  yrs,  $69.2 \pm 6.9$  kg;  $1.66 \pm 0.6$  m) and four ACL-R ( $21.8 \pm 2.1$  yrs,  $67.3 \pm 4.8$  kg;  $1.68 \pm 0.6$  m) recreationally active females volunteered to participate in this study. Participants first completed a 5-minute self-selected warm-up, followed by five box land-and-cut trials from a 30 cm box placed  $\frac{1}{2}$  their height from the force plates. They completed a laboratory-based fatigue protocol, then performed five additional box land-and-cut trials.

A 12-camera motion capture system (200Hz, Vicon) and a force platform (2000Hz, AMTI) were used to collect marker coordinate and GRF data, respectively. Musculoskeletal simulations of the pre- and post-fatigue trials were conducted in OpenSim (v3.2, <https://simtk.org/>). Inverse kinematics and inverse dynamics were used to calculate joint angles and moments from a participant-specific scaled musculoskeletal model [1]. Static optimization was used to decompose joint torques into net muscle forces. Anteroposterior knee joint reaction forces using the muscle forces obtained from static optimization were computed using the JointReaction Analysis in OpenSim. Finally, anteroposterior knee joint reaction force was used to estimate  $F_{ACL}$  relative to the tibial coordinate system using a previously established mathematical ACL model [2,3].

Differences in  $F_{ACL}$  across the entire stance phase between healthy and ACL-R females pre- and post-fatigue was examined via one-dimensional statistical non-parametric mapping (SnPM{F}) 2x2 ANOVAs (group x fatigue). Significance was set at  $p < 0.05$ .

### Results and Discussion

There was no statistically significant group main effect, fatigue main effect, or group  $\times$  fatigue interaction found for  $F_{ACL}$  between healthy and ACL-R females pre- and post- a fatigue protocol ( $p > 0.05$ ). The lack of significance could be attributed to small, uneven sample sizes in the two groups. Descriptively,  $F_{ACL}$  magnitude was lower in both the healthy and ACL-R groups post-fatigue, with the lowest magnitude observed in the ACL-R group at 0.91 BW. Kinematic and kinetic changes at the hip post fatigue in this group could indicate a compensatory mechanism to help stabilize the knee and reduce loading on the ACL post-fatigue.

**Figure 1:** Mean ensemble curves for  $F_{ACL}$  pre- and post-fatigue between healthy and ACL-R females (A) and its respective SnPM{F} output (B) from 0 to 100% of stance phase.

### Conclusions

The study reported no significant differences in  $F_{ACL}$  pre- and post-fatigue in healthy and ACL-R females. Differences in methodology and fatigue protocols, as well as small sample size most likely led to the lack of significant differences in the current study. However, given the limitations to the study, future research should focus on increasing sample size and to grasp a better understanding of how  $F_{ACL}$  is influenced by fatigue and prior ACL surgical intervention.

## Evaluating Anthropometrically Scaled Models of Lateral Pinch to Characterize the Pediatric Hand

Tamara Ordonez Diaz<sup>1</sup>, Jennifer A. Nichols<sup>1</sup>

Email: [tordonezdiaz@ufl.edu](mailto:tordonezdiaz@ufl.edu) [jnichols@bme.ufl.edu](mailto:jnichols@bme.ufl.edu)

### Summary

Musculoskeletal models provide a powerful approach for examining the human hand. We examined lateral pinch simulations using a generic model of the wrist and thumb anthropometrically scaled to represent heights reported across childhood, puberty, older adolescence, and adulthood. Results demonstrated the potential of anthropometrically-scaled generic models to study hand strength across the lifespan, while also highlighting that muscle control strategies may adapt as we age. We concluded that anthropometric scaling can accurately represent age characteristics of the population.

### Introduction

Generic musculoskeletal models are often developed using average data from healthy adult males. Thus, subject-specific or scaled-generic models are needed to represent pediatric populations. To what extent scaled-generic models can accurately represent the spectrum of strength profiles across the pediatric population is unknown. The objective of this study was to evaluate the accuracy of these models by measuring maximum pinch strength, comparing muscle control strategies, and evaluating isometric force scaling.

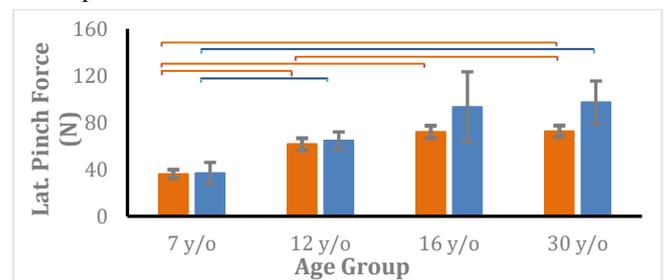

### Methods

Twenty models were scaled from a generic model of the adult wrist and thumb [1] to represent the full range of height (1<sup>st</sup>, 15<sup>th</sup>, 50<sup>th</sup>, 80<sup>th</sup>, and 97<sup>th</sup> percentile) for four ages: 7, 12, 16, and 30 years [2]. For each model, five lateral pinch simulations were performed in OpenSim v. 3.3. Given the contribution of the *flexor pollicis longus* (FPL) is more than 50% for lateral pinch [3], the first set of simulations maximally activated the FPL to simulate maximum pinch strength. Simulations employing different muscle control strategies (50<sup>th</sup> percentile male, age-matched, and literature-based) were then designed to generate the maximum force required for typical activities of daily living. The final set of simulations increased the maximum isometric force of all muscles by a factor of 2. The maximum pinch strength simulations were compared to published experimental data to identify if these models could represent the strength produced at distinct ages [4-9]. To examine how representative the generic muscle control strategy was, the effect of using various control strategies was evaluated. Doubling the maximum isometric force explored the force-length relationship between the muscle's isometric force and lateral pinch force achieved. Paired t-tests were performed to compare the maximum lateral pinch force across age groups for all simulations.

### Results and Discussion

Anthropometric scaling successfully captured age-dependent differences in pinch strength during simulations that maximally activated the FPL (Fig. 1). However, the model's

ability to represent the pediatric population is limited. The 7 y/o models failed to reach the target force of 40 N with all muscle control strategy simulations. Notably, the age-matched muscle control strategy simulations resulted in models activating the extrinsic thumb muscles similarly to published data, but the simulations also heavily relied on the wrist muscles to achieve the target force. Literature-based control strategy simulations failed to run to completion for models scaled below 0.75 corresponding to 132 cm (4 ft. 4 in.) height and showed no improvement for all other models. Linearly scaling the muscle force-generating capacity of all muscles resulted in a nonlinear relationship of maximum lateral pinch force achieved and maximum isometric force.

**Figure 1.** Lateral pinch force versus age for the maximum pinch simulations (orange) compared to experimental data (blue). Error bars represent standard deviation across height.

Given our simulations suggest that muscle recruitment may shift as we age, these models could be used to study how children adapt as their muscles develop and grow stronger. Our simulations were also able to highlight the complexity of the force-length relationship, and how it changes with age and task. The current simulation set-up prevented models younger than 7 y/o to reach completion. However, developing scaled-generic models to represent toddlers will further exemplify whether these results apply to the entire pediatric population.

### Conclusion

Anthropometrically scaled hand models have the potential to represent the scope of strength profiles across the pediatric population. Modeling height difference with age is a critical step toward representing the full diversity of the population. This work motivates future research to elucidate how various musculoskeletal disorders and age-related changes in muscle strength and activation patterns influence hand strength.

## Summary

Various pathologies affect bone alignment in the ankle joint, changing not only the alignment of the joint itself, but also the interaction between its articulating surfaces. Previous definitions have been developed to describe the misalignment of the ankle joint, two of these being the Saltzman angle [1] and the Foot Ankle Offset [2]. These measures, however, do not examine misalignment in all six degrees of freedom. This study examines the parameters of alignment, coverage, and congruity to quantify the alignment of normal ankle joints in six degrees of freedom.

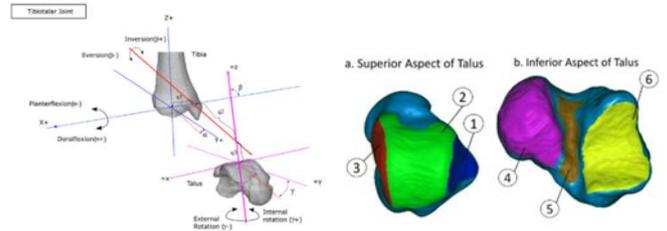

## Introduction

Alignment in this study is examined via a three-dimensional model comparing the translation and rotation of the tibia, talus, and calcaneus. Anatomical frames are defined for the talocrural joint, subtalar joint, and ankle joint complex to quantify the rotation and translation of the joints. Additionally, coverage, defined as the proportion of the articular cartilage region on the bone covered by the contralateral bone, and congruity, defined as the ratio between the standard deviation of the distance map and the average distance within the covered region are calculated, and a database of these measures are compiled and analyzed.

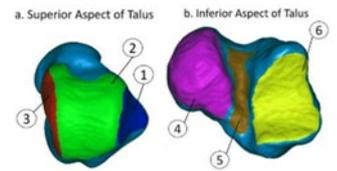

## Methods

Over 100 non-symptomatic subjects were chosen for this study, with the ankle joint CT scanned via Weight-Bearing CT with a resolution of .3mm. 3D bone models were extracted from the CT scan images for the tibia, fibula, talus, and calcaneus. In order to establish the relative orientation of the bones, reference frames were first fully defined for the tibia, talus, and calcaneus. The rotations and translations of the joints were then defined using 313 (z-x-z) Euler angles to define the anatomical frames for the talocrural (Figure 1), subtalar, and ankle joint complex. The anatomical frames were then analyzed using MATLAB to determine the translation in and rotation around the anterior-posterior, medial-lateral, and proximal-distal axes.

For the analysis of coverage and congruity, the ankle joint articular surfaces were identified on the superior aspect (Figure 2a) and the inferior aspect (Figure 2b) of the talus.

**Figure 1:** Anatomical Frame of Talocrural Joint

**Figure 2:** Articulating Surfaces of the a) Ankle Joint and b) Subtalar Joint

Distance maps describing the surface-to-surface distance distribution were produced for each of the regions of interest (Figure 2). The coverage and congruity were calculated from these distance maps for each specimen.

## Results and Discussion

Average coverage and congruity results are displayed in Table 1. Average alignment values in each of the three anatomical frames are displayed in Table 2.

	Coverage	Congruity
Talar Dome	82.49	50.79
Medial Surface	65.45	55.01
Lateral Surface	63.49	58.17
Posterior Surface	82.46	55.23
Central Surface	79.04	66.28
Anterior Surface	33.45	44.52

**Table 1:** Coverage and Congruity of the Joint Surfaces of the Talus

## Conclusions

The alignment, coverage, and congruity parameters determined for normal subjects within this study form a basis for comparison against pathological specimens to identify differences in the pathological cases.

## Summary

Tendon injury treatments have reported mixed success rates and their mechanical implications are unknown. Our goal was to compare the mechanical effects of dry needling (DN), and high-intensity focused ultrasound (HIFU). Fifty *ex vivo* rat supraspinatus tendons were divided into: sham, DN, and 3 HIFU parameter sets: HIFU-1, HIFU-2, and HIFU-3 (n=10/group). Tendons were mechanically tested after treatment exposure to determine elastic modulus, stiffness, and percent relaxation. Outcomes suggest that DN diminishes tendon elastic properties. HIFU preserves elastic properties, with HIFU-1 performing better than HIFU-2 and HIFU-3.

## Introduction

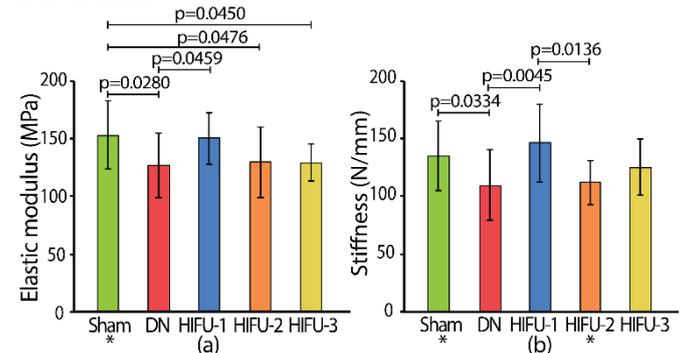

Tendon or ligament injuries at the shoulder represent 81% of all musculoskeletal injuries reported annually [1]. Injured tendons are mechanically inferior, compromising function. Conservative therapies, like dry needling (DN), are widely used; however, DN is invasive and has mixed success rates [2]. As tendons are required to withstand high physiological loads, there is a need for treatments that do not diminish tendon mechanical properties while promoting healing. High-intensity focused ultrasound (HIFU) is an emerging non-invasive therapy that directs ultrasound energy into a well-defined focal volume [3]. Different parameters of HIFU, like pulse length and treatment duration, can be varied to emphasize either tissue heating or acoustic cavitation. In this study, 3 different HIFU parameter sets chosen to emphasize acoustic cavitation were evaluated mechanically and compared to DN and sham.

## Methods

Fifty *ex vivo* rat supraspinatus tendons were divided into: sham, DN, HIFU-1, HIFU-2, and HIFU-3 (n=10/group). For DN, a 30G needle (Tai-Chi, Suzhou, Jiangsu, China) was inserted and quickly removed from the central portion of the tendon 5 times over 12s. HIFU was performed at 1.5MHz with peak +ve and -ve pressure of 89MPa and 26MPa, respectively. The central portion of the tendon was exposed to 1ms pulses @10Hz for 60s for HIFU-1, 10ms pulses @1Hz for 15s for HIFU-2, and 5ms pulses @1Hz for 60s for HIFU-3. Following treatment exposure, tendons were mechanically tested using an MTS 858 Mini Bionix (MTS Systems Corp., Eden Prairie, MN) mechanical testing system, using an established testing protocol [4]. Tendon elastic and viscoelastic properties, including elastic modulus and stiffness, and percent relaxation, respectively, were determined. Statistical analysis was performed using ANCOVA, with sex as covariate, and coefficient of variation in SAS (SAS Institute, Inc., Cary, NC, v9.4), with significance at p<0.05.

## Results and Discussion

Fifty samples were successfully tested; 4 measures were removed as outliers (>2SD outside mean). Elastic modulus of sham was higher than DN (p=0.0280), HIFU-2 (p=0.0476), and HIFU-3 (p=0.0450); modulus of HIFU-1 was higher than DN (p=0.0459) (Fig.1a). Stiffness of sham was higher than DN (p=0.0334); stiffness of HIFU-1 was higher than DN (p=0.0045) and HIFU-2 (p=0.0136) (Fig.1b). Percent relaxation of sham (60.85±15.4%) was higher than DN (50.17±7.6%; p=0.0247) and HIFU-2 (48.90±6.1%; p=0.0069; 1 outlier removed). Results suggest that DN causes a decline in tendon elastic properties. HIFU preserves elastic properties better than DN, with HIFU-1 performing better than HIFU-2 and HIFU-3. Although the percent relaxation of sham was higher than DN and HIFU-2, the coefficient of variation of sham (25.3%) was higher than DN (15.2%) and HIFU-2 (12.4%), possibly due to a higher number of male rats used in sham.

**Figure 1:** (a) Elastic modulus and (b) stiffness of *ex vivo* rat supraspinatus tendons exposed to sham, dry needling (DN), or 3 parameter sets of high-intensity focused ultrasound (HIFU-1; HIFU-2; HIFU-3) settings. \*(n-1) samples due to outlier being removed.

## Conclusions

Tendon mechanical properties in the HIFU-1 group were similar to sham, suggesting that HIFU-1 does not diminish tendon mechanical properties and should be investigated as an alternative, non-invasive treatment for tendon injuries. Further studies are needed to better understand the *in vivo* mechanical and healing effects of DN and HIFU.

## Spatial Distribution of Material Properties Influences Gross and Regional ACL Load Bearing Function

Jillian E. Beveridge, Snehal K. Chokhandre, Ellen M. Klonowski, Kayla Malby, Elise I. Baron, Ahmet Erdemir  
 Musculoskeletal Research Center & Department of Biomedical Engineering, Cleveland Clinic, Cleveland, USA  
 Email: [beverij2@ccf.org](mailto:beverij2@ccf.org)

### Summary

We show that locally assigned ACL material properties based on the distribution of MR  $T_2^*$  relaxation times alters the estimate of tissue reaction force and stress-strain distributions during an anterior drawer test.

### Introduction

The native in vivo function of the anterior cruciate ligament (ACL) and its bearing on long-term joint health following repair or reconstruction remains ill-defined. To this end, we are developing a computational pipeline to estimate the role of localized ACL tissue properties and their influence on tibiofemoral contact mechanics using a computational model that incorporates quantitative magnetic resonance (MR) imaging properties. Here, we describe our approach and preliminary results.

### Methods

**Subject & data acquisition.** A computational model of the porcine anterior cruciate ligament was developed from an 18-month old male Yucatan minipig. All animal procedures were reviewed and approved by our institutional animal care and use committee. MR images were acquired in vivo on a 3T scanner to ascertain tibiofemoral and ACL geometry (double echo steady state sequence; 0.36x0.36x0.7mm resolution) [1] and ACL  $T_2^*$  relaxation time (gradient multi-echo sequence; 0.42x0.42x0.8mm resolution) [2]. **Model parameters:** After manual segmentation, bone surfaces were represented using triangular meshes and the ACL was meshed using linear tetrahedral elements with a mesh density comparable to MR image resolution. Bones were modeled as rigid bodies, and the ACL as a deformable transversely isotropic Mooney-Rivlin material. The ligament was attached to the bones by tie constraints between the surface nodes of the ligament at insertion sites and the bony rigid bodies. Any wrapping of the ligament around bone surfaces was modeled as frictionless contact. A posterior femoral translation of 3 mm was prescribed to simulate an anterior drawer test. **ACL load simulations:** Three conditions were simulated: (1) homogeneous healthy ligament; (2) homogeneous weak ligament; and (3) heterogeneous ligament based on the spatial distribution of MR  $T_2^*$  relaxation times by scaling the local element material coefficients (C1, K, C3, C5) to range between zero and healthy values (Table 1). C2=0; C4=116.22; and lam\_max=1.046 MPa parameters were constant across all simulation conditions.

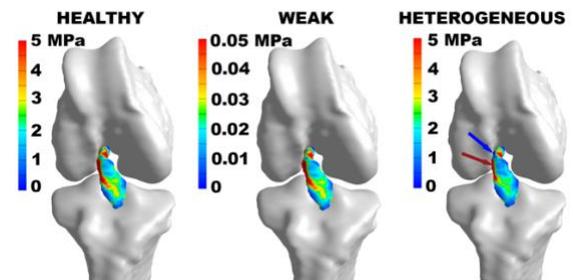

**Table 1:** Model material properties (units in MPa).

	(1) Healthy	(2) Weak	(3) Heterogeneous
C1	1.95	0.0195	0 - 1.95
K	146.41	1.4641	0 - 146.41
C3	0.0139	0.00139	0 - 0.0139
C5	535.039	5.35039	0 - 535.039

Finite element analysis was conducted using FEBio (v2.9). For each simulation, fiber stretch and effective stress distributions were inspected and the reaction forces at 3 mm anterior drawer were extracted.

### Results and Discussion

Under the simulated anterior drawer test, total reaction forces for healthy, weak, and heterogeneous ACL conditions were 398N, 3.98N and 321N, respectively. Effective stress varied across conditions, with the MR  $T_2^*$ -based heterogeneous model demonstrating the greatest variation which was particularly evident between adjacent ligament regions at the proximal third of the ACL (red vs. blue arrows, Figure 1).

**Figure 1:** Effective stress distribution across the 3 ACL conditions. Fiber stretch distribution was similar to effective stress results with the heterogeneous ACL demonstrating the greatest magnitude of localized regional variation.

Our results suggest that greater ACL computational model sensitivity might be achieved by scaling the material properties according to the spatial distribution of MR  $T_2^*$  relaxation times. The 20% reduction in estimated reaction force between healthy homogeneous and heterogeneous models is substantial. Given injured or repaired ligament will likely have a much larger variation in material properties with a tendency towards a higher proportion of weaker ligament [3], taking into account the spatial distribution of weaker regions is likely to be critical for accurately estimating the in vivo mechanical behaviour and (re)injury risk of healing or remodeling ACL.

### Conclusions

Preliminary model outputs show sensitivity to our approach and supports further model development.

### Summary

Although there is still a difference between using the cadavers and the real situation, our study might provide information not only to understand the importance of AOL for the stability of the CMC joint but also to refer the standard in the force and movement mode in clinical examination or traditional rehabilitation programs. In muscle training, for the thumb CMC joint instability, according to results, the training programs included the FDI muscle strengthening could provide stability for subjects with joint problems in some situations. But from another point of view, the joint distance was decreased after FDI training. If applied to some cases that already had OA or bone spurs around the joint, it would cause these groups to have more severe pain or accelerate the production of OA.

### Introduction

Since instability of the thumb carpometacarpal (CMC) joint is such a common issue, but nowadays, there are still many kinds of opinions and methods in the clinical examinations and treatments [1,2]. In this study, we set cadaver models to simulation the modified thumb abduction stress test and frequent functional movement to analyze the CMC joint distance in different muscle loadings. Besides that, we also investigate how the joint change after the AOL ligament injury and whether the hand intrinsic muscle training can provide good joint stability after ligament damage.

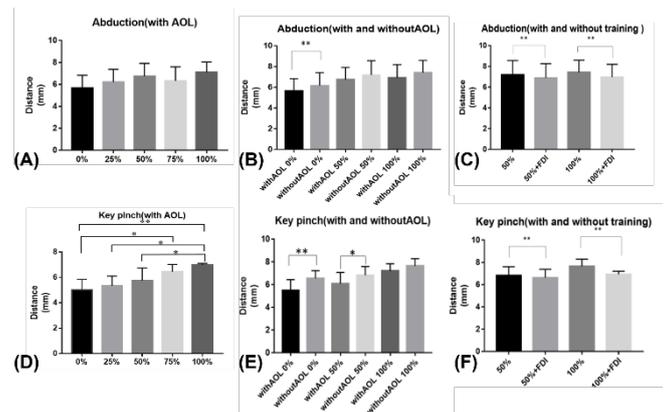

### Methods

A total six left hands was performed in this study. A custom mechanism [3] was used to imitate the subject of performing a thumb abduction stress test and key pinch movement at various muscle maximal loading in different conditions, such as removing the anterior oblique ligament (AOL) and strengthening the FDI muscle. Then, we created 3D images by computer tomography (CT) and calculated the geometric center distance of the thumb CMC joint using software from all experimental data. The paired t-test and one-way ANOVA were used to analyze and set a p-value defined less than 0.05 as statistical significance.

### Results and Discussion

Without removing the soft tissue around the CMC joint, the joint distance increased between 0% and 50% maximal loading in the abduction movement but decreased when the force reaches 75%. However, in key pinch movement, the joint distance was significantly increased as loading increases (P=0.015). After removed the AOL ligament compared with

those who have not been removed, the joint distance increased and reaches a statistically significant under 0% tension (P=0.005) in the abduction and significantly increased at 0% (P=0.005) and 50% (P=0.016) maximal loading in a key pinch. When added to the FDI muscle training, the joint distance reduced compared to before and had statistically significant at 50% and 100% loading in both movements (P<0.01). (Figure 1.) Those data can find out that while the applied force increases, the joint distance also increases gradually. Additionally, after removed the AOL, the joint distance had increased. It means that AOL plays an essential role in stabilizing the thumb CMC joint for movement. It demonstrated that the joint distance decreased after the imitation of the FDI training program in both movements.

**Figure 1:** Distance values of abduction and key pinch movement (A) with the AOL of abduction (B) without the AOL of abduction (C) FDI muscle training of abduction (D) with the AOL of key pinch (E) without the AOL of key pinch (F) FDI muscle training of key pinch

### Conclusions

Our result provides a useful reference for clinical staff as making rehabilitation programs and common suggestions for subjects suffering from joint instability.

## Transfemoral prosthesis user stumble recovery responses for both limbs across swing phase

Maura E. Eveld, Shane T. King, Karl E. Zelik, and Michael Goldfarb  
 Department of Mechanical Engineering, Vanderbilt University, Nashville, TN USA  
 Email: maura.e.eveld@vanderbilt.edu

### Summary

In order to inform fall prevention interventions, four transfemoral prosthesis users who use the Ottobock C-Leg were tripped 3-4 times per limb during treadmill walking using our custom stumble perturbation system. Stumble recovery responses were analyzed along with participant age, prosthesis type, and swing percentage of perturbation.

### Introduction

Transfemoral prosthesis users fall 200x more often than age-matched controls [1]. In order to develop interventions (e.g., prostheses, training) to decrease this population's fall incidence, it is important to understand the deficiencies in the recovery strategies attempted by the individuals as well as the shortcomings in the function of their prescribed prostheses.

For able-bodied adults, responses to perturbations depend on the timing of the perturbation during swing phase and the age of the individual. Typically prescribed prosthetic knees have various joint designs (e.g., single-axis, polycentric) and control schemes (e.g., fixed vs. variable damping), aspects that affect their behavior following perturbations. Thus, understanding how these factors (i.e., age, swing phase, and prosthesis type) affect recovery responses, and how they interact, is crucial to ultimately providing beneficial interventions. While a few studies (e.g., [2,3]) have contributed to this knowledge gap, the cumulative number of data points remains too small to draw strong inferences regarding the nature of such recovery responses, and how prosthesis functionality might mitigate or aggravate the likelihood of a fall.

The overarching goal of our study is to analyze a case series of obstacle stumble events accounting for a range of participant ages, prosthesis types, and points in swing phase. For this abstract we investigate a subset of this case series in order to hold one variable constant (prosthesis type). Specifically, we aim to characterize the strategies attempted and fall outcomes of Ottobock C-Leg users for each limb across swing phase.

### Methods

Four Ottobock C-Leg users were recruited for a stumble perturbation experiment. Each participant experienced 3-4 unexpected obstacle perturbations to each limb, targeted to occur in early, mid, and late swing phase, while walking on a treadmill at 0.8 m/s. The custom obstacle perturbation system and protocol used are detailed in [4]. For each stumble, the recovery strategy attempted (as defined in [2, 4]) and fall outcome (fall identified as >50% bodyweight measured by a load cell in-line with overhead harness) were reported, as well as the swing percentage of the perturbation. Ground-reaction forces and kinematic data were collected, and joint-level kinematics/kinetics were computed.

### Results and Discussion

Swing percentage of perturbation, recovery strategy attempted, and fall outcome are reported for each stumble (Figure 1). Full results/analyses will be presented at the conference; here we highlight a few key results. *Stumbles to sound-side swing phase:* The older participants (P1, P2) never recovered, regardless of swing phase percentage, while the younger participants (P3, P4) recovered from all but one perturbation. The participants who fell were unable to initiate swing in early/mid-stance with their prosthetic limb. These results align with studies of older able-bodied adults, who fall more often due to slower reaction time and less muscle strength. *Stumbles to prosthetic-side swing phase:* Three participants recovered from all mid/late-swing perturbations with a lowering/delayed lowering strategy; the C-Leg's resistance to flexion increases during the extension portion of swing phase (when these perturbations occurred), which prevented buckling and facilitated a lowering step. However, these recoveries involved substantial thigh abduction (avg 31+/-7 deg) to clear the obstacle in the following step due to the C-Leg's insufficient knee flexion; P2's lack of thigh abduction (13 deg) inhibited his ability to clear the obstacle, resulting in a fall.

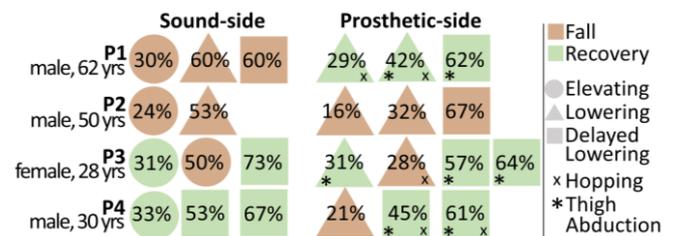

Figure 1: Swing percentage of perturbation (number), recovery strategy attempted (shape, symbol), and fall outcome (color) for each stumble for four C-Leg users.

### Conclusions

For sound-side stumbles, the two older C-Leg users had more difficulty recovering than the two younger participants; they may benefit from assistance initiating prosthetic swing in early/mid-stance. For prosthetic-side stumbles, while flexion resistance prevented prosthetic knee buckling at perturbation, substantial thigh abduction was still essential to recover from mid/late-swing perturbations; additional prosthetic knee flexion in the following step may improve responses.

## Motor Unit Action Potential Features For Robust Motion Classification

Michael D. Twardowski<sup>1</sup>, Michael D. Chan<sup>1</sup>, John P. Chiodini<sup>1</sup>, Serge H. Roy<sup>1</sup>, Paola Contessa<sup>1</sup>, Gianluca De Luca<sup>1</sup>, and Joshua C. Kline<sup>1</sup>

Email: [mtwardowski@delsys.com](mailto:mtwardowski@delsys.com)

### Summary

We investigated the feasibility of using our Motor Unit Drive (MU Drive) neural interface for prosthetic control to provide robust motion classification performance at varying muscle contraction intensities. MU Drive employs algorithms for extracting motor unit action potential (MUAP) features from surface electromyographic (sEMG) signals. We trained and tested a motion classifier using the MUAP-features extracted with MU Drive to discriminate 6 different motions of the wrist and hand from sEMG signals detected from 4 muscles of the upper arm across a range of contraction intensities. Our results demonstrated robust motion classification with a median of 93.3% accuracy and an average delay of 137 ms.

### Introduction

Efforts to improve prosthetic control have led to the development of neural interfaces that employ pattern recognition algorithms trained on myoelectric features from sEMG signals collected from several sites on the residual limb to map the various intended motions of the user. This approach however is confounded by variations in muscle contraction intensity that occur during normal operation of prostheses and that diminish the discriminability of myoelectric features and result in low classification accuracies [1, 2]. To overcome the limitations of traditional myoelectric features, our group has developed MU Drive, a neural interface that employs decomposition methods to access MUAP-based features from the individual MUAP firings within the sEMG signal [3], which are the individual components for controlling force and motion. Our prior work has demonstrated that MU Drive can provide responsive real-time proportional control signals across a range of muscle activation levels [3]. We now investigate the potential of employing MU Drive to extract MUAP-features for enabling robust identification of motion classification and intent.

### Methods

Ten healthy subjects with intact limbs volunteered for this research study (5 males, 5 females; age=33.6±16.2). We placed Trigno™ Galileo 4-pin mini-grids over four muscles of the upper-limb that control motions of the hand and wrist—the extensor digitorum communis, the flexor digitorum profundus, the pronator teres, and the biceps brachii—and recorded sEMG signals during repeated trials of 6 different motions of the hand and wrist—finger flexion & extension, wrist flexion & extension, forearm pronation & supination—performed at targeted muscle activation levels of 30%, 60%, and 100% maximum voluntary sustained activation (MVSA). We filtered the sEMG signals from 20–450 Hz and digitized them at 2.222 kHz using a Trigno™ EMG acquisition system (Delsys Inc.). Features indicative of MUAP shape and

amplitude were then extracted using MU Drive in 100 ms non-overlapping windows and used to train a linear discriminant analysis (LDA) classifier, commonly used in prosthetic applications. For each subject, we trained their LDA classifier using 22% of their motion data, and tested its performance on the remaining 78% of motion data. We timed the algorithm to gauge its real-time efficacy.

### Results and Discussion

MU Drive successfully extracted MUAP-features from each non-overlapping 100 ms window with an average 37.0±1.8 ms computational delay. The LDA classifier demonstrated an average accuracy of ranging from 89.8 to 94.4% across all motions and muscle intensities tested – values substantially higher than those reported in previous studies of traditional myoelectric features [1]. (**Table 1**).

**Table 1:** Classifier accuracies at 30%, 60%, and 100% MVSA levels.

Classifier	MVSA	MVSA60	MVSA30
LDA	94.4±4.8%	91.6±13.9%	89.8±12.6%

Overall, the LDA classifier achieved a median accuracy of 93.3%, indicating that MUAP-features extracted using MU Drive enable motion classification that is robust to changes in muscle contraction intensity.

### Conclusions

These results support the feasibility of our MU Drive neural interface system to robustly detect movement intent at varying intensities of muscle contraction. Future research will refine and integrate motion classifiers based on MUAP-features with proportional control demonstrated in our previous work [3] to provide a comprehensive MU Drive system for improved control of prostheses, and robotics systems.

## Exploring Effects of Prosthetic Ankle and Toe Joint Range of Motion on Activities of Daily Living

Rachel H. Teater<sup>1</sup>, Kirsty A. McDonald<sup>2</sup>, Karl E. Zelik<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Vanderbilt University, Nashville, TN, USA

<sup>2</sup>Department of Exercise Physiology, University of New South Wales, Sydney, NSW, Australia

Email: rachel.h.teater@vanderbilt.edu

### Summary

We are exploring if the addition of ankle or toe joint range of motion could improve the ability of lower limb prosthesis users (LLPUs) to perform activities of daily living: sit-to-stand, squatting, lifting, and lunging. We are collecting data with participants performing these tasks wearing their prescribed passive prosthesis and also the Vanderbilt Powered Ankle (used to emulate design changes in prosthetic ankle and/or toe articulation). Preliminary results from a transtibial LLPU on their prescribed prosthesis show highly asymmetric lower limb loading across tasks, with the intact limb experiencing significantly greater loads than the prosthetic limb.

### Introduction

Most LLPUs wear a passive ankle-foot prosthesis where the ankle joint and foot keel are locked at a fixed angle. A significant percentage of these LLPUs live with mobility challenges that affect their ability to carry out daily activities and live independently [1]. Surveys of transtibial LLPUs have found that 11% cannot stand-up from a chair, 25% cannot pick up an item off the floor, 41% cannot get up from the floor, and 40% do not have independent household mobility [1,2]. Many daily tasks such as standing up from a chair, lunging forward, or squatting down involve ankle and toe flexion in healthy individuals – degrees of freedom that are limited or not included in most passive prosthetic feet. Limitations in ankle and toe joint mobility may contribute to task performance deficits or lead to unsafe compensation strategies. For instance, prosthetic device limitations may lead unilateral LLPUs to perform tasks in a highly asymmetric manner, overloading their intact lower limb and thus contributing to overuse injury or degenerative joint disorder risks. Prosthetic design modifications could potentially improve their comfort, safety, or ability to complete certain daily tasks, or do so with less overloading of their intact lower limb. To investigate this, we aim to characterize how LLPUs perform common everyday movements while wearing their prescribed passive ankle-foot device, and assess if adding prosthetic ankle and toe joint range of motion aids LLPUs by improving functional ability, symmetry, and/or perceived stability.

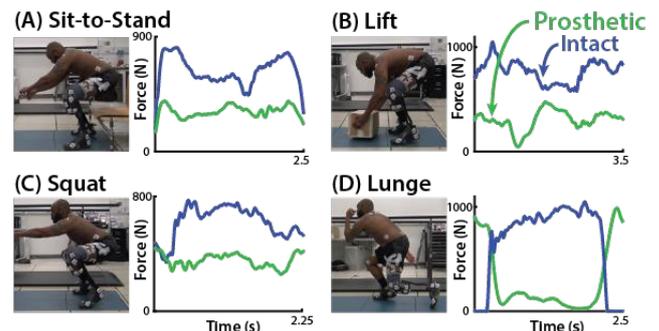

### Methods

Through reviewing the scientific literature and interviewing local LLPUs, physicians, and prosthetists, we identified several tasks that LLPUs often avoid or find challenging and have the potential to be improved by modifying prosthetic ankle-foot design. We are now conducting a human movement study evaluating transtibial LLPUs during these identified tasks: sit-to-stand, lifting, squatting and lunging. To address the first objective, we are collecting data with users performing variations of all tasks in their prescribed passive prosthesis. We then use the Vanderbilt Powered

Ankle to emulate various device design modifications that may improve the ability of LLPUs to complete these tasks, i.e., adding ankle and/or toe joint flexion/extension. We are collecting participant feedback on perceived effort, stability, and comfort as well as motion capture and ground reaction force (GRF) data.

### Results and Discussion

Preliminary data from one transtibial LLPU (K4 mobility level) wearing his prescribed prosthesis (Fillauer AllPro) are presented here. The participant was able to complete all tasks, but expressed that standing up from a low chair and lunging with his prosthesis forward were extremely difficult. Vertical GRFs during tasks that are expected to be symmetric (sit-to-stand, squatting, lifting) showed the intact limb often experienced more than twice the load of the prosthetic limb (Fig. 1A-C). When lunging with the intact limb forward, the participant's intact limb experienced approximately nine times more force than the prosthetic limb (Fig. 2D). Initial healthy control data indicates that the leading limb usually experiences only about twice the force of the prosthetic limb during lunging. This study is ongoing and additional findings will be shared at the conference.

**Figure 1:** Vertical GRF of a transtibial LLPU performing (A) sit-to-stand, (B) lifting (10 kg), (C) squatting, and (D) lunging with his prescribed prosthesis.

### Conclusions

Preliminary results indicate that LLPUs adopt a high degree of asymmetry to complete common tasks, and there may be opportunities to improve symmetry, stability, or functional ability through prosthetic design modifications to the ankle or toes.

# Bone contact differences of conical and cylindrical endoprostheses for transtibial percutaneous osseointegrated prostheses

Carolyn E. Taylor<sup>2,3</sup>, Heath B. Henninger<sup>2,3</sup>, Kent N. Bachus<sup>1,2,3</sup>

<sup>1</sup>Department of Veterans Affairs, Salt Lake City, Utah, United States of America

Email: [carolyn.taylor@utah.edu](mailto:carolyn.taylor@utah.edu)

## Summary

This research developed, validated, and utilized virtual implantation of transtibial percutaneous osseointegrated (OI) endoprostheses for prosthetic limb attachment. The area of virtual bone in contact with two virtual endoprosthesis designs (cylindrical and conical) were analyzed. The results indicate that for transtibial residual limbs greater than 20% residual length, a conical endoprosthesis has a greater ratio of contact area to bone removed when compared to a cylindrical endoprosthesis. Neither design appears optimal for very short amputations of less than 20% residual length due to a high rate of cortical penetration through a thin non-circular medullary canal. Though transfemoral OI attachment systems have demonstrated clinical success in transtibial amputees, this research suggests that not all transfemoral designs are suited for transtibial use, and further research is necessary before utilizing existing percutaneous OI systems for these patients.

## Introduction

Percutaneous OI systems are used to attach prosthetic limbs to the residual bone of an amputee. Most clinical systems rely on conically shaped press-fit or cylindrically threaded fixation to create intimate contact of the endoprosthesis surface to the host bone to encourage skeletal fixation. All devices used clinically were initially developed for the femur, then applied in the tibia [1, 2] without translational research to support either similar, or better clinical results. While there has been some success, continued reports of aseptic loosening [3] indicate that endoprosthesis design may need to be customized for the transtibial population. This research used virtual implantation to estimate contact between the bone and simplified conical and cylindrical endoprosthesis designs.

## Methods

Virtual implantation procedures were validated on 27 cadaver tibias using a conically shaped design [4] as a template for systems with circular cross-section. Part comparison between virtual and surgical preparations confirmed accuracy within CT resolution of 1 mm.

Then, CT scans were obtained and reconstructed for 20 specimen pairs (40 bones). Virtual implantation was conducted using commercially available software (3-Matic

v13.0, Materialise, Plymouth, MI). A 3 cm long, conical (2° taper angle) and a 3 cm long cylindrical endoprosthesis shape were virtually implanted into the medullary canal of these bones at 20, 30, 40, 50, 60, 70, and 80% residual length. The percent of bone-endoprosthesis contact and the percent of bone volume removed during implantation were calculated. The ratio of these two values indicates the amount of bone-endoprosthesis contact per volume removed, and normalized the data.

## Results and Discussion

For the short residual limbs of less than 20% residual length, 72% resulted in cortical penetration at the proximal tip, independent of the design of the endoprosthesis. This also occurred in 50% of cylindrical implantations and 20% of the conical implantations at 80% residual length (Table 1). All instances where the bone penetrated completely through the cortex were removed from compiled results.

Comparing cylindrical to conical designs showed that the cylindrical implants achieved 12.0±6.5% more bone-endoprosthesis contact, but with 4.8±2.5% more bone removed (Table 1). Except for the 20% residual length, all the independent residual lengths showed that when the contact area data was normalized with the bone removal data, that the cylindrical endoprosthesis achieved the greater contact at the expense of greater amounts of bone removed. Therefore, while the cylindrical design may result in greater bone contact, it also removes bone that could compromise the structural integrity of the construct. In contrast, the conical design is more efficient by achieving approximately 30% more contact per unit bone removed.

## Variable Stiffness Foot provides Users with Adjustment of Knee and Ankle Mechanics

Kieran M. Nichols<sup>1</sup>, Peter G Adamczyk<sup>1</sup>

<sup>1</sup>Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, USA

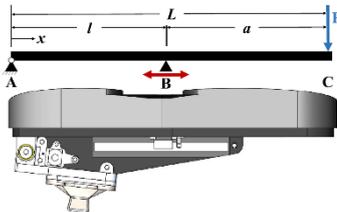

Email: knichols4@wisc.edu

### Summary

The Variable Stiffness Foot prosthesis can modulate its forefoot stiffness through the deflection of a compliant cantilever-beam keel and adjustable support fulcrum. Participants tested the effects of this modulation on leg mechanics in walking using three different VSF stiffnesses. As the VSF stiffness increased, participants exhibited less dorsiflexion and more plantarflexor moment, more knee extension, more knee flexor moment, and less power flow through the ankle. These modulations could be controlled to aid users in walking across various terrain or different speeds.

### Introduction

The Variable Stiffness Foot (VSF) is an energy storage and return (ESR) prosthesis that can passively store and return energy through the deflection of a compliant cantilever-beam forefoot keel [1]. It is a semi-active prosthesis [1] that allows real-time control of stiffness that can be dependent on the type of activity (standing, flat ground walking, ramp and stairs walking). The VSF prototype's effective stiffness is modulated by a support fulcrum moved by a motor and belt.

**Figure 1:** side drawing of the VSF highlighting the cantilever mechanics [1].

Previous studies in prosthetics found that increased range of motion for stairs and ramps is associated with improved gait [2]; a stiffer ankle (increased moment for small change of angle) is helpful for standing stability [3]; and a compliant forefoot returns more energy to the rest of the body [4]. We hypothesized that increasing forefoot stiffness would lead to decreasing ankle dorsiflexion angle, increasing peak ankle moment, and decreasing uniform deformable body power (related to decreasing energy returns in push-off), along with increasing knee extension angle and knee flexor moment.

### Methods

Seven persons with trans-tibial amputation walked across two force plates (one foot on each plate) in a motion capture lab. The participants walked with three different VSF stiffness settings (compliant-1, medium-2, and stiff-3; each scaled to each person's body mass) for 3 trials at  $1.1 \pm 0.1$  m/s.

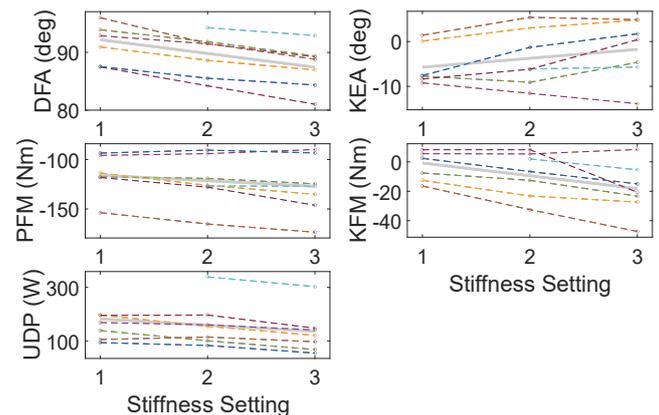

Motion and force data were processed to estimate joint angles and moments using standard inverse dynamics, and power flow through the ankle from the prosthesis using a deformable body model (Unified Deformable power, UDP) [5]. Peak values of ankle dorsiflexion angle (DFA), plantarflexor moment (PFM), midstance knee extension angle (KEA) and

knee flexor moment (KFM), and UDP were computed for each stride on the prosthetic side and averaged across the three trials for each stiffness setting. Mixed linear effects models were used to estimate the sensitivity of these metrics to stiffness settings, their significance (p-value), and the coefficients of determination ( $r^2$ ) of their regressions.

### Results and Discussion

Stiffer VSF settings led to reduced DFA ( $r^2=0.97$ ,  $p<0.0001$ ), increased KEA ( $r^2=0.88$ ,  $p=0.0001$ ), more negative PFM ( $r^2=0.95$ ,  $p<0.0001$ ), more negative KFM ( $r^2=0.88$ ,  $p=0.0001$ ), and reduced UDP ( $r^2=0.97$ ,  $p<0.0001$ ) during toe off, which correlates with reduced push off energy. Interestingly, more extended knee angle was associated with more negative knee flexor and ankle plantarflexor moments.

**Figure 2:** mixed linear effect trends for ankle and knee angles, moments, and UD power. The grey bar represents the mixed linear effects fit of all subjects for the given metric. Plantarflexion/flexor (ankle) and flexion/flexor (knee) are in the negative direction.

### Conclusions

The VSF enables modulation of mechanical outcomes through controlled stiffness. Automated, real-time stiffness control could enable adaptation to terrain conditions such as sandy, muddy, wet or icy ground as well as stairs and ramps, or to alter biomechanical loads such as undesirable knee moments.

## Summary

Recently, foot-ankle exercises have been recommended for people with diabetic neuropathy (DPN) risk 1 and 2; however the effects of this type of intervention on foot motion during gait is yet to be determined. We designed a randomized controlled clinical trial RCT (NCT02790931) aiming to evaluate the effects of a 12-week physiotherapeutic foot-ankle exercises supervised program on foot-ankle kinematics in people with DPN. Fifty-six subjects were enrolled in this study and were allocated into the control (CG) and intervention groups (IG). Plug-In Gait and Oxford Foot Model setup protocols were used for gait kinematic acquisition at baseline and 12 weeks after the intervention. After the intervention, IG compared to CG increased forefoot relative to hindfoot dorsiflexion range of motion (ROM) ( $p < 0.0131$ ) during gait stance phase.

## Introduction

DPN evolves progressively with sensitivity and motor deficits including vibratory, thermal, tactile, proprioception sensitivities, atrophy of foot-ankle extrinsic and intrinsic muscles, foot deformities, and all these alterations usually ended up affecting gait mechanics and balance [1,2]. Physiotherapeutic supervised exercises targeting foot-ankle function may be beneficial for people with DPN and they are now part of international guideline recommendations for people at risk of diabetic foot disease. Few RCTs evaluated the effects of foot-related strengthening and mobility exercises in different outcomes - especially biomechanical outcomes - the majority are of low quality, present small effect sizes, and do not involve exercises that specifically target the main musculoskeletal dysfunction in people with DPN. This study aimed to assess the effect of a 12-week physiotherapeutic foot-ankle exercises supervised program on foot-ankle kinematics in DPN people.

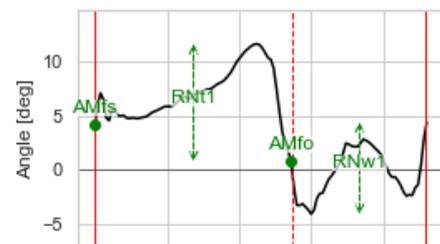

## Methods

Fifty-six participants of both sexes with clinical diagnosis of type 1 or 2 diabetes and DPN were randomly allocated to CG ( $n=26$ ,  $61.3 \pm 8.48$  yrs) or IG ( $n=30$ ,  $63.0 \pm 10.7$ ) and foot-ankle kinematics were evaluated at baseline (T0) and week 12 (T12) after face-to-face physiotherapeutic foot-ankle exercises by 8 cameras at 100 Hz (VERO, Vicon). Plug-In Gait and Oxford Foot Model setup protocols were used. Participants walked barefoot at a self-selected speed on a walkway and 3 valid steps (stance phase) on left side were acquired. Digitisation, 3D reconstruction of the markers' positions and filtering of kinematic data were performed in NEXUS software (v. 2.10.3). Kinematic data were processed using a zero-lag 2<sup>nd</sup>-order low-pass filter (6Hz). Kinematics were computed with the open-source Python package pyCGM2 ([www.pycgm2.github.io](http://www.pycgm2.github.io)) replicating the Vicon Plug-In Gait protocol and Plug-In of Oxford Foot Model. The variables calculated were: ROM of

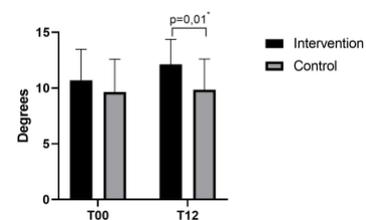

first metatarsal, midfoot and rearfoot joints relative to the proximal segment. Comparisons between groups and assessments (T00 and T12) were performed by 2-way ANOVAs (groups and repeated measures) to each variable followed by Bonferroni post hoc ( $p < 0.05$ ).

## Results and Discussion

After 12 weeks, the IG improved ROM of forefoot relative to hindfoot dorsiflexion, and the difference to the CG was 2.6 degrees ( $p < 0.0131$ ), suggesting a better foot adaptability during stance phase [3], because the increase in the forefoot relative to hindfoot dorsiflexion may assist the arch raising mechanism at the end of stance phase. There were no other differences in any other biomechanical variable.

**Figure 1:** Example of a kinematic temporal series with forefoot relative to hindfoot dorsiflexion (degrees). RNt1 = dorsiflexion degree

**Figure 2:** Forefoot relative to hindfoot dorsiflexion (degrees) mean and standard deviation for Intervention and control groups at baseline (T00) and week 12 (T12).

## Conclusions

This study evaluated foot-related biomechanical outcomes after 12 weeks of foot-ankle exercise protocol focused on improving intrinsic foot muscle functionality and showed positive changes in the IG on forefoot relative to hindfoot dorsiflexion, suggesting a better foot adaptability during gait stance phase.

# Effects of Short-Term Cycling Intervention on Knee Biomechanics in Cycling with Augmented Visual Biofeedback for Patients with Total Knee Arthroplasty

Songning Zhang<sup>1</sup>, Erik T. Hummer<sup>2</sup>, Jared Porter<sup>1</sup>, Harold Cates<sup>3</sup>

<sup>1</sup>Department of Kinesiology, Recreation, and Sport Studies, University of Tennessee, Knoxville, TN, USA

<sup>2</sup>Center for Mobility and Rehabilitation Engineering Research, Kessler Foundation, West Orange, NJ, USA

<sup>3</sup>Tennessee Orthopaedic Clinics, Knoxville, TN, USA

Email: [szhang@utk.edu](mailto:szhang@utk.edu)

## Summary

The purpose of this study was to examine effects of short-term cycling intervention with augmented feedback of vertical pedal reaction force (PRF) on asymmetry and inter-limb biomechanical differences in patients with total knee arthroplasty (TKA). The results showed that asymmetry indices (AI) for knee extension moment (KEM) showed clinical improvements after the intervention.

## Introduction

Patients with TKA experience inter-limb differences of vertical ground reaction force and KEM in walking [1] and cycling [2]. These inter-limb differences persist following rehabilitation and may lead to contralateral knee osteoarthritis and TKA. Intervention may improve the observed asymmetry. There is a lack of information on effects of cycling interventions for this patient group. The purpose of this study was to examine the effects of short-term cycling intervention with augmented feedback of vertical PRF on asymmetries of vertical PRF and KEM and biomechanical inter-limb differences in patients with TKA.

## Methods

Ten unilateral TKA patients attended a 6-session cycling intervention over two weeks and were tested on their cycling biomechanics before and after the intervention. During the intervention, participants were provided with visual biofeedback on their vertical PRFs of both lower limbs and asked to reduce AI below 10% during training bouts. Each session included multiple 5-minute cycling training bouts.

During the two test sessions, participants cycled on cycle ergometer (Excalibur Sport, Lode) in two randomized workrate conditions [80 and 100 Watts (W)] at a cadence of 80 RPM. Participants cycled for one-minute in each condition, with data collection occurring in the final 10 seconds. Three-dimensional motion capture (240 Hz, Vicon) and PRF data (1200 Hz, Kistler) were collected. A one-way repeated ANOVA was used to evaluate AIs and a 2 x 2 (limb x time) repeated measure ANOVAs were run on the mean

data for the discrete secondary variables for 80 and 100 W conditions separately. Effect size (ES) was assessed using partial eta squared ( $\eta^2_p$ ).

## Results and Discussion

After intervention, vertical PRF AI decreased from 5.4% to -3.0% at 80 W ( $p = 0.256$ ,  $\eta^2_p = 0.141$ ) and 1.4% to -3.9% at 100 W ( $p = 0.479$ ,  $\eta^2_p = 0.064$ ). KEM AI decreased from 25.7% to 15.7% at 80 W ( $p = 0.499$ ,  $\eta^2_p = 0.052$ ) and 23.6% to 13.7% at 100 W ( $p = 0.395$ ,  $\eta^2_p = 0.092$ ). The ANOVA results for secondary variables showed peak posterior PRF at 100 W increased following the intervention compared to pre-training (Table 1). Additionally, there was significantly greater posterior PRF in the non-replaced limb for 80 and 100 W compared to replaced limb. Peak KEMs for both work rates were lower for the replaced limb (Table 1). Additionally, the replaced limbs showed decreased knee extension ROM compared to the non-replaced limbs.

These results suggest that the short-term cycling intervention with augmented biofeedback did reduce KEM asymmetry by 10% with medium ES, indicating a clinically relevant reduction [3].

## Conclusions

While not statistically significant, reductions in KEM asymmetry of 10% or greater could indicate clinically relevant changes. The cycling intervention paired with augmented feedback may be beneficial in reducing the asymmetry during stationary cycling.

<sup>†</sup> Corresponding author, j\_shin@kaist.ac.kr

### Summary

Stroke is one of the leading causes of death and the primary cause of disability. Rehabilitation treatments using exogenous electrical stimulation (ES) have been utilized successfully in a clinical setting, but the precise mechanism of how ES works remain elusive. In this study, we first established a 3D stroke model by forming multicellular spheroids and applying oxygen-glucose deprivation and reperfusion (OGD-R). We then tested the effectiveness of ES on the cells of the stroke model based on the changes in the phenotypes and gene/protein expressions. We found the compromised neuroplasticity after OGD-R stimulation and the partial recovery of neuroplasticity by electrical stimulation.

### Introduction

According to a recent report, a stroke occurs in one out of five persons during a lifetime and has become one of the leading causes of death and primary cause of disability worldwide. Recent studies have shown that the ES can increase brain plasticity and improve rehabilitation efficiency. However, the poor understanding of the mechanism poses many obstacles to the clinical application of the ES. Therefore, we employed 3D multicellular spheroids that can simulate the brain's three-dimensional microenvironment to examine their morphological and biological changes following the ES treatment.

### Methods

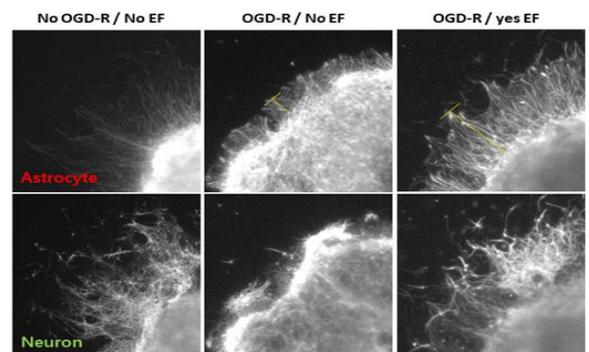

Cells were extracted from the cortex of postnatal one-day rats and maintained in Neurobasal™ Medium with 2% B-27™ Supplement (50X), 1% GlutaMAX™ Supplement and 1% Penicillin/Streptomycin. To form 3D cellular spheroids, the cell suspension was plated on 96-well Corning® Ultra-Low Attachment Products. Also, the oxygen-glucose deprivation and reperfusion (OGD-R: 5% CO<sub>2</sub>, 94% N<sub>2</sub>, 1% O<sub>2</sub>, 4 hours) process was utilized to construct a stroke model on the Day 7 of the *in vitro* culture. For ES, dcEF was applied at 2.0V/cm for 1 hour. 2D spreading assay was performed to examine cellular morphology on a poly-d-lysine (PDL) coated cover glass after the ES, and immunofluorescence staining was performed after three days to check any ES-induced morphological changes. Total RNA was extracted 30 minutes after the ES, followed by qPCR to assess the genetic changes.

### Results and Discussion

Based on immunostained images, we found number and density of neurites decreased after OGD-R compared to those of the control, which recovered slightly following the ES. Considering that many scientists have used the number and density of neurites as indicators of structural neuroplasticity, we found that both OGD-R and electrical stimulation had

immediate effects on the plasticity change in an opposite manner.

When the expression of neuroplasticity-related genes (Arc, C-fos, Zif268) were assessed, significant increases were shown in Arc (6.5 folds) and C-fos (3.4 folds) in the normal brain model and C-fos (7.1 folds) and Zif268 (1.9 folds) in the stroke model compared to non stimulated group. Furthermore, when comparing the conditions without the ES, the stroke model exhibited a significant increase in Arc (4.6 folds) and a significant decrease in Zif268 (2.6 folds) compared to the control. The ES seemed to increase neuroplasticity because at least two of the neuroplasticity indicators were significantly increased by the ES in all conditions. Also, we found the response to electrical stimulation varies before and after OGD-R. Based on that results, we could infer that OGD-R stimulation affects signals related to neuroplasticity.

**Figure 1:** Immunofluorescence staining results in normal brain model, stroke model with and without electrical stimulation conditions (Astrocyte: GFAP, Neuron: Tuj1).

### Conclusions

We found a significant decrease in neurite length and density after OGD-R and a partial increase after electrical stimulation. Also, we found increasing neuroplasticity markers by electrical stimulation in both the normal brain and stroke brain and change in the reaction by OGD-R. It is necessary to experiment on the common markers of neurite change and neuroplasticity to identify the relationship between OGD-R and electrical stimulation.

## Predicting Gait Events from Handle Forces in an Instrumented Posterior Walker

### Summary

The human-device interface of patients using a posterior walker is not well understood. In this study, how users load a posterior walker is analyzed through utilization of a posterior walker with instrumented handles. Through collection of CP and typically developed users walking with this instrumented walker, we found a consistent local maximum of downward and forward force occurs prior to foot strike and foot off.

### Introduction

Human gait has been studied extensively. How assistive devices, such as posterior walkers, affect gait is much less well defined. The interaction between the human and the device must be understood, given many individuals with walking disorders, due to neuromuscular disabilities, such as cerebral palsy (CP), use assistive devices to aid their mobility [1].

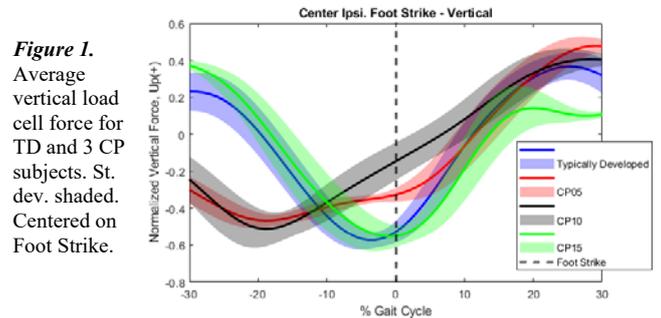

In the case of the posterior walker, introducing powered wheels could be highly beneficial to the user. Specifically, children with CP typically are weaker and fatigue faster than their typically developed (TD) peers, and have been shown to do 59% more work per unit mass, on average, than TD children [2]. Posterior walkers are used by people with CP to decrease load on their lower limbs and increase their stability. These benefits come at the metabolic cost of pulling the walker along with them. Powering the walker would negate this effort. Additionally, adding a control to this power could allow energy to be injected into the gait cycle to further increase the gait efficiency of the user. In order to apply this control appropriately, the location of the user in their gait cycle must be known. The aim of this work is to show that gait events can be detected from forces applied by the user to the handles of the posterior walker.

### Methods

A typical posterior walker (Nurmi Neo, Ottobock) was instrumented at both handles with a 6 DoF load cell (LC, ATI) to capture all forces (1000Hz) applied through the handles of the walker. 9 TD users (15.6 ± 5.7 y.o.; 3F) and 14 CP users (12.2 ± 3.5 y.o.; 5F) walked, with this instrumented walker, at their self-selected walking speed along a level, straight path. Walking kinematics were collected using an 8 camera motion capture system (Vicon) at 100 Hz. Gait events were determined from collected motion capture data, and one stride was defined as foot strike to ipsilateral foot strike. A minimum of 65 strides of each subject were used in this analysis. LC force data was filtered at 3 Hz [3], segmented to the stride, and then normalized by excursion of force over the stride to investigate the pattern of loading on the walker handles.

### Results and Discussion

In the TD population (blue in Fig. 1), a consistent pattern of a local minimum in the vertical direction is applied by the user before ipsilateral foot strike and contralateral foot off (relative to load cell, listed in Table 1). The CP group shows a much larger variance in this pattern across the group. When looking at each CP subject, it is seen that a consistent strategy for loading the walker is adopted. The group variation arises from different strategies adopted by users.

**Figure 1.** Average vertical load cell force for TD and 3 CP subjects. St. dev. shaded. Centered on Foot Strike.

Given the small within-subject standard deviation in LC minimum to gait event (mean ± 4.17 %GC), a method of event detection could be developed for the TD population, then this control method could be tuned to each specific walker user to account for the inter-subject variation seen in the population with CP. A similar pattern occurs in the loading of the axial direction, and relative to foot off.

**Table 1.** Location of load cell pattern characteristic relative to gait event. Reported as % Gait Cycle (±SD).

Axis	LC Min. Leading Ipsilateral Foot Strike		LC Min. Leading Contralateral Foot Off	
	TD	CP Group	TD	CP Group
Downward	3.5 (±2.5)	3.94 (±7.25)	15.27 (±2.5)	17.44 (±5.67)
Forward	3.1 (±3.0)	5.0 (±10.3)	14.89 (±3.2)	13.94 (±7.82)

This shows that we can predict gait events based on the characteristics of the load applied to the handles of the walker in a non-pathologic population. This ability will allow us to investigate ways to increase the gait efficiency of the user walking with a posterior walker. However, more investigation is necessary of the pathologic population, to find which users may benefit most from the additional aid offered by a powered posterior walker.

### Conclusions

Gait events can be predicted from handle usage. This will enable us to develop more efficient walker designs to help increase the mobility of users.

## Protocol for Improving Familiarity with a Lower-Limb Robotic Exoskeleton in Able-Bodied, First-Time Users

Jan Lau<sup>1</sup>, Katja Mombaur<sup>1</sup>

<sup>1</sup>Canada Excellence Research Chair Human Centered Robotics and Machine Intelligence Lab, Dept. Systems Design Engineering, University of Waterloo, Waterloo, Canada

### Summary

Various lower-limb robotic exoskeletons have been created to target different healthcare needs, but no research has been done on developing a proper procedure for users to get accustomed to wearing and moving with one, and the instruction manuals provided are insufficient. A pre-test was conducted to observe the challenges of wearing an exoskeleton for the first time. Pre-test results showed safety concerns and a steep learning curve. This paper outlines a protocol that can potentially improve first-time users' comfort to interact with an exoskeleton. Since the execution of the full procedure was disrupted by a lab closure due to COVID-19 restrictions, the full experimental results will be presented at the conference.

### Introduction

Lower-limb robotic exoskeletons have been developed for applications such as spinal cord injury (SCI) and stroke rehabilitation. So far, no procedures are available to help familiarize users how to move with one. Although instruction manuals are provided, the information is either insufficient or lacking in this regard.

A pre-test with two subjects was performed to identify the actions of a first-time user wearing an exoskeleton. The tasks were sit-to-stand, stand-to-sit, and walking. They experienced difficulty balancing when performing sit-to-stand, had lower back pain, and were startled from the exoskeleton's predefined gait pattern due to the lack of familiarity in motor interaction. Both are young, healthy, and able-bodied graduate students, which leads to the assumption that the initial exoskeleton experience would be worse with patients. Therefore, a need exists for a protocol that can better prepare able-bodied, first-time users to move with an exoskeleton.

Figure 1: A startled pre-test subject lost balance when walking.

### Methods

The device used is the Twin developed by Istituto Italiano di Tecnologia (IIT). Made for people with SCI, its four actuators enable flexion/extension at the hips and knees [1]. The experiment includes ten subjects who are evenly divided into control and experimental groups.

The significance of each exercise is explained to the subject to better retain the information [2]. Protocol is shown below.

### Preparation (Control + Experimental groups)

1. Adjust the forearm crutches appropriate to the subject.
2. Create a new profile of the subject on the Twin tablet.

### Tutorial (Experimental group only)

1. Perform crutches exercises without exoskeleton.
  - a. Bring crutches backwards while sitting.
  - b. Perform sit-to-stand and stand-to-sit with crutches.
  - c. Walk around with crutches
  - d. Practice turning by pivoting.
  - e. Repeat 1c but shift weight to stationary leg for each step.
2. Demonstrate Twin's sit-to-stand, stand-to-sit, and walking motions without subject wearing it.
3. Don Twin and safety harness on subject.
4. Lift subject 30 cm off the ground with a patient lift.
5. Activate walking motion to familiarize subject with Twin's gait pattern without the risk of falling.

### Exo Session (Control + Experimental groups)

1. Perform sit-to-stand and stand-to-sit wearing Twin.
2. Walk in Twin while being supported by a person.
3. Walk in Twin while being supported by a lift.

System Usability Scale (SUS), NASA Task Load Index (TLX), and a customized survey are used for measuring Twin's usability, subjects' mental workload, and subject's comfort level respectively. The customized survey is completed twice – before Tutorial/Exo Session and after Exo Session – to record how the comfort levels have changed. SUS and TLX are completed after the Exo Session. The selection of these questionnaires was inspired by the ones used for evaluating the don/doff procedure of a wrist exoskeleton [3].

### Results and Discussion

Due to COVID-19, the full procedure that would have been executed in mid-January 2021 was disrupted by a lab closure. Full experimental results will be presented in the conference.

### Conclusions

The protocol introduced could potentially improve user-exoskeleton interaction and the support provided by the device. In the future, it will be adjusted to geriatric users.

### Acknowledgments

This research was undertaken thanks to funding from the Canada Excellence Research Chairs Program.

### Summary

This study investigated the effects of different footwear on running biomechanics in youth. Fourteen male participants (8-12 years old) ran in 3 different footwear conditions (barefoot, traditional, and minimal shoes) and had lower extremity kinematics and vertical ground reaction force characteristics collected and analyzed. Results showed that running barefoot and in minimal shoes significantly increased the average vertical loading rate (AVLR), when compared to traditional shoes. Increased AVLR has been associated with increased risk of running injury. There were also significant changes in sagittal plane knee and ankle kinematics. This is a unique analysis of the effects of footwear on the running biomechanics in youth, and the first study to specifically evaluate the effects of footwear on AVLR in youth. The dramatic effect on AVLR provides insight into the relative risk of overuse injury with minimal shoe or barefoot running in youth.

### Introduction

The biomechanics of running injuries have been extensively studied in adults [1-3], but very little research has been conducted with youth, particularly related to footwear. The purpose of this study was to compare running biomechanics (loading rate and sagittal plane knee and ankle kinematics) in male youth between 3 different footwear conditions.

### Methods

Fourteen active male youth (8-12 years old) participants had running biomechanics (ankle and knee sagittal plane kinematics and vertical ground reaction force characteristics) collected and analyzed using an 8-camera 3-D motion capture system (Vicon) and in-ground force plates (AMTI) in three different footwear conditions (barefoot, traditional, and minimal shoe). (Figure 1) A post-hoc visual analysis of foot strike was also performed.

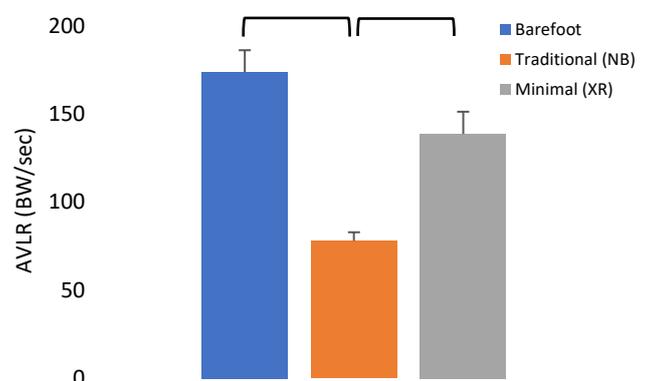

**Figure 1:** The two types of shoes used in this study. Left, minimal shoe (Xero Prio Youth). Right, traditional shoe (New Balance 880)

### Results and Discussion

The AVLR was significantly greater running barefoot (173.86 bodyweights/second (BW/s)) and in the minimal shoe (138.71 BW/s) compared to the traditional shoe (78.06 BW/s),

( $p < 0.001$ ). (Figure 2) There were significant differences between shoes for knee flexion at initial contact (KFIC) ( $p = 0.002$ ), knee sagittal plane excursion (KSE) ( $p < 0.001$ ), peak dorsiflexion (PDF) ( $p < 0.001$ ) and dorsiflexion at initial contact (DFIC) ( $p = 0.028$ ). Barefoot KFIC ( $14.02 \pm 4.15^\circ$ ) was significantly greater than in the minimal ( $10.51 \pm 5.73^\circ$ ) and traditional shoe ( $9.44 \pm 5.60^\circ$ ). KSE in the traditional shoe ( $27.42 \pm 4.70^\circ$ ) was significantly greater than barefoot ( $20.97 \pm 4.01^\circ$ ) and in the minimal shoe ( $23.94 \pm 5.91^\circ$ ). PDF barefoot ( $14.03 \pm 3.10^\circ$ ) was significantly less than the minimal ( $18.38 \pm 4.82^\circ$ ) and traditional shoe ( $20.06 \pm 2.74^\circ$ ). DFIC in the traditional shoe ( $3.43 \pm 3.93^\circ$ ) was significantly greater than barefoot ( $0.24 \pm 2.65^\circ$ ). No participants displayed a transition to, or any instances of, forefoot strike during this study.

Dramatically increased AVLR is noteworthy because of the association with injury, specifically tibial and metatarsal stress fractures [2] and plantar fasciitis [3]. The lack of any instances of forefoot strike is counter to a recent literature review which concluded that minimal shoes may encourage the development of a forefoot strike running pattern in youth [4].

**Figure 2:** Average Vertical Loading Rate in bodyweights per second. Significant differences are bracketed.

### Conclusions

Footwear significantly affected the running biomechanics of youth and caused immediate alterations in sagittal plane ankle and knee kinematics as well as AVLR. Acutely, running barefoot or in a minimal shoe dramatically increased the AVLR, which has been associated with injury, compared to a traditional shoe.

## Summary

Biomechanical loads (e.g. vertical peak positive acceleration; PPA) from research-grade inertial measurement units (IMUs) have been correlated with lab-based metrics (e.g. ground reaction force loading rate) and running-related injuries (e.g. tibial stress fracture). Most commercially available IMUs are mounted either on the shoelaces or embedded in the insole and their validity has not been investigated. The purpose of this study was to assess the validity of two commercially available IMUs during running when compared to a research-grade tibia-mounted IMU. A secondary aim was to determine the effect of footwear on validity. We found poor to moderate validity between a tibia-mounted IMU and two commercially available IMUs located on the shoelaces and insole. Footwear (level of cushioning) also influenced the degree of validity, suggesting that both location of fixation and type of footwear should be taken into account in future research and in clinical applications.

## Introduction

Wearable technology has made it possible for runners to quantify biomechanical loads (e.g. peak positive acceleration; PPA) using commercially available inertial measurement units (IMUs). Vertical PPA of the tibia has been associated with running-related injuries (e.g. tibial stress fracture) [1] and has been correlated with the vertical ground reaction force loading rate [2]. However, while PPA is often measured in a lab setting at the tibia, consumer-grade IMUs are often fixated on the shoelaces or embedded in the insole. The effect of these fixation locations on the magnitude of the PPA is unknown. Therefore, we aimed to assess the validity of two commercially available IMUs during running when compared to a tibia-mounted IMU. A secondary aim was to determine the effect of footwear on validity.

## Methods

Healthy runners ran on a treadmill at their preferred speed in three footwear conditions (neutral, minimalist, maximalist). Three IMUs were affixed at the distal tibia (IMeasureU, Vicon, Oxford, UK), shoelaces (RunScribe, San Francisco, USA), and insole (Plantiga, Vancouver, Canada). Intraclass correlation coefficients (ICC<sub>2,1</sub>) were calculated for PPA between the tibia-mounted IMU (IMU-Tibia) and the commercially available IMUs for each footwear condition.

**Table 1:** Validity of peak positive acceleration (PPA) from a lace-mounted and insole-embedded inertial measurement unit (IMU) in three different footwear conditions. Values represent ICC<sub>2,1</sub> with 95% confidence interval. †  $p < .05$

Criterion Reference	Footwear Condition	Plantiga Insole (PPA)	RunScribe (Impact)
Tibia-mounted IMU	Neutral	0.62 (-0.08, 0.87) <sup>†</sup>	0.60 (-0.06, 0.85) <sup>†</sup>
	Minimalist	0.31 (-0.90, 0.75)	-0.72 (-3.46, 0.34)
	Maximalist	0.74 (0.24, 0.91) <sup>†</sup>	0.72 (0.24, 0.90) <sup>†</sup>

Significance was set at  $p < 0.05$ .

## Results and Discussion

Using the IMU-tibia as the criterion reference for PPA, ICC<sub>2,1</sub> values for the RunScribe and Plantiga IMUs were significant in neutral and minimalist footwear conditions only, ranging from 0.60 to 0.74 (Table 1), representing poor to moderate validity [3]. ICC values of >0.90 are considered desirable for clinical measurements [3]. As such, both devices may have some clinical limitations for use as a proxy for vertical PPA at the tibia. Further, footwear had a clear effect on the validity of the signal from both devices, with the minimalist footwear resulting in insignificant correlations and the maximalist condition resulting in the highest correlations.

**Figure 1:** Tibia-mounted (IMeasureU), lace-mounted (RunScribe), and insole-embedded (Plantiga) inertial measurement units.

## Conclusions

Our findings indicate that two commercially available IMUs located on the shoelaces and insole represent poor to moderate validity when acting as a surrogate for a tibia-mounted IMU for vertical PPA. Footwear (level of cushioning) also influences the degree of validity. Location of fixation and type of footwear, therefore, should be taken into account in future research and in clinical applications.

# TRICEPS SURAE MUSCLE-TENDON PROPERTIES AS DETERMINANTS OF THE METABOLIC COST IN TRAINED LONG-DISTANCE RUNNERS

Esthevan Machado<sup>1</sup>, Fábio J. Lanferdini<sup>2</sup>, Edson S. da Silva<sup>1</sup>, Jared R. Fletcher<sup>3</sup>, Jeam M. Geremia<sup>1</sup>, Marco A. Vaz<sup>1</sup>, Leonardo A. Peyré-Tartaruga<sup>1</sup>

## Summary

This study verified which muscle architecture and tendon property variables of the triceps surae are determinants of running metabolic cost (Cr) in trained long-distance runners. Ultrasound and isokinetic dynamometry were used to determine the muscle-tendon unit structural and mechanical variables. The Cr was evaluated by the running economy test. Cr at submaximal velocities (12 and 16 km.h<sup>-1</sup>) was mainly determined by greater gastrocnemius medialis pennation angle, larger Achilles tendon cross-sectional area, and lower maximal tendon stress.

## Introduction

The muscle-tendon unit is one of the most important structures for human running due to its role in generating tension and storing (and releasing) elastic energy [1]. During each running stride, the muscles produce force and perform mechanical work, while the lower-limb tendons store and release elastic energy, reducing Cr [1]. However, as the triceps surae muscle generates tension actively, it seems to be the dominant structure determining the Cr. Thus, this study aimed to determine which triceps surae muscle architecture and tendon property variables are related to Cr.

## Methods

Seventeen trained male long-distance runners (34.2 ± 7.4 years) participated in this study (Ethics Committee approval number: 2.437.616). Ultrasound was used to determine the muscle architecture [fascicle length (FL), pennation angle (PA) and muscle thickness (MT)] of the gastrocnemius medialis (GM), gastrocnemius lateralis (GL) and soleus (SO), and the Achilles tendon cross-sectional area (CSA), resting length and elongation as a function of plantar flexion torque during maximal voluntary plantar flexion. From these data, Achilles tendon force-elongation and *stress-strain* relationships were determined. Then, Cr was measured during submaximal steady-state running (5 min) at 12 and 16 km.h<sup>-1</sup> on a treadmill. Stepwise multiple linear regression was used to determine the relationship between independent variables (tendon resting length, CSA, force, elongation, stiffness, stress, strain, Young's modulus, FL, PA and MT) with Cr (J.kg<sup>-1</sup>.m<sup>-1</sup>) at 12 and 16 km.h<sup>-1</sup>.

## Results and Discussion

Greater GM's PA and larger Achilles tendon CSA were Cr determinants at 12 km.h<sup>-1</sup>, whereas greater GM's PA and

lower Achilles tendon stress were Cr determinants at 16 km.h<sup>-1</sup> (Table 1).

GM's PA is higher in long-distance runners than sprinters and non-active subjects [2]. Greater PA is determined by a higher number of myofibrils per fiber (i.e., higher in-parallel sarcomere numbers), thereby increasing muscle force [3]. Thus, the entire muscle needs to recruit fewer motor units to perform the same task, probably decreasing Cr. However, we were unable to find studies relating PA with Cr. Moreover, a large Achilles tendon CSA and lower tendon stress may be associated with an improvement in the tendon's ability to store and release elastic energy [5] and with a better force distribution by tendon area [6], improving muscle-tendon force transmission and running economy by decreasing Cr.

**Table 1.** Determinants of the Cr at 12 and 16 km.h<sup>-1</sup>.

Depend. Variable	R <sup>2</sup>	P-value	Indicator	Standardized Coefficients (β)	P-value
Cr-12 (J.kg <sup>-1</sup> .m <sup>-1</sup> )	0.48	0.010	CSA (mm)	-0.514	0.019
			PA-GM (°)	-0.429	0.043
Cr-16 (J.kg <sup>-1</sup> .m <sup>-1</sup> )	0.57	0.003	PA-GM (°)	-0.528	0.010
			Stress (MPa)	0.494	0.014

CSA (Achilles tendon cross-sectional area); PA-GM (Gastrocnemius medialis PA); Cr-12 and Cr-16 are running metabolic costs at 12 and 16 km.h<sup>-1</sup>, respectively.

## Conclusions

Cr in trained long-distance runners is determined by greater GM's PA, due to a higher in parallel sarcomere number that increase muscle force. Larger Achilles tendon CSA and lower tendon stress increase the tendon's ability to store and release elastic energy, with better force distribution per tendon area at submaximal velocities (12 and 16 km.h<sup>-1</sup>).

## Mechanical Symmetry in Elite Middle Distance Runners

Geoffrey T. Burns<sup>1</sup>, Kenneth M. Kozloff<sup>1</sup>, Jessica M. Zandler<sup>1</sup>, Ronald F. Zernicke<sup>1</sup>

<sup>1</sup>University of Michigan, Ann Arbor, Michigan, USA

Email: gtburns@umich.edu

### Summary

Gait asymmetries are linked to running experience and ability, yet observations in elite-level runners and across large ranges of speeds are limited. This investigation explored symmetries of mechanical characteristics in elite and sub-elite middle distance runners across 10 speeds. Both groups exhibited low levels of asymmetry, and the elite runners had further reduced asymmetry in their intra-stride vertical oscillations and step characteristics. These data provide evidence and context for using mechanical symmetry metrics in athlete monitoring.

### Introduction

Gait asymmetries are a common focus of coaches and clinicians for assessing running biomechanics. Greater movement symmetry has been associated with greater performance capacities [1,2], and inducing step asymmetries decreases one's running economy [3]. As a potential barometer for athlete development, training adaptation, and injury rehabilitation [4], a more comprehensive understanding of asymmetry patterns in highly developed runners would validate its efficacy as an assessment tool.

Observations in elite runners have, generally, been restricted to single speeds [1], yet asymmetries are modulated by speed in recreational runners [2]. Middle distance runners are a revealing population in which to explore speed-dependent mechanical patterns, as their training encompasses a large breadth of speeds [5].

The goal of the current study was to examine system-level mechanical symmetry and its variability via spring-mass behavior [6] in world-class middle distance runners within and across a wide range of training and racing speeds.

### Methods

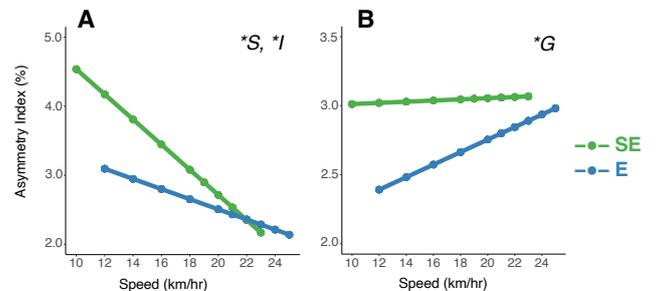

Ten elite level (E) male middle distance (MD) runners (1500 m: 3:37.3±3.6s) and 10 highly trained male sub-elite (SE) MD runners (1500 m: 4:07.6±3.7s) were recruited. They ran on a treadmill instrumented with a pressure platform at 4 low-intensity speeds for 4 min (E: 12-18 km/hr; SE 10-16 km/hr) and 6 high-intensity speeds for 30 s (E: 20-25 km/hr; SE 18-23 km/hr). Temporal measures were continuously recorded.

Spatiotemporal (i.e., contact time ( $t_c$ ), flight time ( $t_f$ ), duty factor (DF), step length (SL), and step frequency (SF)) and spring-mass (i.e., leg stiffness ( $k_{leg}$ ), vertical stiffness ( $k_{vert}$ ), and vertical oscillation (VO)) characteristics were calculated [7]. An asymmetry index (AI) [4] for each stride cycle and a rolling AI were calculated within each speed for each subject. Coefficients of variation were calculated within each speed. The effects of ability (E vs. SE) and speed were assessed with linear mixed-effects models. Model coefficients were assessed for significance at a type I error control of  $p < 0.05$ .

### Results and Discussion

For each runner (mean±SD), 1770±79 stride cycles were captured across the 10 speeds. Both groups exhibited low intra-stride AIs across all measures, including (grand mean ± standard error):  $t_c$  (1.6±0.1%),  $t_f$  (2.9±0.1%), DF (1.6±0.1%), SL (1.4±0.1%), SF (1.4±0.1%),  $k_{leg}$  (4.1±0.2%),  $k_{vert}$  (2.9±0.1%), and VO (2.8±0.1%). Rolling AIs yielded similar results across all measures. These results are consistent with their high experience and performance levels [1,2]. Both groups increased their AIs across speeds for SL, SF,  $k_{leg}$ , and  $k_{vert}$ . AIs decreased across speeds for  $t_f$ , and there was a significant group interaction (Figure 1).

E runners had lower AIs across speeds for VO (-0.4%) (Figure 1), SL (-0.2%), and SF (-0.2%), consistent with elite long distance runners at a single speed [1] and suggestive of greater movement efficiency [3].

**Figure 1:** Asymmetry indices within strides across speeds for (A) flight time and (B) vertical oscillation. Significant effects are indicated as \*G (group), \*S (speed), and \*I (interaction).

There were no group differences in AI variability within speeds. However, in both groups, variability in the AI increased as speed increased for  $t_c$ ,  $t_f$ , DF,  $k_{leg}$ , and  $k_{vert}$ .

### Conclusions

Highly trained MD runners with high performance capacities exhibited low levels of gait asymmetries. Elite-level runners exhibited greater symmetry in their vertical oscillations and step characteristics. Asymmetries were also speed-dependent in both groups. Monitoring and analysis of system-level gait asymmetries in runners may have useful application in informing individual-specific development trajectories, performance opportunities, and rehabilitation strategies.

## Summary

This study combined gait analysis, musculoskeletal modeling, finite element analysis, and a fatigue life prediction algorithm to investigate the effect of different exercise protocols on the tibial fatigue life in physically active males and females. Our results showed that both higher running speed and sex could be determinants of tibia stress injuries.

## Introduction

The prevailing understanding of the bone stress injuries (BSI) etiology points to multi-factorial injury mechanisms, in part caused by repetitive, cyclical loading [1]. *In silico* studies of training habits, including changes in running speed, landing patterns, and other factors on tibial stress injury formation, can provide important insights into BSI prevention. This study aimed to computationally examine the effect of different exercise protocols on tibial fatigue life in a sample of male and female runners during walking and three speeds of running.

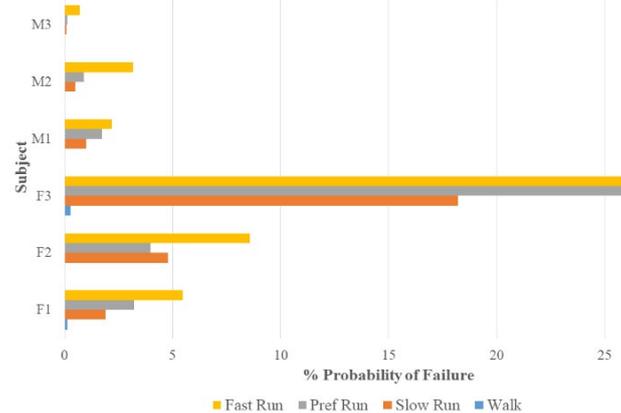

## Methods

Three male and three female participants running >16 km/week were extracted from an existing data set (Meardon et al., accepted) and analyzed for this study. All subjects were between 19-24 years. Four gait conditions were tested and analyzed in this study: walking (1.3 m/s), preferred running and  $\pm 10\%$  preferred running speed. Next, all participants underwent magnetic resonance imaging (MRI) of their right tibia with a 1.5-T scanner (Philips Achieva). A previously established musculoskeletal model was used to estimate muscle forces across the stance phase [2]. Finite element analysis was conducted in FEBio [3] through an automated MATLAB (MathWorks Inc) script. The models were fixed at the proximal end of the tibial shaft and loads were applied at the distal end of the shaft. The probability of failure accounting for repair and adaptation was calculated based on the approach developed previously [4,5] over 100 days. Subject-specific loading frequency was normalized by assuming the same running/walking distance of 4.8 km/day for all subjects.

## Results and Discussion

Our results showed that the probability of BSI formation was generally lower for slower gait conditions (Figure 1). Furthermore, female subjects, on average, had a higher mean peak probability of failure (the probability of failure on day 100) in all four gait conditions. Furthermore, we observed

differences in spatial distribution and magnitudes of strain and stress predicted in the tibia by finite element analysis under different gait conditions.

**Figure 1:** Peak probability of tibial fatigue failure for each subject and gait condition (M =male, F = female).

## Conclusions

Our *in silico* results using subject-specific images suggests markedly reduced fatigue life in both sexes when progressing from a walk to run and with increasing running speed, supporting previous research. Tibial fatigue life in females was disproportionately reduced with increasing speed compared to males. We posit that sex-based differences in tibia shape and gait mechanics underpin the reduced fatigue life observed in this study and the increased incidence of BSI in females.

## Female Runners Demonstrate a Greater Decrease in Knee Flexion with Age than Males

Heather M. Hamilton<sup>1</sup>, Max R. Paquette<sup>2</sup>, Rumit Singh Kakar<sup>1</sup>

<sup>1</sup>Old Dominion University, Norfolk, VA, USA; <sup>2</sup>University of Memphis, Memphis, TN, USA  
Email: hmcco006@odu.edu

### Summary

Increased age is associated with decreased peak dorsiflexion and knee flexion in male and female runners. Females demonstrate a greater decline in peak knee flexion compared to males with age, which may contribute to decreased shock absorption. It is important to understand sex differences in biomechanics of aging runners to maximize performance and minimize risk of running-related injury (RRI).

### Introduction

Aging runners demonstrate changes in running biomechanics, specifically decreased ankle and knee joint excursion [1-3]. Limited evidence suggests males and females demonstrate different changes in running biomechanics with age [4], which may be related to unique physiological changes that females experience during the aging process that affect the musculoskeletal system [5]. It is therefore important to consider separate-sex analyses when studying the effects of age on running biomechanics. The purpose of this study was to determine the relationship between age and lower extremity running kinematics separately for male and female runners at two different speeds.

### Methods

Male (n = 33) and female (n = 46) runners (ages 18-65 years) ran at self-selected long distance (JOG) and maximal running (MAX) pace on a treadmill. Lower extremity joint kinematics were collected using 3D motion capture (Vicon®). Linear regression was used to determine the relationship between age and sagittal plane peak joint angles of the dominant limb during stance phase for male and female participants. Speed was controlled for in the first block of the regression model.

### Results and Discussion

In males for JOG (2.83 ± .51 m/s), there was a significant negative relationship between age and peak knee flexion, and the relationship between age and peak ankle dorsiflexion neared significance (Table 1). For MAX (4.41 ± .71 m/s), there was a negative relationship between age and peak knee flexion only. In females for JOG (2.66 ± .30 m/s) and MAX (3.80 ± .61 m/s), there were significant negative relationships between age and peak dorsiflexion and peak knee flexion

(Table 1). For JOG, there was a significant age by sex interaction effect for peak knee flexion ( $p = .022$ ) (Figure 1). No other significant interaction effects were observed ( $p > .082$ ). Results show that age influences peak knee flexion and perhaps more so in females compared to males. Females demonstrate a greater decline in peak knee flexion with age compared to males, which may reflect increased knee joint stiffness [1]. Findings are consistent with studies reporting decreased ankle and knee excursion in aging runners [1-3].

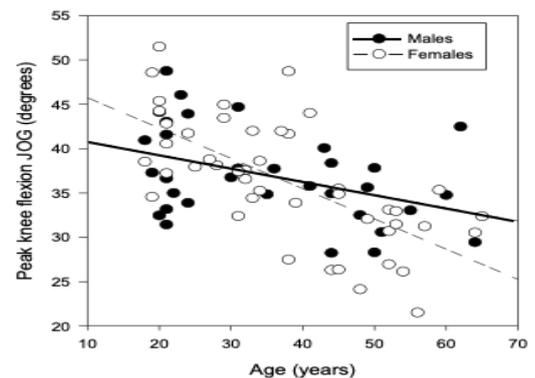

Figure 1: Relationships between age and peak knee flexion (JOG).

### Conclusions

Decreased knee flexion as observed here may suggest increased knee stiffness, which has been reported as a predictor of RRI [6]. Female runners over the age of 50 years are more likely to experience RRI [7]. It is therefore important to understand the sex differences in aging-related changes in running biomechanics to develop training and rehabilitation programs in this population.

## The Effect of Increasing Step Rate on Foot Progression Angle During Running

Kathryn A. Farina<sup>1</sup>, Michael E. Hahn<sup>1</sup>

<sup>1</sup>Bowerman Sports Science Clinic, University of Oregon, Eugene, Oregon, USA

Email: kfarina@uoregon.edu

### Summary

Foot progression angle (FPA), a measure of transverse foot orientation, may influence rearfoot motion and injury risk. The effects of increasing step rate (SR), a popular gait retraining technique, on FPA are unknown. Twenty runners ran at their preferred, +5%, and +10% of preferred SR, and FPA was calculated. A significant difference in FPA between the preferred and +10% condition was observed, indicating increasing SR may be a tool for altering FPA during running.

### Introduction

Increasing SR during running has become a popular method in gait retraining for injury prevention and recovery. FPA is a measure of the degree of toe-out or toe-in orientation of the foot [1]. Excessive toe-out may lead to increased pressure on the medial side of the foot, and could influence rearfoot eversion, a potential mechanism related to common running related injuries [1,2,3]. The purpose of this study was to assess the effects of increasing step rate on FPA during running.

### Methods

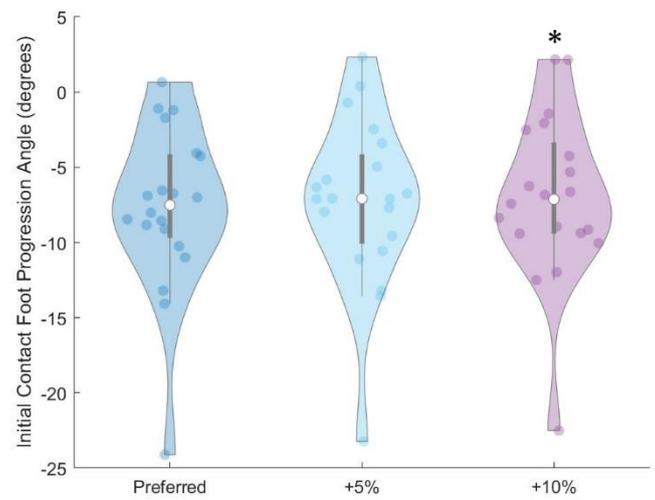

Twenty runners (11 male; 24.9 ± 8.7 years old; 173.7 ± 9.8 cm; 64.7 ± 11.3 kg; 34.5 ± 17.1 miles per week) gave informed consent to participate in this IRB-approved study. Participants had to run at least 15 miles per week, and be pain free at the time of testing. Participants ran on a force-instrumented treadmill (Bertec, Columbus, OH) while marker position data (Motion Analysis Corp., Rohnert Park, CA) were collected ( $f_s = 1000$  and 200 Hz, respectively) under three conditions while wearing standardized, neutral shoes (Brooks Launch). Participants ran at their preferred running pace (3.33 ± 0.4 m/s) at preferred SR, +5%, and +10% of preferred SR for three minutes each. Participants were cued by metronome set to goal SR for each of the increased conditions. Twenty strides were recorded during the final minute of each condition.

Data were analyzed using Visual3D v5 (C-Motion Inc., Germantown, MD). Marker coordinate and force plate data were filtered with a 4<sup>th</sup> order lowpass Butterworth filter at 10 and 30 Hz, respectively. FPA was calculated as the relative difference between the rearfoot segment and the lab coordinate system in the transverse plane. The FPA at initial contact was tested using a repeated measures ANOVA for comparison between SR conditions. Statistical parametric mapping (SPM) was used to test for differences throughout stance.

### Results and Discussion

Significant differences were observed between SR conditions, with the preferred SR (175 ± 7) being significantly lower than

the +5% (185 ± 9) and +10% (192 ± 9) conditions ( $p < 0.001$ ), confirming that the SR protocol was effective. Repeated measures ANOVA revealed a significantly greater toe-out orientation (more negative) at initial contact in the preferred SR condition ( $-7.72 \pm 5.5$ ) compared to the +10% condition ( $-7.03 \pm 5.5$ ) ( $p = 0.041$ ), but not the +5% condition ( $-7.29 \pm 5.6$ ) (Figure 1). No clusters during stance reached critical threshold in SPM analysis.

**Figure 1:** Violin plot showing distribution of FPA at initial contact between the preferred, +5%, and +10% SR conditions. Negative values indicate a toe-out orientation. \* = significant difference from preferred condition.

The majority of participants displayed FPA at initial contact between 5 and 10 degrees of toe-out. There was a wide distribution in angles, likely due to varying foot strike patterns among participants. However, the majority of participants displayed a less toed-out initial angle with increased SR. Although significant, these changes were small, with the difference in mean values between the preferred and +10% condition only being 0.7 degrees (range: 0.01-3.27 degrees), raising the question of practically meaningful effect.

### Conclusions

These findings indicate that increasing SR may be a feasible gait retraining method to alter FPA during running, and potentially reduce rearfoot eversion. More research is needed to understand the influence of SR on rearfoot motion, FPA, and these effects on running related injury development and rehabilitation.

## Transverse thorax-pelvis movement patterns in runners with and without mild non-specific low back pain

Email: [msceledon@uc.cl](mailto:msceledon@uc.cl)

### Summary

It remains unclear how a pain condition leads to changes in mobility of runners with low-back pain (LBP). We evaluated runners with and without mild LBP and found an out-phase pattern (segments rotating in opposite directions) for thorax-pelvis coordination. This pattern tends to overload the lumbar region by inducing larger rotations, which can be a determinant factor for mild LBP in runners.

### Introduction

Two intersegmental patterns for thorax-pelvis coordination have been studied in runners with and without LBP [1]. The in-phase pattern occurs when the pelvis and thorax rotate in the same direction, whereas in the out-phase pattern pelvis and thorax rotate in opposite directions [1]. It is unclear whether mild LBP may influence these kinematics characteristics of the running or whether runners without pain also show an in-phase or out-phase pattern. Here we investigate the presence of the in-phase or out-phase thorax-pelvis patterns in runners with and without mild LBP.

### Methods

This experiment was approved by the local institutional ethics committee (IRB #78835317.8.0000.5323) and included 20 trained runners. Among them, 10 (4 women) had mild LBP, with age 40(8.7) years old and an Oswestry score of 10.5(4.8) point, and 10 (4 women) had no LBP, with age 37.2(6.1) years old and an Oswestry score of 0.0(0.0) points. They should have run at least 15 km per week in the past 12 months. The 3D kinematics analysis was performed during treadmill running at a speed corresponding to 75% of their personal best 5 km time [10.7 (1.3) km/h for runners without LBP and 10.3 (1.2) km/h for runners with LBP]. The movement was captured after they ran 5 kilometers. Fifteen infrared cameras (Vicon Motion Systems) tracked the full-body plug-in-gait set markers at 120 Hz. Data were low-pass filtered with a 4th order Butterworth filter and cut-off frequency of 6 Hz. The runners were grouped by an in-phase or out-phase pattern by comparing their rotation directions in the whole time series. From the entire 10 running cycles at kilometer 5th, the absolute mean angle in the transverse plane between the thorax and pelvis was estimated. After confirming the normal data distribution, the patterns groups were compared with a two-tailed independent t-test and 5% alpha. The proportion of runners showing each coordination pattern was also described.

### Results and Discussion

At the transverse plane, the angle between thorax-pelvis for the in-phase pattern was 24.6(9.0) degrees, and for the out-phase was 52.7(6.6) degrees ( $P < 0.001$ , Figure 1). It suggests that a larger rotation of the lumbar region is found in runners with and without LBP. This may lead to increased motor

control demands in the lumbar region. When comparing the groups, an out-phase pattern was more prevalent among runners with mild LBP. Although not evaluated here, this coordination pattern may alter lower limb kinematics, like the stride length, and further influence the running technique. On the other hand, debilitating pain may cause stiff joints. The heterogeneity findings (the proportion between with and without pain) may indicate different running adaptations across the participants. In consequence, it raises some questions: is the nervous system adjusting the thorax-pelvis pattern to reduce pain/speed resulting in an in-phase pattern? Has a percentage of out-phase pattern been an insufficient adjusted pattern, a sign of uncontrolled or recovered runners? How does the pattern change to face the pain in runners? What are the physiological thresholds of in-phase or out-phase patterns that the nervous system can have?

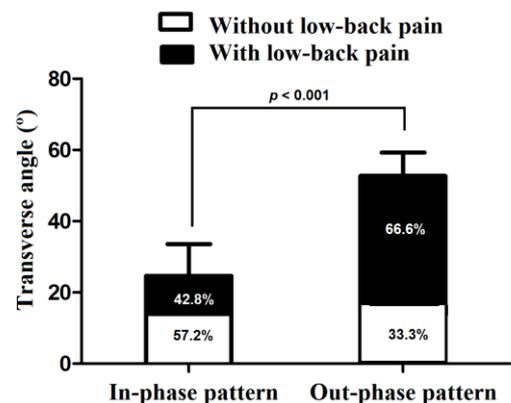

Figure 1: Transverse angle of thorax-pelvis for the in-phase and out-phase pattern and proportion of the patients with and without low-back pain.

### Conclusions

The out-phase pattern was more commonly observed among runners with mild LBP. However, a causative model, where the pain modulates the thorax-pelvis pattern, is needed to understand better how and why the lumbar region kinematics' adjustments occur during running.

## Quantifying Change Of Direction Movements In Youth Soccer Players Using Wearable Technology

Mathieu Chin, BSc<sup>1</sup>, Lauren Benson, PhD<sup>1</sup>, Aki-Matti Alanen, PT, MSc<sup>1</sup>, Carla van den Berg, MSc<sup>1</sup>, Kati Pasanen, PT, PhD<sup>1,2,3,4</sup>

### Summary

Using inertial measuring unit (IMU), this study looked to determine the differences in mean peak acceleration between the dominant and non-dominant leg amongst male and female youth soccer players during preplanned 135°, 90° and 180° change of direction (COD) movements.

### Introduction

Soccer is one of the most popular sports worldwide with over 265 million players. Being a sport with high rates of change of direction movements (COD), there is also a high incidence of traumatic non-contact knee and ankle injuries, with the majority of ankle and knee injuries occurring in non-contact movements, such as those seen in COD movements [1, 2].

The use of wearable devices has allowed researchers to better understand sport movement patterns beyond a typical laboratory setting [3]. There is a paucity of research which quantifies the movements of youth soccer players during a COD movement using wearable technology. This study will contribute objective IMU data to the youth soccer literature on leg-to-leg differences during COD movements.

### Methods

Cross-sectional study. Sixty-one male (n=29) and female (n=32) youth soccer players between the age of 15-17 were recruited using a convenience sample. Athletes were fitted with an IMU (Shimmer3) with corresponding 4K video being recorded as they performed consecutive 135° cut turn, 90° cut turn, and 180° pivot turn using both legs. Video analysis was completed using Dartfish 10 to identify the timing of the movements with accelerometer data being processed using MATLAB. T-tests were conducted to determine leg-to-leg differences with p<0.05. Statistical analysis was completed using Stata software.

### Main Outcome Measures

Primary outcomes from this study were obtained using IMU devices containing triaxial accelerometers, which recorded the mean peak accelerations of final foot contacts (acceleration, m/s<sup>2</sup>) comparing the players' dominant leg to their non-dominant leg.

### Results

Mean peak acceleration was greater in the dominant leg turn when compared to the non-dominant leg turn for the 180°

COD movements for both males (Dominant: 55.6 (SD: 8.3) m/s<sup>2</sup>, Non-dominant: 51.3 (SD: 7.7) m/s<sup>2</sup>; p=0.0336) and females (Dominant: 45.4 (SD: 8.8) m/s<sup>2</sup>, Non-dominant: 40.8 (SD: 6.4) m/s<sup>2</sup>; p=0.0326). There was no statistical significance for the 135° and 90° COD movements.

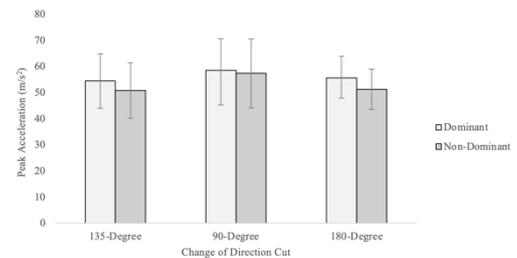

Figure 1. Comparison of the mean peak acceleration in the dominant and non-dominant leg in male youth soccer players.

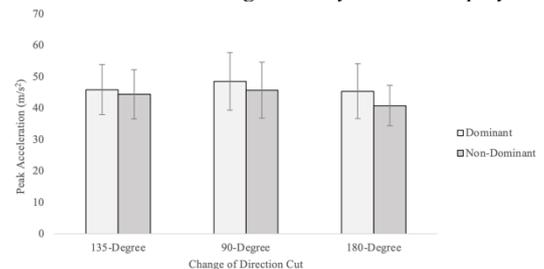

Figure 2. Comparison of the mean peak acceleration in the dominant and non-dominant leg in female youth soccer players.

### Conclusion

Youth soccer players may exhibit greater mean peak acceleration and loading in their dominant leg when performing a 180° COD movement. Future analysis can monitor mean peak accelerations over time to better understand its relationship to injury and training.

## A systematic review: Long range correlations in running gait

Taylor J Wilson<sup>1</sup> & Aaron D. Likens<sup>1</sup>

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA

Email: twilson50@unomaha.edu

### Summary

Long range correlations (LRCs) are apparent in human walking and running gait and are indicative of a healthy system. A systematic review (SR) was completed to determine the typical LRC patterns in running. 20 articles were included in the SR. LRCs in running gait tend to be similar to the LRCs in walking gait, with fatigue contributing to a negative effect on the LRCs.

This SR could have implications on training guidelines for coaches and physical therapy methods to increase the LRCs in running gait for healthier functioning. More research is needed to determine how LRCs depend on running surface and what effect disease has on LRCs of running gait.

### Introduction

Much research has been dedicated to measuring the health benefits of running, but only a few studies have examined how running patterns change over time. Long range correlations (LRCs) characterize the degree to which movements are correlated from one moment to the next. LRCs are found in many human activities, including walking and running. Assessing LRCs is important because the presence of LRCs has been associated with health, while the absence of LRCs has been noted as a marker of disease [2]. Hence, more research is needed to understand the meaning of LRCs in running gait.

A systematic review (SR) was completed to look at the effects of running gait on LRCs and the implications this could have on human health, performance, and rehabilitation. The aims of this review were to: identify the typical LRC patterns in human running gait, the effect that running/walking has on LRCs, the effect of injury/disease on running gait, and the effect that surface has on the LRCs of running gait.

### Methods

PRISMA guidelines were followed for this SR. PubMed, IEEEExplore, Scopus and Web of Science were searched until November 2020 using the SR tool Rayyan. Exclusion criteria were: Non-experimental studies, non-humans, walking only, non-running, non-LRC analysis, and non-experiments. Two independent raters (TW, AL) screened articles for exclusion.

### Results and Discussion

200 studies fell within our criteria. After review and deliberation, 20 articles were included in our SR. Our review revealed that, in general, gait characteristics of running seem indicative of LRCs and are similar to those found in walking gait. LRCs are apparent in both treadmill (TR) and overground running (OR). Results comparing OR and TR, however, are mixed, with some papers showing TR produces greater LRCs [5], while others show the opposite trend [3].

Surprisingly, we did not find any studies comparing LRCs as a function of health; however, two articles directly measured the effect of injury on the LRCs in running gait. One of those articles found only small differences in LRCs between injured and non-injured runners [6], compared to a significant difference in LRCs between the two groups [7]. The fatigue state of the runner may determine the magnitude of LRCs: One article showed a U-shaped trend in LRCs with highest levels of LRCs at the beginning and end of a run [8]. Other articles showed a linear decrease in LRCs with fatigue [1]. Speed may produce a similar U-shaped LRC trend in running gait [5], but this effect was not consistent in this review [6].

### Conclusions

We conducted this review to uncover the typical LRCs of running gait in several contexts. With mixed results, our review suggests that, like walking, running gait exhibits patterns of LRCs that seem to vary according where running takes place and the state of the runner. If, as our review implies, fatigue produces measurable changes in LRCs, then tracking LRCs in a workout program could enhance injury prevention measures and speed up recovery. Our results also suggest new training possibilities that could enhance adaptability of the system. Training outside the preferred speed may increase LRCs, which could, in turn, improve recovery times and prevent injury. Furthermore, measuring the LRCs of locomotion is highly recommended due to its good reliability [4], and non-invasive nature compared to other methods of recording fatigue, like taking lactate levels and measuring intramuscular EMG signals during a run.

More research is needed to determine how LRCs depend on running surface. By determining the surface that produces the highest LRCs, this will benefit coaches/physical therapists to prescribe appropriate surfaces for their athletes/patients to improve healthier functioning. Lastly, our review suggests a strong need for further research into the timing of gait when running; due to mixed results concerning running surface, no research related to disease and running, and the relatively low number of papers that have investigated LRCs in this context.

## The Between-day Repeatability for Peak Tibial Acceleration During Track Running

### Summary

Tibial acceleration measurements must be reliable to ensure validity for longitudinal studies. This study determined the reliability of measuring peak tibial acceleration during overground track running, on three separate days, each averaged over a range of five to 200 strides. Overall, peak tibial acceleration measurements showed moderate to good between-session reliability. Averaging the peaks from 50 or more strides is required to achieve good reliability.

### Introduction

Peak tibial accelerations (PTA) can be measured by an inertial measurement unit (IMU) and is considered practical for assessing and monitoring runners outside of the lab [1,2]. One previous study reported excellent within-session reliability but poor-to-moderate between-day reliability [2]. However, the study only analyzed four strides taken from separate short running bouts within the lab. These results may not be fully applicable to real-world running assessments, where PTA is measured for consecutive strides over longer runs and outside of lab conditions. Moreover, analysis of additional running strides has been suggested to improve IMU reliability [2,3]. Currently, there is a lack of evidence to fully assess the between-day reliability of PTA averaged over multiple consecutive strides. The number of strides needed to obtain adequate reliability is also yet to be determined. Hence, the aims of this study were to determine between-day reliability of axial PTA measured continuously during an overground run and determine if averaging more strides would improve between-day reliability.

### Methods

Eleven recreational runners (6F, 5M; age =  $23.9 \pm 3.8$ ) participated in this study. All participants completed three identical testing sessions at an indoor running track (200 m). Session 2 and 3 were conducted within one week (range: 1-7; median: 3 days) and three weeks (range: 16-30; median: 22 days) from the first session (Baseline).

During each session, an IMU containing a tri-axial accelerometer (Shimmer3®; Shimmer Inc., Ireland) was securely attached to the anteromedial aspect of the right tibia, with the y-axis aligned with the long axis. After a 5-minute warm-up, participants ran along the running track at a self-selected speed ( $3.15 \pm 0.37$  m/s) for 2 km. Acceleration data were sampled at 500 Hz.

Acceleration data were low pass filtered at 70 Hz. Data collected during the first and last minute were discarded to account for the acceleration and deceleration phases. Peaks identified within each stride cycle from the y-component of

the acceleration data were considered axial PTA and these values were averaged across the first 5, 10, 15, 20, 50, 100, 150 and 200 strides for subsequent analyses.

Test-retest reliability was evaluated by intraclass correlation coefficients (ICC<sub>2,k</sub>) calculated using a two-way mixed effects model, mean of k measurements with absolute agreement. Values of <0.5, 0.5-0.75, 0.75-0.9 and >0.9 were interpreted as poor, moderate, good and excellent, respectively [4].

### Results and Discussion

Paired *t*-tests showed no significant difference in mean PTA between Baseline and Session 2 ( $p=0.10-0.39$ ) or Session 3 ( $p=0.06-0.15$ ). When Baseline was compared to Session 2, ICC ranged from 0.73 to 0.86 (see Figure 1) and reliability was considered good when a minimum of 10 strides were used for analysis and peaked when using more than 50 strides. For Baseline compared to Session 3, ICC ranged from 0.64 to 0.73 and reliability was considered good when using more than 50 strides for analysis.

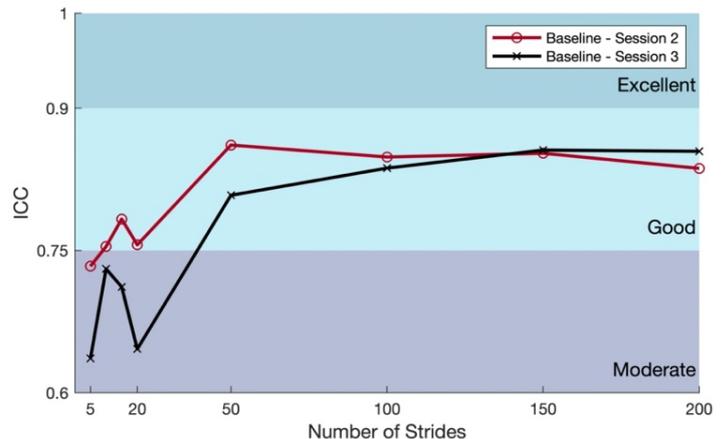

Figure 1: Between-session reliability of PTA averaged across different number of strides.

### Conclusions

Axial PTA showed moderate to good between-session reliability for overground running. Future studies should average axial PTA over at least 50 strides for good reliability.

## Potential influence of stiffening elements on metatarsal-phalangeal joint flexion and running economy

### Summary

Composite plates inserted into the midsoles of running shoes have gained popularity while their mechanics and interaction with human biomechanics remain unclear. Horizontal and vertical ground reaction force data from distinct plantar regions combined with 3D motion capture reveal that a composite plate may not alter the time, magnitude, or distribution of force on the plantar surface, and therefore, would not contribute to increased running economy.

### Introduction

The proliferation of running shoes constructed with composite plates and stiffening elements has been motivated by an attempt to improve running economy and facilitate faster times in competition. The technology has gained wide adoption within the manufacturing industry and the running community despite the absence of a plausible mechanism<sup>1</sup>. This study analyzes the ground reaction forces (GRF) from spatially distinct plantar regions together with 3D motion capture. Our results provide possible indications on how footwear stiffening elements may impact running economy. The analysis reveals how the propulsion forces of each foot region change with time for a 2<sup>nd</sup> class lever (foot-ankle)<sup>2</sup> and how the forces may not be altered in the presence of a stiffening plate.

### Methods

Vertical GRF (vGRF), horizontal GRF (hGRF), and motion capture measurements were made simultaneously for 10 healthy human participants and 120 trials of barefoot walking and running on a 10 m gait lab runway. All individuals provided written informed consent for the IRB approved study. The runway was equipped with an embedded force plate, Matscan system (Tekscan Inc.), and 3D motion detection (Vicon).

The Matscan dense grid of force sensors allowed precise delineation of the plantar regions, their respective vGRF profiles, and temporal alignment with hGRF measurements from the force plate (Fig. 1). The foot, ankle, and leg markers' trajectories were overlain on the GRF profiles to correlate lever function with plantar regional force and time.

### Results and Discussion

vGRF direction is determined by the position of the center of mass (CoM) relative to the center of force on the plantar surface. During the first portion of the ground contact phase, the CoM lies posterior to the center of force and the hGRF is directed rearward, creating a braking force that decelerates the CoM<sup>3</sup>. vGRF amplitude is at maximum when the CoM is directly above the center of force, the calcaneus is at its lowest elevation, and the metatarsal-phalangeal joints (MPJ) have no flexion. hGRF becomes forward directed as the CoM moves anterior to the center of force and the metatarsal and phalangeal regions account for the entire GRF.

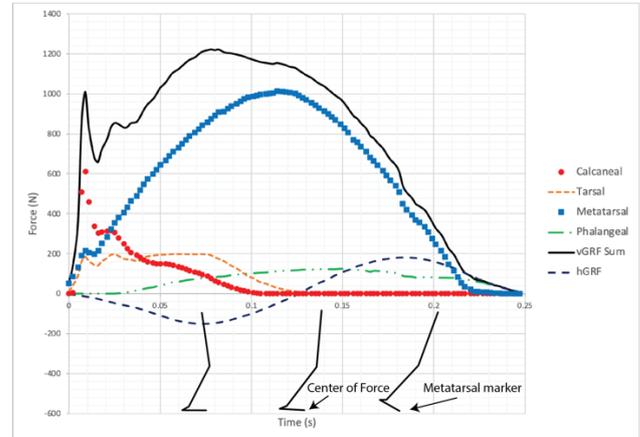

Fig. 1. Plantar regional vGRF and total hGRF with leg trajectory snapshots aligned with force profile time, in a running trial.

In the foot-ankle 2<sup>nd</sup> class lever, the MPJs make up the fulcrum and also function as load bearing hinges. The vGRF data reveal how the distribution of force between the metatarsal and phalangeal regions remains constant during MPJ flexion, indicating that force is not transferred from metatarsals to phalanges and is consistent with the 2<sup>nd</sup> class lever configuration. This function allows the metatarsals to smoothly transmit leg force both vertically and horizontally throughout the stride and flexion at the MPJ.

### Conclusion

A composite plate extending under the MPJ requires additional force in order to dorsiflex and may also reduce the range of motion at the MPJ<sup>2</sup>. However, since the MPJ functions to maintain the distribution of force between the metatarsal and phalangeal regions during flexion, not to transfer force, the composite plate may not alter the external power consumed in accelerating the CoM. It follows that if a composite plate may not alter the external power output, but that it may increase the internal power required during MPJ flexion, then a composite plate may decrease, but may not increase running economy. Further study is warranted to establish the precise impact of stiffening plates crossing the MPJ.

## Summary

Here, a novel multiscale musculoskeletal (MS) finite element (FE) modeling pipeline is established with a focus on a rapid clinically feasible assessment toolbox. To do this, an electromyography (EMG) assisted muscle-force driven FE model with fibril-reinforced poroviscoelastic (FRPVE) cartilages and menisci was coupled with an atlas-based FE modeling toolbox. The pipeline was then used to investigate the mechanical responses of knee cartilage and menisci during different activities and exercise of knee osteoarthritis (KOA) individuals. The pipeline showcases fast subject-specific MS-FE analysis of knee mechanics during functional activities.

## Introduction

Knee mechanics (i.e., tissue stress and strain) are known as crucial quantities in the genesis of MS disorders. However, current multiscale simulations that estimate these quantities are time consuming and require in-depth modeling expertise, and therefore, cannot be used to assist clinical decision making. Hence, our primary aim was to introduce a novel multiscale MS-FE analysis pipeline focusing on its feasibility for a rapid clinical toolbox to investigate multilevel mechanics of the knee load-bearing tissue. Second, we used the pipeline to explore cartilage mechanics during different daily activities and rehabilitation exercises of individuals with KOA.

## Methods

Fifteen KOA participants performed six different daily tasks and seven rehabilitation exercises while marker trajectories, ground reaction forces, and EMGs (from 8 muscles of the leg of interest) were recorded. Magnetic resonance images (MRI) were acquired to create FE models. The pipeline (Figure 1) exploited an EMG-assisted MS-FE model with FRPVE cartilages and menisci [1]. The EMG-assisted MS analyses were conducted within CEINMS toolbox [2]. To provide our workflow with rapid FE modeling, an atlas-based FE modeling toolbox [3] was adapted to create subject-specific FE model geometries consisted of femoral, tibial, and patellar cartilages, menisci, and knee ligaments.

## Results and Discussion

The estimated joint contact force, contact area [4], and muscle activations were comparable with experiments. Creating models took less than one hour per subject and running the simulations took ~16-40 hours, depending on the task. This

makes the pipeline feasible for clinical assessments, compared to manual workflow that typically takes more than a week.

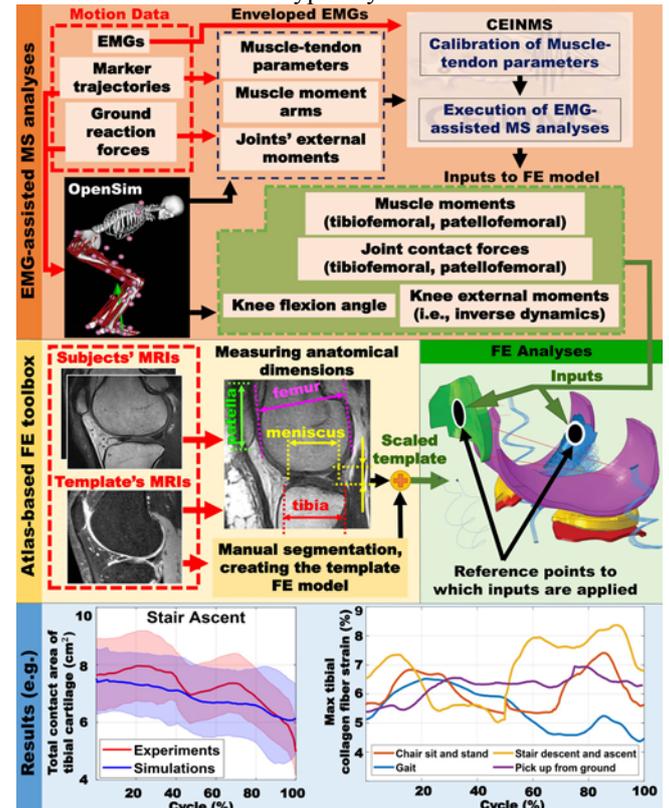

Figure 1. Illustration of the pipeline. Red arrows show raw inputs.

## Conclusions

This study showcases the usability of the pipeline as a rapid MS-FE modeling toolbox to investigate in-depth tissue mechanics of various tasks and individuals with MS disorders (e.g., KOA) promisingly beneficial in clinical assessments.

### Summary

Abnormal loading of the knee after injuries or obesity is thought to contribute to the development of osteoarthritis (OA). Small animal models have been used for studying OA progression mechanisms. However, numerical models to study cartilage responses under dynamic loading in small animals have not been developed. Hence, a finite element (FE) model of a rat knee was created to evaluate cartilage biomechanical responses during gait. Model estimations showed that the greatest contact pressure, strain, and stress values occur in both medial and lateral compartments of the tibial plateau at ~85% of the stance phase. This approach can be used to investigate the biomechanical effects of gait abnormalities on cartilage tissue in rat knee joints.

### Introduction

Abnormal loading of the knee joint after overuse, severe injuries, or obesity might lead to cartilage degeneration which contributes to the development of osteoarthritis (OA). Experimental animal models have been used in orthopaedic research for studying the progression of OA. In preclinical research, small animal models (e.g. rodents) are commonly used as they are cheaper and less time consuming for changes in primary outcomes to occur compared to large animal models. For example, rodent gait compensations have been evaluated in conjunction with biological markers of OA after ACL transection [1]. The effect of these compensations on cartilage loading and mechanics can be assessed using numerical models. However, computational models for joints of small animals have not been reported in the literature. Hence, our primary aim was to develop a FE model of the rat knee joint to evaluate the cartilage biomechanics during gait.

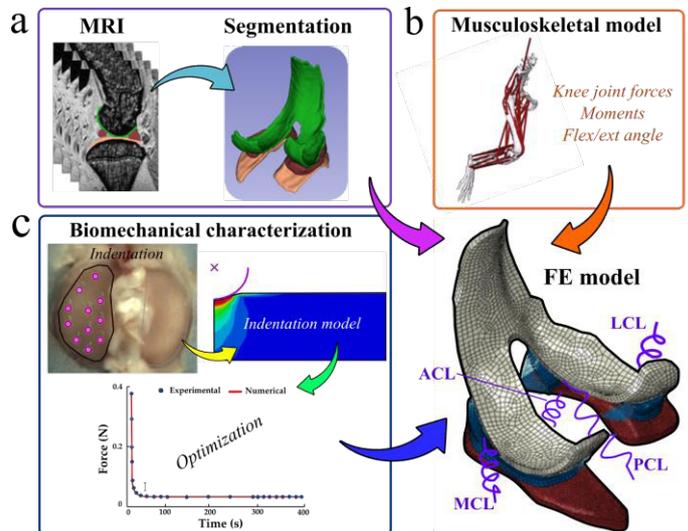

### Methods

**MRI protocol:** An intact right lower limb of a cadaveric rat without known musculoskeletal disorders (Sprague Dawley, 56-week-old male) was imaged using an 11.74 T  $\mu$ MRI scanner (MGE sequence, FOV (mm)=14.25x9.5x9.5, isotropic resolution: 37 $\mu$ m). The MRI data were used for segmenting the knee geometries in 3DSlicer (<http://www.slicer.org>). The geometries were imported into Abaqus where the FE mesh was constructed using 8-node hexahedral linear poroelastic (C3D8P) elements. **Musculoskeletal modeling:** A previously developed OpenSim musculoskeletal model of the rat lower limb was used to determine the joint loading during simulated gait [2]. The flexion-extension angle, moments, and translational knee forces were extracted and implemented into the FE model. **Biomechanical cartilage characterization:** Fibril-reinforced poroelastic (FRPE) material properties of rat cartilage were acquired using previous experimental indentation measurements [3]. The FRPE cartilage parameters were obtained by fitting the simulated stress-relaxation curve to the mean stress-relaxation curve of control group animals ( $n=6$ ) [3]. **FE knee joint model:** Cartilages and

menisci were modeled using an FRPE material. The fitted FRPE material parameters, depth-dependent collagen fibril architecture, and fluid fraction distribution were implemented [4]. The tibial cartilage-bone interface was fixed in all directions and bones were assumed rigid. Following an initial contact step, the stance phase of the rat's gait was simulated (Figure 1).

### Results and Discussion

Numerical results showed that the greatest contact pressure (0.25 MPa), reaction force (7.2 N), fibril strain (0.6%), maximum principal strain (3.5%), fluid pressure (9.2 MPa), and maximum principal stress (7.5 MPa) averaged over the contact area in the tibial cartilage surfaces were obtained at ~85% of the stance phase. This approach allows for future investigation of the biomechanical effects of pathological conditions in small animal preclinical OA models.

**Figure 1:** Workflow of the study. (a) Rat knee geometry, (b) motion and loading during gait from a musculoskeletal model, and (c) FRPE material properties from indentation tests were implemented into the FE model.

### Conclusions

Our novel simulation approach can be utilized to evaluate the effect of knee joint disorders and gait impairments on cartilage biomechanical responses in small animal models.

## Approximation method to calculate the elasticity tensor for hyperelastic finite element models

Manuel Lucas Sampaio de Oliveira<sup>1</sup>, Thomas K. Uchida<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, University of Ottawa, Ottawa, Ontario, Canada  
Email: mdeol080@uottawa.ca

### Summary

Rubber-like or hyperelastic materials are used in a broad range of applications, including vehicle tires, seals, base isolation of buildings, and biomedicine. Predicting the behaviour of these materials is crucial for design and analysis. In this work, we develop a user material in Ansys using an approximation formulation to improve computational performance during finite element analyses. The stress and strain produced by three constitutive models are compared to those of analytical models as well as built-in Ansys models. The approximation improves simulation time while introducing relatively small errors that may be acceptable in many applications.

### Introduction

Hyperelastic models have been used to study the behaviour of many biological tissues including breasts, ligaments, arteries, and skin [1]. Many commercial software packages include built-in hyperelastic materials such as the Mooney–Rivlin and Yeoh models. These models assume that the material has isotropic properties; however, we often wish to include the effects of anisotropy by considering a strain energy that includes invariants associated with a preferred direction of stretch. Anisotropy can be useful for simulating polymers and fibered soft tissues such as ligaments [2] and muscles [3].

Ansys is a popular finite element analysis software and supports user material (“USERMAT”) subroutines to implement user-defined models. These subroutines provide as outputs the Cauchy stress and the tangent modulus, also referred to as the elasticity tensor or material Jacobian. The Cauchy stress is relatively straightforward to calculate; however, the tangent modulus is more complicated due to the presence of a fourth-order tensor, making the calculations more cumbersome to program and more time-consuming to evaluate. To reduce the computational expense of computing the elasticity tensor, we explore the use of an approximation of the tangent modulus proposed by Miehe [4]. This approximation relies on the perturbed deformation gradient and does not substantially compromise the convergence rate.

### Methods

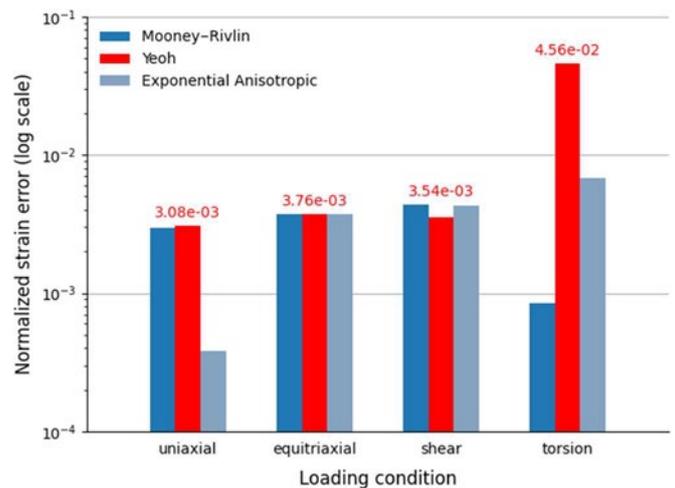

A USERMAT routine is implemented in Ansys in a systematic way, allowing one to easily implement different hyperelastic models. We test the Mooney–Rivlin and Yeoh models as well as the exponential form of the strain energy for an anisotropic material. The built-in Ansys model is used as the gold standard. A single-element cube is simulated under uniaxial, equitriaxial, shear, and torsion loads. We compare the stress and strain of our approximation and analytical model implementations against the built-in Ansys model. Finally, an analysis with different mesh refinement is performed to determine how the error is affected by mesh size.

The approximation method is based on perturbations of the deformation gradient. The performance of each model is assessed by calculating the normalized root-mean-square error (NRMSE) of stress and strain for  $N$  nodes:

$$\text{NRMSE} = \sqrt{\sum_{i=1}^N [( \text{Predicted}_i - \text{Actual}_i ) / \text{Actual}_i ]^2 / N}.$$

### Results

The average stress and strain errors were on the order of  $10^{-2}$  to  $10^{-4}$  for all models and loading conditions; normalized strain errors are shown in Figure 1. Specifically, the results are shown for four loading conditions: a uniaxial test with a displacement of 0.5 applied to one face with the opposite face constrained; an equitriaxial test with a displacement of 0.5 applied to three faces with the opposite faces constrained; a shear test with a lateral displacement of 0.5 applied to the top face with the bottom face constrained; and a torsion test where opposing 50 N forces are applied to the top and bottom faces.

**Figure 1:** Normalized root-mean-square error in strain for three material models with approximation, in four loading conditions.

### Conclusions

Analytical and approximate models all have relatively small errors when compared to the results from the built-in Ansys models. Complex models can be implemented easily and without substantial loss of precision using an approximation of the tangent modulus.

### Summary

A statistical shape model (SSM) was created for an active young adult population and used to predict tibia and fibula geometries for young and older adults from anatomical bony landmarks. Reconstruction errors with respect to computed tomography (CT) data were quantified and compared to errors from isometric scaling. The SSM estimated tibia and fibula geometries from landmarks with lower error (RMSE young = 1.62 mm, old = 2.12 mm), when compared to isometric scaling (RMSE young = 1.78 mm, old = 2.86 mm). The smaller errors for the young adults suggest a model specific to the population of interest provides excellent reconstruction accuracy; however, the SSM was still able to predict tibia and fibula geometries in older adults with 26% lower error than isometric scaling when shape variation is taken into account.

### Introduction

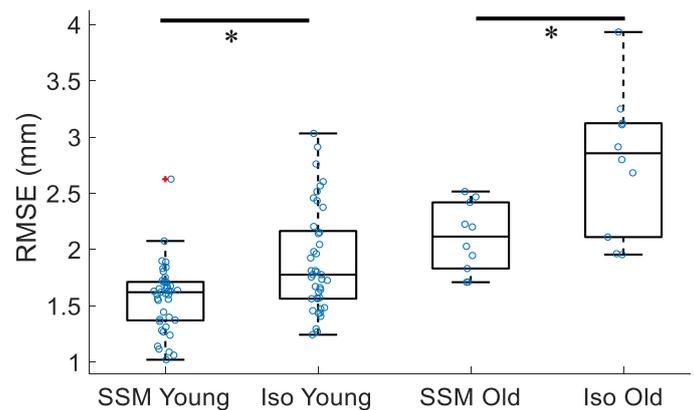

Bone geometries in musculoskeletal models are commonly defined by isometrically scaling 'generic' models [1], which does not necessarily capture potentially important morphological differences among individuals. SSMs provide an alternative method to incorporate participant-specific bone geometry into musculoskeletal models as they can reconstruct geometry from anatomical landmarks. However, previous SSMs of the tibia and fibula were trained and tested on a wide range of ages [2,3]; a SSM more specific to the population of interest may provide better results. The aims of this study were to: (1) create a SSM of the tibia and fibula for a healthy young adult population and evaluate the accuracy of reconstructions from landmarks compared to isometric scaling, and (2) to evaluate reconstruction accuracy in older adults.

### Methods

A SSM of the tibia-fibula complex was created using CT data from 41 young adults (22 F, 18-24 years). Nine landmarks were digitised on the bone surfaces. A leave-one-out analysis was performed, where a participant was removed from the SSM and reconstructed from the landmarks in two ways: (1) SSM-based reconstruction, where the average shape was morphed along eight principal components to match target landmarks, and (2) isometric scaling. Errors in surface geometry compared to CT segmentations were quantified. Landmarks were also digitised on bone surfaces of ten older adults (4F, 71-98 years). The SSM developed for the young adult group was used to reconstruct tibia and fibula geometries in the older group; reconstruction errors were again quantified and compared to isometric scaling. Wilcoxon signed-rank tests were performed to compare error measures between SSM and isometric scaling methods.

### Results and Discussion

In the young group isometric scaling errors (median (IQR), RMSE = 1.78 (0.62) mm, maximum error = 5.84 (2.62) mm) were 51-54% lower compared to previous studies [2,3]. SSM reconstruction further reduced errors (RMSE = 1.62 (0.35) mm, maximum error = 5.12 (1.63) mm,  $p < 0.001$ , Fig. 1).

**Figure 1:** Root mean square errors for surface geometry reconstructions (SSM-landmark and uniform scaling methods) for young and older participants (circles). + represents an outlier. \* indicates a significant difference between SSM and isometric scaling.

In the older group, errors were smaller in SSM (RMSE = 2.12 (0.63) mm, maximum error = 7.01 (1.28) mm) compared to isometric scaling (RMSE = 2.86 (1.08) mm, maximum error = 9.14 (4.19) mm,  $p \leq 0.009$ ). Errors for both SSM and isometric scaling in the older group were generally larger than errors in the younger group but were still 22-34% lower compared to previous studies [2,3]. This may be explained in part by the use of more landmarks and principal components in SSM reconstructions as well as bone-surface landmarks in isometric scaling.

### Conclusions

The SSM predicted tibia and fibula geometries from bony landmarks with high accuracy, improving upon isometric scaling. Errors were larger for the older adults, suggesting that some geometric variation due to age was not captured in the model; still, errors for older adults were low compared to previous studies. In summary, the SSM provided excellent reconstructions of the tibia-fibula complex in young adults and appears robust enough for older adults as well.

# Design and Evaluation of a Mixed Reality Spine Surgical Simulator Benchtop Configuration Based on the Workspace of Haptic Device and Simulator Users

Sneha Patel<sup>1</sup> and Mark Driscoll<sup>1</sup>

<sup>1</sup>Musculoskeletal Biomechanics Research Lab, Department of Mechanical Engineering, Faculty of Engineering, McGill University, Montreal, Canada

Email: mark.driscoll@mcgill.ca

## Summary

Current surgical simulators have either virtual or physical components. In the present study, the surgical area is modelled virtually and physically therefore requiring matching reference models for natural manipulation of the surgical tools while interacting with the simulator. This study collected path trajectories of experienced spine surgeons in a novel spinal fusion surgical simulator and the workspace of the haptic device to determine the appropriate configuration of the mixed reality surgical simulator. The results suggest differences between users and the selected configuration encompassing the required workspace for the surgery.

## Introduction

Minimally invasive spine surgeries are complicated and require complex motor skills due to the proximity of the spine to neural and vascular components and limited access to the surgical area. Without proper training serious complications can occur in these procedures [1].

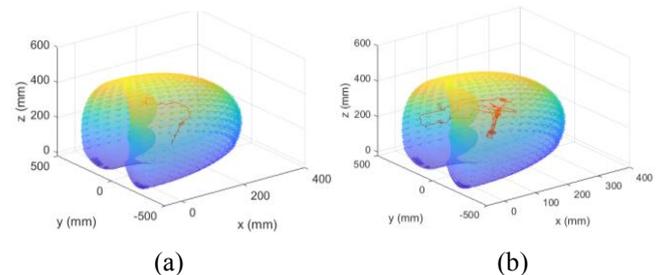

Teaching hospitals strive to address the need for intensive training in this field while mitigating the risks associated with conventional training. Therefore, several use virtual reality simulators to provide residents a platform to improve their motor skills without risk to patients. In minimally invasive simulators, haptic feedback is essential due to the limited visual cues available from the surgical area. Therefore, most commonly, a haptic device or a physical model is used in the simulator [2, 3]. The purpose was thus to conceive a workspace, encompassing haptic and physical models, while enabling fluent surgical maneuvers.

## Methods

First, the workspace adopted by experienced surgeons relative to that of the haptic device was evaluated, during surgical port insertion and discectomy, to optimize the design of the benchtop. This consisted of a model of the surgical area, sensors, and the haptic device. Kinematic analyses for the haptic device, were completed to develop the workspace of the haptic device. The haptic device modelled the tools and collected the path trajectory until the surgeons considered the task completed. Surgeons completed the same surgery on a cadaver before using the simulator to encourage fluid maneuvers. User trajectory was then superimposed on the haptic device workspace in order to determine the ideal configuration of the benchtop. Statistical analyses were then conducted to test the effects of surgical experience on the trajectory and workspace of the user in the simulator.

## Results and Discussion

Figure 1 shows that the workspace of the user is always encompassed by the workspace of the haptic device. In figure 1(a) they have the freedom to move throughout the benchtop model. In figure 1(b) the user's movement is limited to the cylindrical port through which the procedure is completed.

**Figure 1:** (a) Illustrates the trajectory of a surgeon, red, encompassed in the workspace of the haptic device for which heights were adjusted whereas (b) shows their trajectory through a cylindrical port during discectomy.

A Kruskal-Wallis Test assessed the trajectories of the subjects. Results of the analysis suggest user trajectories to be very different despite their surgical experience and that the selected configuration meets the needs of surgeons performing fusion surgery while enabling fluid maneuvers. The Spearman correlation compared the trajectory volume during each task versus the surgeons' experience. The results suggest a correlation between the two variables and the importance of this metric to assess the user in the simulator.

## Conclusions

This study presents a method to determine and evaluate the configuration of a mixed reality surgical simulator using the workspace of the haptic device, the surgery workspace, and user trajectories in the simulator.

### Summary

Running, a common recreational activity for maintaining health, has received little research in terms of knee joint contact mechanics. Further, there is a gap in knowledge for predicting knee contact mechanics before and after transverse plane deformity. A finite element model of the knee was employed to simulate corrective osteotomies and investigate changes in knee compartment contact mechanics. Our findings show that medial and lateral compartment stress can be modeled and simulated as a function of osteotomy angle.

### Introduction

Lower limb malalignment in the sagittal, frontal, or transverse planes, is a common problem affecting individuals with osteoarthritis (OA). It is not clear how the initial posture or corrective osteotomies affects knee joint stress. Derotation osteotomy of the femur has been shown to treat either femoral retroversion or excessive anteversion [1]. Computational methods have been used to study lower limb malalignment and surgical repair. Still, there is paucity of in-vivo, in-vitro, and in-silico data from which the effect of transverse plane osteotomies upon knee contact mechanics may be predicted. The central hypothesis is that transverse plane osteotomies will modify medial and lateral compartment stress.

### Methods

Our computational model was constructed from a 50-year-old, 65 kg male cadaveric specimen. MRI data of the left lower limb was segmented in Mimics (Materialise, Leuven) and exported to CATIA (Simulia, Vélizy-Villacoublay) to create 3D models of each tissue (bones, cartilage, meniscus, capsule and primary ligaments). The 3D tissue models were meshed and assembled in ABAQUS (Simulia, Vélizy-Villacoublay). The finite element model was augmented by including the patella and associated cartilage, ligaments, and the quadriceps-patellar tendon [2]. The native knee was in 35° of femoral anteversion (0° model), compared to 14±7.8° for the general population [3]. We simulated mid-femur transverse plane osteotomies of -20°, -10°, 0°, 20°, 30°, 40°, 50°, 55°, and 60° (retroversion (-) / anteversion (+)). All osteotomy corrections were made with respect to the native knee alignment of 35° degrees anteversion. Inverse dynamic forces and moments were acquired from the Leon Root, MD Motion analysis laboratory (height, weight, age, and sex matched). Specifically, the loading from 45% of the gait cycle, where peak internal/external moments occur, was applied. Input forces and moments were transformed to account for osteotomy correction angle. Von Mises and Tresca stress were computed for all tissues in the joint.

### Results and Discussion

Different osteotomy angles provided varying medial and lateral compartment stress magnitudes at the cartilage-

cartilage and cartilage-meniscus interfaces (**Fig. 1, Fig. 2**). **Fig. 1** illustrates the cartilage-meniscus stress in the medial and lateral compartments as a function of osteotomy angle, where 0° is the native alignment. In **Fig. 2** the cartilage-cartilage interface is depicted for the medial and lateral compartments across all osteotomy angles.

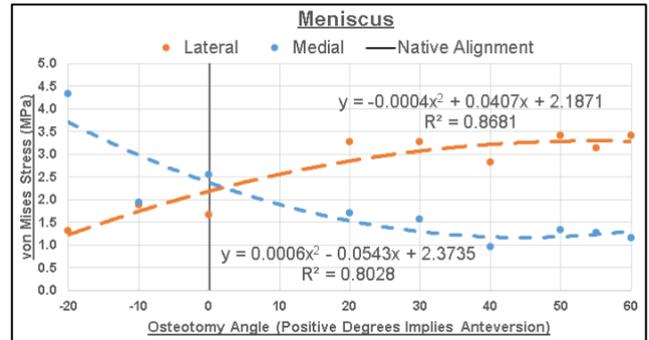

Fig. 1: Peak Meniscus von Mises Stress

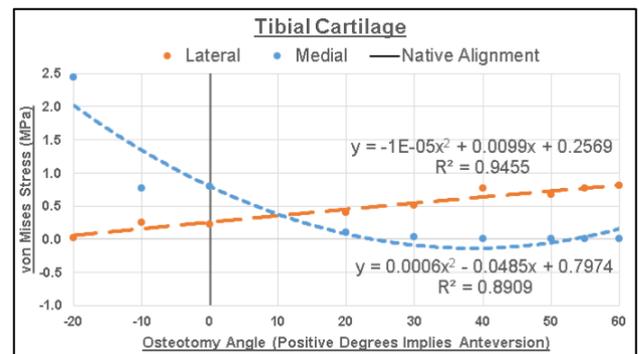

Fig. 2: Peak Tibial Cartilage von Mises Stress

Forces and moments were larger in the lateral compartment, as expected for running, for the anteverted osteotomies. As shown in **Fig. 1** and **Fig. 2**, there is a trade-off between medial and lateral compartment stress as a function of osteotomy angle. The results depicted in this study correspond to the specific knee modeled and cannot be generalized. It is possible that other knees could have different peak stresses in different locations due to their different geometries.

### Conclusions

In support of the hypothesis, simulation of medial and lateral compartment stress in running varied across transverse plane osteotomy angles. The anteverted osteotomies resulted in higher lateral compartment stress. This work represents a first step towards the development of surgical treatment planning tools to aid surgeons in making informed decisions when planning osteotomies.

### Summary

Musculoskeletal models enable subject-specific analyses through controlled variation of biomechanical parameters. However, modeling even simple tasks requires assumptions about unmeasurable Hill-type muscle parameters. We tested an approach to estimate these parameters from simulated lateral pinch force using artificial neural networks. Our results suggest classifying muscle parameters from pinch force is feasible, but complex models may require more input features.

### Introduction

Musculoskeletal models of the thumb are defined by over 109 independent biomechanical parameters [1]. Many of these parameters are difficult or impossible to measure *in vivo*, hindering development of subject-specific models. In this study, we present a data-driven approach to estimate the maximum isometric muscle force (unmeasurable parameter) from pinch force (measurable clinical outcome). Leveraging forward dynamic simulations and artificial neural networks (ANNs), we elucidate the role maximum isometric force of extrinsic muscles plays in lateral pinch force generation.

### Methods

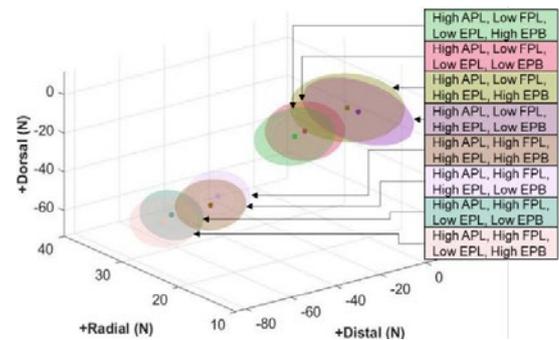

Four datasets of lateral pinch force were produced via forward dynamics in OpenSim v 3.3 [2]. A thumb model [1] was varied by adjusting maximum isometric force of the extrinsic thumb muscles [*abductor* (APL), *flexor* (FPL), and *extensor* (EPL) *pollicis longus* and *extensor pollicis brevis* (EPB)]. Datasets 1 through 4 contained 120, 1024, 3197, and 4096 simulations as 1-4 muscles were adjusted, respectively. The output of each simulation was a three-component pinch force vector versus time. The time-series force data was separately input into 2 ANNs: *feedforward* and *long short-term memory* (LSTM). Feedforward ANNs lack feedback within the structure [3], but are less computationally costly. LSTMs have feedback and thereby “memory” [4], which can aid study of time-dependent activities. Each ANN included 4 input nodes (time and three-component force vectors), 4 hidden nodes, and 1 hidden layer. Labeled data were grouped by whether the varied muscles were above (“High”) or below (“Low”) mean maximum isometric force. Modifying more muscles resulted in more labeled groups, requiring 2, 4, 8, or 16 output nodes for Datasets 1-4, respectively. Mean and standard deviation (SD) of thumb-tip force for each group were calculated. To reduce overfitting, 5-fold cross validation was used. Accuracies and losses were analyzed, and a two-sample t-test compared peak accuracies of each ANN and dataset.

### Results and Discussion

The mean and distribution of final thumb-tip forces within Dataset 4 revealed the relative contributions of extrinsic

muscles (Figure 1). No overlap within 1 SD occurred between groups with a high FPL maximum isometric force and that with a low one. Little overlap occurred between groups of high and low APL maximum isometric force. Both ANNs saw a decrement in performance for datasets which altered more muscles. In the feedforward ANNs, the peak accuracy for Dataset 1 was 93.2%, but 37.4% for Dataset 4. For the LSTM ANNs, the peak accuracy for Dataset 1 was 93.8%, but 34.8% for Dataset 4. Losses became substantially less stable for more complex datasets for both ANNs. Two-sample t-tests revealed that only analysis of Dataset 2 produced significantly different peak accuracies ( $p < 0.05$ ), which were higher for the LSTM than the feedforward ANN. Peak accuracies for all datasets were well above random guess.

The decrement in model performance for more complex datasets may be attributable to redundancies in muscle function. Notably, the EPL and EPB are extensors of the thumb, with the APL assisting in extension as well [5]. As Datasets 3 and 4 included changes to combinations of these muscles, the classification task of the ANN became more challenging. Optimization of ANN width and depth may benefit classification [6, 7], as well as the inclusion of more measureable inputs (e.g. kinematics, EMG)

**Figure 1:** Thumb-tip forces for part of Dataset 4. Ellipsoid centers represent mean force and radii represent 1 SD

### Conclusions

Our investigations tested the feasibility of using ANNs to predict muscle parameters from lateral pinch force. This framework is a first step toward estimating subject-specific muscle parameters from minimal, measurable data.

## Objectively Defining Design Parameters Associated with Self-Selected Lumbar Support Prominence

Jessa M. Buchman-Pearle, Kayla M. Fewster, Brendan L. Pinto, Jack P. Callaghan

Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada

Email: jessa.bpearle@uwaterloo.ca

### Summary

Participants self-selected lumbar support prominence (LSP) and vertical location in an automotive seat through a series of systematic adjustment trials. The average LSP setting was set for a one-hour driving simulation, followed by one final LSP adjustment trial. Multiple linear regressions revealed low to strong model fit between anthropometric characteristics and seated lumbar flexion, seatback average pressure, and contact area. Following the driving protocol, participants preferred changes to seat settings that decreased lumbar flexion and increased seatback pressure. These findings suggest that integrating subject-specific design parameters and methods for determining seat preference may reduce maladaptive tissue adaptations and discomfort associated with prolonged sitting.

### Introduction

Automotive seat design parameters, such as the addition of a lumbar support prominence (LSP), has the potential to impact postural changes that may lead to low back pain during prolonged driving [1,2]. LSP preferences tend to vary across individuals, specifically between males and females [3]. Therefore, this study investigated subject-specific parameters which may alter LSP preference and associated variables, before and after a prolonged driving simulation.

### Methods

Forty participants (21M/19F, mean height =  $1.70 \pm 0.10$  m, mass =  $72.1 \pm 16.5$  kg, BMI =  $24.7 \pm 3.8$  kg/m<sup>2</sup>, waist and hip circumference =  $79.5 \pm 13.6$  and  $97.6 \pm 12.1$  cm) completed six automotive seat-adjustment trials, a one-hour driving simulation, and one final seat-adjustment trial after driving. For the initial adjustment trials, three trials began with the LSP fully disengaged and down, and three with the LSP fully engaged and up, allowing the participant to freely position the LSP. The average chosen LSP setting (prominence and vertical location) was used for the prolonged driving simulation. Sagittal lumbar angles were calculated from triaxial accelerometers over the pelvis and L1. Seatback pressure distribution and motion of the trunk and pressure mat were also recorded.

Backward stepwise linear regressions were performed between participant anthropometry, standing lumbar angle, and lumbar sagittal range of motion on: 1) selected LSP, 2) seated lumbar flexion, 3) average seatback pressure, 4) seatback contact area, and 5) height of the centre of pressure (CoP) above the midpoint of the iliac crests. LSP was also input into the regressions for the remaining four dependent variables. Five two-way mixed ANOVAs ( $\alpha = 0.05$ ) were performed to determine the effects of time and sex.

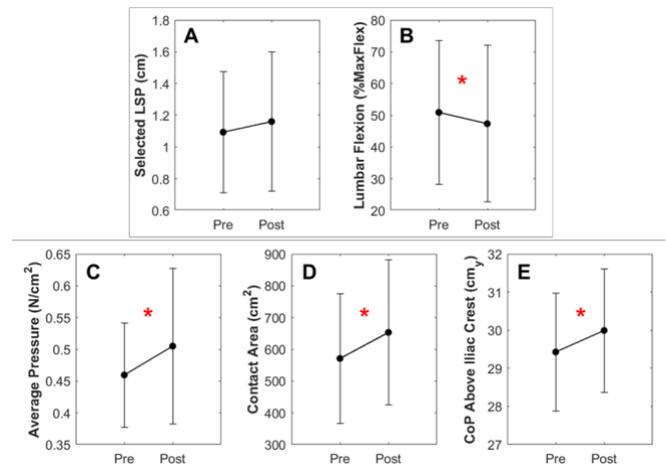

### Results and Discussion

Significant regression models ( $p \leq 0.005$ ) were produced for seated lumbar flexion, average seatback pressure, and

seatback contact area (Table 1). There was a significant main effect of time ( $p \leq 0.017$ ) for all variables except LSP (Figure 1). There was a main effect of sex for contact area as area was  $140.3$  cm<sup>2</sup> greater for males than females.

**Table 1:** Summary of regression models which reached statistical significance ( $p < 0.01$ ).

Dependent Variable	R	R <sup>2</sup>	Independent Variable
Seated Lumbar Flexion	0.56	0.32	Standing lumbar angle
Average Pressure	0.44	0.19	LSP
Contact Area	0.73	0.53	Height and mass

**Figure 1:** Pre- and post-driving simulation comparisons where red asterisks indicate a significant difference ( $p < 0.05$ ).

### Conclusions

The correlations between standing lumbar angle, height, mass, and dependent variables describing automotive seat preference suggests that these subject parameters should be considered in future automotive seat design. Additionally, the decrease in lumbar flexion and increase in seatback pressure without a significant change in LSP suggests that the method for seat-adjustment facilitates effective LSP selection across subjects. Further, utilizing this method may reduce the need for seat adjustments, wherein cueing short-term postural adjustments may be preferred.

<sup>1</sup>Division of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, CA, USA

<sup>2</sup>Department of Biobehavioral Sciences, Teachers College, Columbia University, New York, NY, USA

Email: yueai@usc.edu

## Summary

We compared trunk muscle activation and co-activation during symptomatic and asymptomatic periods of persons with recurrent low back pain (rLBP) as well as back-healthy controls (CTRL) using the Balance-Dexterity Task (BDT). Persons who were actively in pain (rLBP-A) exhibited transverse plane trunk muscle co-activation patterns similar to CTRL, whereas persons in symptom remission (rLBP-R) demonstrated decreased co-activation of these muscles.

## Introduction

Trunk control strategies in persons with rLBP are task-dependent, where submaximal tasks such as the BDT tend to elicit decreased activation compared to maximal tasks [1]. Previous research using the BDT suggests that rLBP individuals who were asymptomatic when tested showed reduced trunk kinematic coupling along with lower deep-to-superficial trunk muscle activation ratios compared to CTRL [2]. The influence of pain status in persons with rLBP on trunk muscle co-activation is unknown. Therefore, the purpose of this study was to investigate trunk muscle co-activation in and out of pain in persons with rLBP compared to CTRL. We hypothesized that persons with rLBP, regardless of pain status, will exhibit reduced trunk musculature co-activation compared to CTRL, and these individuals will have higher co-activation during their symptomatic periods compared to asymptomatic periods.

## Methods

19 persons with rLBP (F=13, M=6; 25.3±5.2 years) and 19 matched CTRL (F=13, M=6; 26.9±3.4 years) were tested. rLBP were tested first in pain (Visual Analog Scale (VAS, 0-100): 38.9±19.2 mm), then out of pain (VAS: 1.4±2.4 mm).

The BDT required participants to stand on the supporting limb and exert a downward compression force onto either a stable block or an unstable spring with their non-stance limb to sustain an individualized force target. Surface EMG was used to collect activation levels for 8 muscles at 1500Hz (bilateral Longissimus, Rectus Abdominis (RA), External Oblique (EO), Gluteus Medius (GM)), and signals were processed using a 4<sup>th</sup> order Butterworth filter with a 50ms moving window. Activation amplitudes were normalized to the stable block condition. Muscle co-activation indices for 12 between-muscle pairings were derived using the Falconer and Winter method [3], where the co-activation levels for each muscle pairing were normalized to the sum of their individual activation levels. Statistical analysis was conducted using linear mixed-effects models.

## Results and Discussion

All muscles showed significantly greater activation levels in the spring condition than the block condition ( $p < 0.05$ ). Except for bilateral RA, all muscle pairings exhibited greater co-activation in the block condition than the spring condition ( $p < 0.001$ ). rLBP-R showed less bilateral EO (R-L EO) co-activation than rLBP-A and CTRL, while no difference was found between rLBP-A and CTRL (Fig 1). No difference was found between rLBP-A and rLBP-R in other muscle pairings, so data was pooled between pain statuses and compared to CTRL. Pooled rLBP data showed greater decreases in right RA and right GM co-activation from block to spring in the rLBP group than the CTRL ( $p = 0.035$ ).

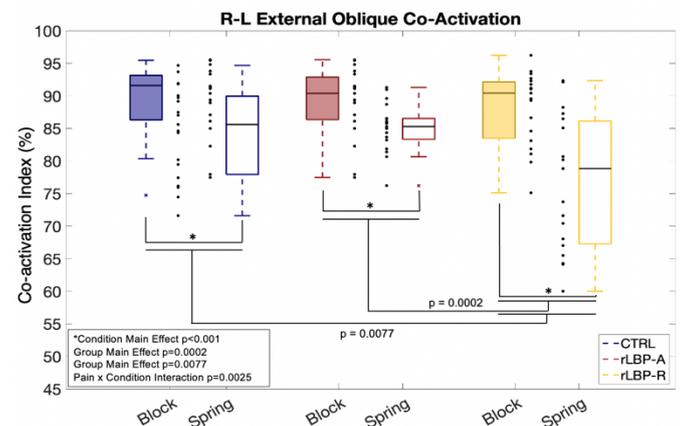

Figure 1: R-L EO Co-activation per condition and group.

## Conclusions

Persons with rLBP exhibited more R-L EO co-activation in active pain than in remission, but the co-activation levels in active pain were not greater than those in CTRL. The lower co-activation of R-L EO during asymptomatic periods may cause excessive intersegmental motion as has been observed in this task previously [2] that may predispose persons to experience repeated bouts of pain.

# Exploring the Correlation Between Rotational and Translational Joint Passive Stiffness – A Porcine *in-vitro* Investigation

Kayla M. Fewster, Jeff M. Barrett, Jack P. Callaghan  
 Department of Kinesiology, University of Waterloo, Waterloo, ON  
 Email: [kfewster@uwaterloo.ca](mailto:kfewster@uwaterloo.ca)

## Summary

Different clinical test paradigms evaluating spine stiffness rarely agree, we hypothesized this may be because they assess different modes of loading. Translational anterior and posterior shear, and rotational flexion and extension stiffnesses were measured on 48 porcine functional spinal units. Linear regressions were performed between these measures. Only a weak positive correlation between posterior and extension stiffness was found.

## Introduction

Spinal range of motion is an important clinical measure and can provide insight into the state of degeneration or injury of an intervertebral joint. This clinical significance has been emphasized through numerous *in-vitro* studies observing significant correlations between state of degeneration and structural properties of the functional spinal unit (FSU) [1–3]. However, *in-vivo* clinical assessments of spinal stiffness have weak correlations between one-another [4]. We hypothesized that these findings may be partially explained by anisotropy of the FSU and different loading paradigms across clinical testing. If the stiffness of isolated FSUs differs across loading paradigms, then it may explain the variability in findings from clinical assessments. Therefore, the purpose of this investigation was to quantify the relationships between rotational and translational stiffness *in-vitro*.

## Methods

48 porcine cervical FSUs (20 C34, 28 C56) underwent rotation range of motion testing (ROM) ( $\pm 8\text{Nm}$  moment applied at  $0.5^\circ/\text{s}$ ) followed by translation ROM testing ( $\pm 400\text{N}$  shear load applied to the caudal vertebra at  $0.2\text{mm}/\text{s}$ ) while simultaneously exposed to  $300\text{N}$  of compression. Porcine cervical FSUs were used as surrogates for the human lumbar spine due to the anatomical and functional similarities. Following testing, moment-angle curves from flexion-extension ROM testing and force-displacement curves from shear ROM testing, were created to quantify flexion and extension rotational stiffness and anterior and posterior shear translational stiffness. Correlations between all four measures were completed (RStudio, version 1.2.5033) and significant relationships were assessed at an *a-priori* level of significance ( $\alpha$ ) of 0.05.

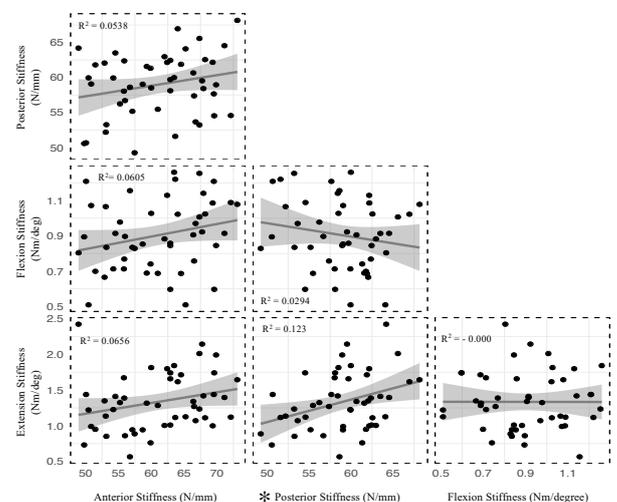

## Results and Discussion

Descriptive statistics for each outcome measure are presented in Table 1. No strong correlations ( $R^2 > 0.80$ ) were observed between any of the outcome variables explored in this investigation (Figure 1). Of the six correlations completed,

only one was statistically significant. Specifically, posterior translational stiffness was weakly correlated with extension rotational stiffness ( $p = 0.0146$ ;  $R^2 = 0.123$ ).

**Table 1:** Summary of the stiffness values measured in the specimens along with standard deviations.

Anterior Stiffness (N/mm)	Posterior Stiffness (N/mm)	Flexion Stiffness (Nm/deg)	Extension Stiffness (Nm/deg)
$61.0 \pm 6.8$	$59.8 \pm 4.4$	$0.903 \pm 0.198$	$1.33 \pm 0.40$

**Figure 1:** Correlations and their  $r^2$  values for each of the six correlations completed. Overall, none of the variables explored in the study were highly correlated, and only extension and posterior stiffness values were significantly correlated.

## Conclusions

This investigation demonstrated poor correlations between rotational and translational stiffness metrics. Such results support conflicting findings of tissue stiffness *in-vivo*. Results from this investigation suggest that clinicians should be cognizant of which degrees-of-freedom they are assessing in the spine, as their stiffness values may vary independently.

### Summary

By considering the incidence of anterior cruciate ligament (ACL) injuries and the high reinjury rates, there is no agreement on which is the best criteria to plan the athletes return on field after ACL reconstruction [1]. The aim of this study is to identify a suitable protocol for assessing ACL injury biomechanics directly on the field, thus taking into account the role of the sport specific environment.

### Introduction

Anterior cruciate ligament (ACL) injury is multifactorial and involves biomechanical, anatomical and neuromuscular factors, such as excessive knee valgus moments or large anterior tibial translation [2]. Hence, screening methods should be linked to the mechanical etiology of ACL injuries in order to effectively identify ‘at-risk’ athletes [3]. This study aims at validating the adoption of a biomechanical assessment that can be performed on the field by means of video cameras and plantar pressure for ACL injury risk assessment [4].

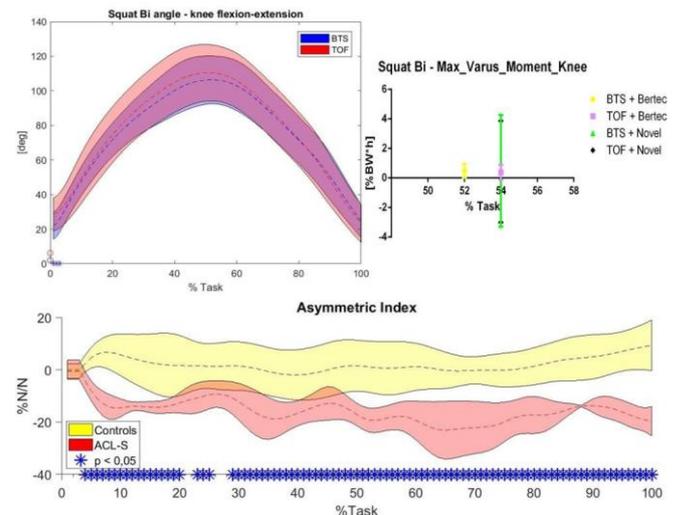

### Methods

After signing informed consent, 7 subjects were acquired: 6 controls (age  $27.3 \pm 4.4$  years, BMI  $27.8 \pm 1.9$  kg/m<sup>2</sup>), 1 ACL-injured subject (ACL-S) 3 months after the surgery (age 27 years, BMI 22 kg/m<sup>2</sup>). Data were simultaneously acquired by means of a stereophotogrammetric system (6 TVC, BTS) synchronized with two force platforms (Bertec), a video-based system (8 TVC, GoPro Hero 7) and plantar pressure insoles (PedarX, Novel). Controls performed three mopedalic and bipodalic squats, while the ACL-S performed only bipodalic squats. Reflective markers were applied as in [5] and trajectories reconstructed through stereophotogrammetry and automatic tracking [4] (a self-developed software Track on Field (TOF), BBSof S.r.l., validated in [6] was used). Joint kinematics [5,6] and kinetics [4,5] provided through the following set-up were compared: Stereophotogrammetry and force plates (set-up\_1) [5]; Stereophotogrammetry and plantar pressure (set-up\_2) [4]; video cameras and force plates (set-up\_3); video cameras and plantar pressure (set-up\_4) [4]. Wilcoxon signed rank test ( $\alpha=0.05$ ) was used to compare the data across the different set up and the asymmetry index (AI) was calculated [7]. The comparison between controls and ACL-S was performed through Wilcoxon rank sum test ( $\alpha=0.05$ ). To assess the inter-operator variability of the video tracking the Standard Error (“SE”) [8] was calculated (2 operators).

### Results and Discussion

Reliability and repeatability results showed good agreement between angles calculated with both systems, (Fig.1, Up) and a low inter-operator variability. In the comparison of the joint

moments across the different set-up, larger differences were observed in the monopodalic squats, especially in the central phase, at the hip joint, between set-up\_1 and 4. Statistically significant differences were observed on joint angles, moments and the AI (Fig. 1, Down) between controls and ACL-S in every tested condition.

**Figure 1:** Up Left, the knee flexion-extension angle, BTS, in blue and TOF, in red. Up Right, the knee varus torque peak calculated for each set-up, value and occurrence within the task. Down, the AI, controls in yellow and ACL-S in red.

### Conclusions

Reliability tests results’ are encouraging toward the adoption of set-up 4 which can be easily applied on field. Comparison in terms of joint kinetics, showed good agreement among the different evaluations. The significant differences observed between set-up\_1 and 4 were mainly due to differences between force plate and plantar pressure measures.

### Summary

Using a full-body induced power analysis (IPA) of baseball pitching, we found that direct contributions to power of the throwing arm and ball velocity were primarily made by torques at the shoulder and by velocity-dependent effects.

### Introduction

In an open kinetic chain such as baseball pitching, the velocity of the throwing arm is affected by the mechanical power through the chain via coordination of proximal-to-distal segmental motion, where muscular torques can induce accelerations of anatomically remote segments through dynamic coupling [1,2]. However, traditional inverse dynamics approaches are insufficient in decomposing the components of segmental motion that contribute to the energy and velocity of throwing arm [3]. Previous researchers have implemented induced acceleration analysis (IAA) models to perform this decomposition in baseball pitching but did not include lower body contributions [1,4]. Hence, the purpose of this study was to use a full-body IAA to examine how muscular and non-muscular torques contribute to the induced power of the throwing arm and to the forward velocity of a pitched ball in collegiate baseball players.

### Methods

This retrospective study was approved by the institutional review board at Wake Forest University. Data from 17 collegiate pitchers (age =  $20.4 \pm 1.2$  years, height =  $1.87 \pm 0.05$  m, mass =  $94 \pm 7$  kg) were examined from in-season pitching analyses. Each participant threw 12 various types of pitches to a catcher at a regulation distance (18.4 m) away from a mound instrumented with three force platforms (AMTI, Watertown, MA) while 3D motion data were captured at a sampling rate of 400 Hz using a marker-based motion analysis system (Qualisys, Göteborg, Sweden) [1]. Ground reaction force (GRF) data were collected at a sampling rate of 1000 Hz.

A 14-segment model was configured and implemented in Visual 3D (C-Motion, Germantown, MD). The joint accelerations were estimated using the following IAA equation:

$$\ddot{\theta} = I^{-1}(\theta)[\tau + V(\theta, \dot{\theta}) + g(\theta)]$$

where  $\ddot{\theta}$  = generalized accelerations vector,  $I^{-1}$  = inverse of the system inertia matrix,  $\tau$  = vector of the net muscular torques,  $V(\theta, \dot{\theta})$  = vector due to velocity-dependent (Coriolis, centripetal) forces, and  $g(\theta)$  = gravitational force. By taking the product of each force or torque component and the corresponding velocity vector, an induced power analysis (IPA) of the throwing arm was performed [1]. All IAA

equations were derived in SD/Fast (PTC, Cambridge, MA) and implemented in Visual 3D. The mechanical work of the throwing arm was computed via time integration of the induced power between the instants of maximum knee height in the stride phase and ball release. Likewise, the induced ball velocity was calculated by time-integrating the induced acceleration of each source.

### Results and Discussion

The IPA showed that the velocity-dependent torque represented the largest proportion (65%) of the energy transferred to the arm at  $0.93 \pm 0.62$  J/kg followed by the shoulder torque (29%). Only 6% of the power was directly induced by the motion of the other segments in the kinetic chain. This finding aligns with previous IPA studies which showed how pelvis and trunk motion indirectly contribute to the power of the throwing arm via the velocity-dependent torque [1,3]. Similarly, the results of this IAA indicated that the largest contributions to ball velocity came from the shoulder and velocity-dependent torques (Figure 1).

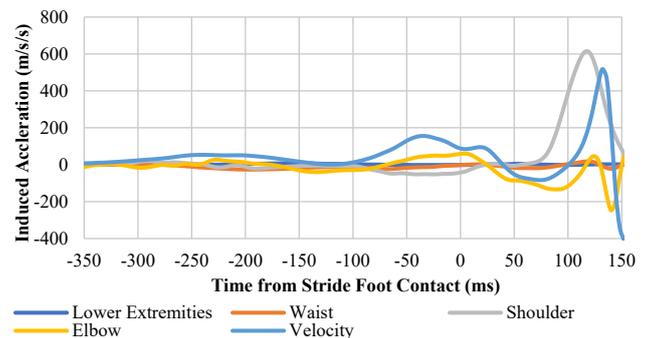

Figure 1: IAA components of a representative fastball pitch

### Conclusions

These findings provide evidence to support the notion that the dynamic coupling effects of segmental motion are the primary contributors to the energy and velocity of the throwing arm.

### Acknowledgments

The authors thank Tom Kepple of C-Motion for the development of the IAA plug-in and technical contributions.

## Center of Mass Vertical Velocity in Short Misses in the Basketball Shot

Casey Wiens<sup>1</sup>, Jill L. McNitt-Gray<sup>1,2</sup>

Departments of <sup>1</sup>Biological Sciences and <sup>2</sup>Biomedical Engineering, University of Southern California, Los Angeles, CA, USA  
Email: cwiens@usc.edu

### Summary

When shooting a basketball, the body's center of mass velocity and the velocity generated by the arms determine the ball's velocity at release and, subsequently, the ball's flight trajectory. Misses short of the hoop are thought to be due to low body center of mass vertical velocity, which is regulated in part by the net vertical impulse generated during the ground contact. We hypothesized that short misses occur when the body's center of mass vertical velocity at release is lower than normal due to less net vertical impulse generated during ground contact. The results indicate less net vertical impulse generated during ground contact and longer time in the air before release contributed to low body center of mass vertical velocity in short misses. Identifying the cause of missed shot attempts for individual players is expected to provide meaningful insights when providing feedback and designing individualized training programs to improve accuracy.

### Introduction

During a basketball shot, the ball velocity, angle, and distance to the rim at release determine the ball's trajectory. Ball velocity at release is influenced by the body's center of mass velocity – generated during the ground contact duration before release and altered by any time in the air before release – and the velocity generated by the arms [1]. A recent study indicated that the contribution of the body's center of mass vertical velocity (CM Vv) to the ball vertical velocity at release depends on the time of ball release relative to the body CM trajectory's apex during the shot [2]. When a player misses a shot short of the rim (short miss), coaches have suggested a lack of force generated during ground contact as a potential cause [3]. In this study, we hypothesized that lower CM Vv at release occurs in short misses compared to the successful shots made by the same player and that lower CM Vv at release was a result of less net vertical impulse generated during ground contact in the short misses compared to the successful shots made by the same player.

### Methods

Seven recreational basketball players (4 female, university club and recreational leagues players) provided informed consent in accordance with the institutional review board for human subjects. Each participant attempted a minimum of 10 shots from 4.57 m (free throw line) and 6.02 m (American high school three-point line) distances.

Two portable force plates measured ground reaction forces (Kistler, 1200Hz) generated by each leg. The duration between ground departure and ball release defined time in the air before release. The CM Vv at ball release was calculated using net vertical impulse generated from shot initiation to ground departure and the time in the air before release.

Successful shots entered without touching the rim or touched the inside of the rim. Short misses were shots aligned with the rim but fell short of the rim.

Lower than normal CM Vv at ball release and net vertical impulse generated were magnitudes below the lower quartile (less than 75%) of all successful shots performed by the same player. Longer than normal time in the air before release were magnitudes above the upper quartile (more than 75%) of all successful shots performed by the same player.

### Results and Discussion

Overall, 12 of the 118 shots analyzed were considered short misses. CM Vv at release was in the lower quartile in five of the 12 short misses: two from lower net vertical impulse generation and four from longer time in the air before release (Figure 1). Differences in CM Vv at release between successful and short shots at the same distance resulted from differences in net vertical impulse generated by the player during ground contact and time in the air before release (Figure 1). The greater the net vertical impulse generated, the greater the CM Vv available at ground departure. The longer the time in the air before release, the greater the reduction in the available CM Vv before release.

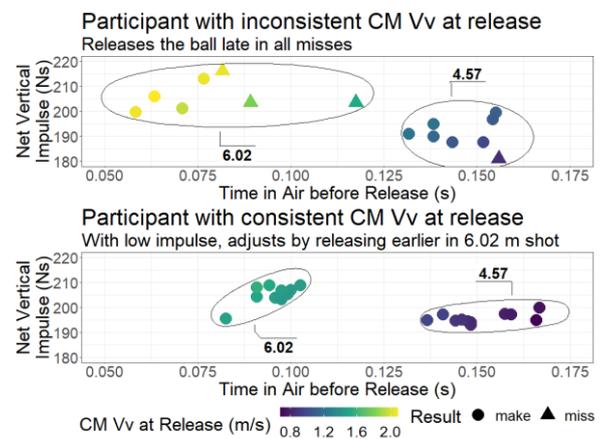

Figure 1. CM Vv at release, net vertical impulse, and time in air before release for two participants in shots from two distances.

### Conclusions

A lower CM Vv – resulting from lower net vertical impulse generated during contact and longer time in the air before release – occurred in less than half of the shots that missed short of the rim. Short miss tendencies varied between players.

## Correlation Between the Kinematic Analysis and the Field testing on the Efficiency of the Forehand Throwing on Ultimate Frisbee.

Salcedo E<sup>1</sup>, Aedo E<sup>2</sup>, Argothy R.<sup>1-3</sup>

<sup>1</sup> Master of Physiotherapy in Sports and Physical Activity - Medicine School Facultad de Medicina National University of Colombia

<sup>2</sup> Biomechanics Laboratory - Applied Sports Science Unit (UCAD) - Ministry of Sports - Chile

<sup>3</sup> Physical Culture Research Center (CICFI) - Military School of Cadetes - Bogotá Colombia  
Email: [reargothyb@gmail.com](mailto:reargothyb@gmail.com)

**Summary:** the objective of this study is to evaluate the association between the systematic analyses of the forehand vs the field test of the throwing of the Frisbee. 15 athletes are evaluated (9 men's and 6 woman's) (age: 23 +- 4 years, weight 65.7 +- 12.3 kg) of a team of ultimate of high level that competes at national level. We realize a 3D analysis (qualisys System) and we place skin markers on the scapular waist, arms and core. The field test is performed with 20 throws of the Frisbee at 30 and 40 meters. It was found significant correlations between the throwing of the 30 mts, the angular speed of the acromion (  $p = 0.028$ ) and the core inclination (  $p = 0.028$ ). It was identified the importance of the bending angle of the elbow (average of  $117^\circ \pm 15.2$ , ( $p = 0.044$ )) on the distance of throwing. It is identified the systematic parameters that determine the effective sport gesture for the throwing at 30 and 40 meters

**Introduction:** On the ultimate Frisbee, perform throwing's with big distances is a competitive advantage to accumulate points in an efficient way, it's considered the speed of the throwing as a determinate variable to achieve greater distances of the disc. However the position that the athletes take is determinant to perform the sport gesture in a harmonic way and with a good energy transfer between the muscular segments that helps to prevent sport lesions and mechanic alteration that modify the sport performance. For this fields test are performed that allows to measure the efficiency of the throwing's. However, since it is a mix game, where men's and women's participate, several of the gestures performed are adopted to the texture and physical capacity and the accommodations that are learned on the course of the sport life. The objective of the present study is to determine the associations that exist between the field test (throwing of ultimate Frisbee) vs the Systematic analysis of the upper body and the core.

**Methods:** 15 athletes were participating, 9 man's, 6 woman's (Age: 23+- 4 old, weight: 65.7+- 12.3 kg) that are members of a team of ultimate that competes at national level. All the athletes has the right side as dominant hemibody. Two test were performed. 1) Tridimensional systematic analysis

through a 3D capture system (qualisys system), passive markers were placed on the right and left acromion, spinous apophysis of C7 and T10. Right epicondyles of the hummers and bilateral radial styloid process. The systematic variables were: angular speed of the acromion (left acromion – right acromion) bending angle of the upper body on the in coronal plane (C7 – T10) bending and extension angle of the elbow (acromion-lateral hummers epicondyle- radial styloid process) 2) technique test of the throwing and catching of the Frisbee at 30 and 40 meters. 20 throwing's are performed at each distance and is being qualified the amount of hits that has to get to the established point. A statistical analysis is performed through SPSS (v25) through the test of Pearson.

**Results and discussion:** Significant correlations are being observed about the throwing at 30 meters vs the angular speed of the acromion ( $p = 0.028$ ) and core inclination on the coronal field ( $p = 0.028$ ) and the elbow bending (average bending  $117^\circ \pm 15.2$ , ( $p = 0.044$ )). However, on the 40 meters only on the elbow bending significant correlations were observed. Like the angular speed on the shoulders that increases the speed of spin on the ultimate players (Sasakawa and cols (2017)),

**Conclusion:** And the sport gesture of the ultimate is related with a mayor angular speed of the acromion and the bending of the core, helps to the 30 meters throwing; perform a elbow bending close to  $117^\circ$  ensures accurate sport gesture on the throwings at 30 and 40 meters

### Summary

The landing on the dismount of an apparatus in artistic gymnastics is one of the most challenging skills in this sport. This work investigates the determinant factors to spiked landing.

### Introduction

In artistic gymnastics, a failure in the landing can take chances of podium in championships [1]. In order to reduce the chance of errors, dismounts are performed repeatedly during training sessions. The side effect of this practice is the increased exposure to the risk of musculoskeletal injury by mechanical overload or trauma [2,3]. The aim of this study was to clarify the determining biomechanical factors for optimal landing in artistic gymnastics (i.e., no step needed to achieve a rest state after contact with the ground).

### Methods

An analytical interpretation model was proposed for the biomechanical factors governing the landing, based on an inverted pendulum system in which the gymnast was represented by the segment connecting the ankle joint center to the body center of mass (ank-CM) at the instant of collision. Selected by sampling (7 national elite gymnasts with international ranking) and methodological convenience (modeling and experimental), the dynamics of the horizontal bar dismount in double salto backward stretched (DSBS) was characterized. The Principal Component Analysis (PCA) was adopted to measure the predictive potential of the state variables defined by the biomechanical model for discriminating the success and failure conditions. Finally, a set of successful configurations was interpreted.

### Results and Discussion

An almost absolute ability to discriminate between conditions (91% of cases) in the cumulative three axes of variability was revealed by the PCA. The combinations of angular momentum, angular position, angular velocity of the body and horizontal and vertical velocities of the CM were

considered sufficient to establish the ideal conditions for the DSBS in the pre-collision ( ).

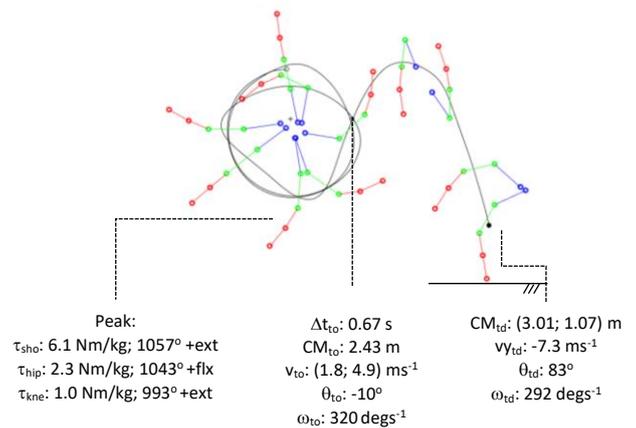

Figure 1: Biomechanical profile of the DSBS dismount.

### Conclusions

The analytical model demonstrated a high sensibility for landing body angle, in which variations greater than 7 degrees make the landing in resting conditions unlikely, and a significant influence of angular momentum, angular velocity and linear velocity for the DSBD landing in the horizontal bar routine.

## Summary

Musculoskeletal injury in sport result from acute high magnitude loads or cumulative exposure without adequate recovery. Monitoring loading during high impact sports such as basketball may help to identify risk for injury. Wearable sensors allow for the measurement of impacts in real-world game play and training. Practices result in the greatest exposure to impact events but at lower magnitudes compared to games. Cumulative exposure is increased for higher minute per game players which may result in increased risk for injury.

## Introduction

Basketball is characterized by maneuvers such as jumping, cutting, and running that result in varying intensities of impact loads to the lower limbs. High magnitude loads and cumulative exposure throughout the season may increase risk of bone stress injury. Few studies have captured impact loads during live game play or longitudinally. The purpose of this study was to characterize the intensity and cumulative exposure of tibial accelerations in basketball players during games and practices.

## Methods

One division III men's college basketball team, consisting of 17 players (mean (SD): height= 1.84 (0.07) m, weight = 82.1 (8.5) kg, age = 20 (2) years), were recruited for this study. All participants provided informed consent prior to the 2019-2020 season. Triaxial accelerations were collected throughout the regular season during games and practices using inertial measurement units (Blue Trident, IMeasureU, Auckland, NZ; 1600 Hz, +/- 200 g). IMUs were taped bilaterally to the distal antero-medial tibia by athletic training staff. Session footnotes were created to identify the beginning and end of games and practices. Data were uploaded to a web-based dashboard for step identification using a proprietary algorithm. The peak resultant tibial acceleration was identified for each step. Data were subsequently downloaded for further processing.

Total steps and the proportion of steps categorized as Low (<8g), Medium (8-25g), and High (>25g) accelerations were calculated for all sessions for each leg. Cumulative load (CL) was calculated as the cumulative sum of each step multiplied by its acceleration magnitude. Cumulative bone stimulus was

also calculated to incorporate the relative importance of the impact load magnitude to the number of load cycles [1].

All metrics were averaged between sides and then across players for practices and games, separately. Game and practice data were separated based on average minutes played per game. A high minutes (HM) group played > 10 mins. per game and a low minutes (LM) group played < 10 mins. Comparisons were made qualitatively between the HM and LM groups using median and interquartile ranges.

## Results and Discussion

A total of 29 sessions were collected consisting of 9 games and 20 practices. A median of 6 games and 17 practices were collected per player. Practices had more steps and higher cumulative load than games in both HM and LM groups (Table 1). During games, the HM players had a 15% lower proportion of Low impacts compared to LM group. This reduction was accompanied by a 6-7% increase in High and Medium impacts. High variation in exposure and accumulation of impacts was evident between players due to minutes per game. Practices account for the majority of steps and cumulative exposure to impact accelerations throughout a basketball season. For players that play high minutes per game, however, cumulative bone stimulus was similar between games and practices. While more minutes per game results in more steps, the increased bone stimulus was due to an increased proportion of higher magnitude impacts during higher intensity game play.

## Conclusions

Impact magnitudes and exposure during basketball are highly dependent on session type (practice vs game) and minutes per game. Higher impacts during increased game play may result in increased risk for injury.

## Acknowledgments

Funding for this work was provided by the National Basketball Association and General Electric.

### Summary

We examined the roles of each leg in generating linear and angular impulse in pitching fastballs performed by professional pitchers. As previously reported, before ball release, the back leg generated forward linear impulse, while the front leg generated backwards linear impulse. Surprisingly, the back leg generated more forward angular impulse than did the front leg. This newly uncovered role of the back leg towards forward angular momentum can assist future training approaches.

### Introduction

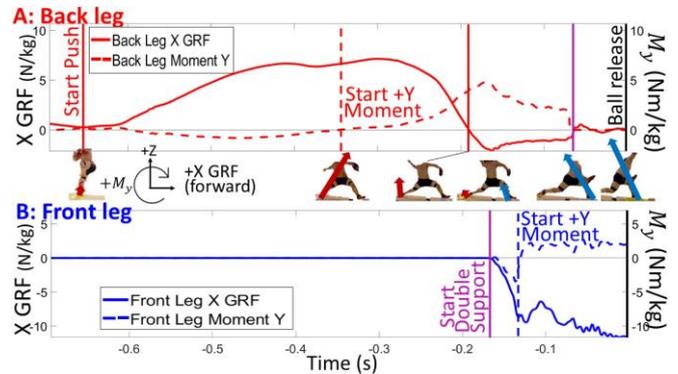

Ground reaction force (GRF) impulse can provide more information about the profile of the force-time curve and how the pitching action is performed than peak GRF alone [1]. Using energy flow analysis in young pitchers, it was reported that the back leg transfers linear power and the front leg generates rotational power [2]. This study compared the roles of each leg by studying the linear and angular impulse generated by the control of the GRF and moment about total body center of mass (TBCM).

### Methods

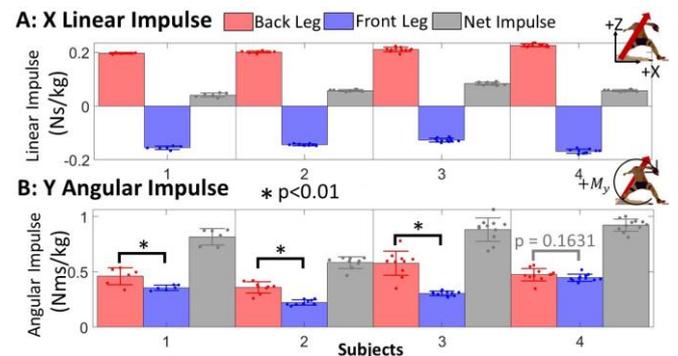

Professional pitchers ( $n=4$ ) volunteered for the study in accordance with the IRB. They pitched six to eleven fastballs from the stretch position on an instrumented mound while kinematic and kinetic data were collected (Bertec 1000/1080 Hz, Optitrack 250/360 fps). We excluded pitching trials that were rated unrepresentative/poor by the pitchers. The data were processed in MATLAB (Mathworks). The variables of interest were “X GRF”, the forward directed GRF, and “My”, the moment applied about the Y-axis passing through the TBCM (forward rotating moment) (Figure 1). These two variables were integrated to find the X Linear Impulse and Y Angular Impulse, respectively, for each leg and both legs (net) from the beginning of the push phase until ball release. The push phase began the last time Z GRF decreased before increasing to its peak. Within subject, paired T-tests were used to compare the impulse generated by each leg ( $\alpha=0.05$ ).

### Results and Discussion

The back leg generated positive X Linear Impulse, and the front leg generated negative X Linear Impulse, resulting in a net positive X Linear Impulse before ball release (Figure 2A). This led to forward momentum of the body. Both legs generated positive Y Angular Impulse, which led to forward rotation of the body towards accelerating the ball (Figure 2B). Surprisingly, the back leg generated more positive Y Angular Impulse than the front leg did.

**Figure 1:** Exemplar X GRF and Moment about the Y-axis ( $M_y$ ) vs. time applied by the (A) back and (B) front legs (Subject 2).

**Figure 2:** (A) X Linear Impulse and (B) Y Angular Impulse (B) for the back (red), front (blue), and net impulse (gray) during fastballs.

We found that the role of the back leg transitioned from linear propulsion to forward angular rotation before double support. We also found that the front leg initially generated negative Y Angular Impulse, slowing the forward rotation. To maximize forward rotation, it may be helpful to increase the back leg’s contribution to rotation and reduce the front leg’s negative Y Angular Impulse. Our future research will enroll more pitchers to better understand the role of each leg towards linear and angular momentum control.

### Conclusions

This study uncovered the role of the back leg not only in linear propulsion, but also in generating more forward angular impulse than the front leg. Maximizing forward angular impulse may contribute to increased pitching performance.

### Summary

Landing from a jump is associated with lower extremity injuries such as ACL ruptures. Clinical tests are commonly employed to detect altered movements that may be related to the risk for this injury. Here, we investigate the potential of clinical tests to predict trunk control during landing tasks. Knee and hip strength are the most important clinical outcomes related to trunk control during unilateral landings.

### Introduction

Poor trunk control is a risk factor for ACL injury [1] and a frequent component of the mechanism of injury [2]. Evaluation and monitoring of this risk factor typically require expensive, time-consuming and complex laboratory tests. Sometimes biomechaical risk factors can be estimated by clinical tests more accessible to monitor athletes in the field [3]. However, the relationship between clinical tests and trunk control during drop landing has not been adequately investigated. Here we determine whether clinical tests can predict trunk biomechanics during the performance of unilateral landing tasks.

### Methods

The local institutional ethics committee approved this study. Forty-seven recreational athletes (24±3 years old, 80±13 kg of body mass, 177±6 cm of height) completed a battery of clinical tests, and 3D kinematics assessment of unilateral drop jump tasks. Clinical tests were the Lunge, lateral step down, single, triple, and crossover hop tests, star excursion balance test (SEBT), knee flexor and extensor strength, and hip abductor and adductor strength (hand-held dynamometer). 3D kinetics and kinematics were sampled at 2000Hz and 200 Hz, respectively, during the landings. Trunk angles were determined at initial contact (threshold of 20N) and maximal knee flexion of the landing phase. Stepwise multiple regression analyses were performed for each dependent variable when  $p \leq 0.20$  (Pearson's or Spearman's tests). Global effect size ( $f^2$ ) was computed with interpretation: small to  $\geq 0.02$ , medium to  $\geq 0.15$ , and large to  $\geq 0.35$ .

### Results and Discussion

The clinical tests predicted trunk sagittal angles for landing on the preferred and non-preferred legs (Figure 1, low to high effect sizes) and trunk frontal angles for the preferred leg (Figure 2, moderate to large effect sizes). Knee strength was the most important predictor of sagittal angles for both legs. For the frontal plane angles, hip abductor's strength had an important role.

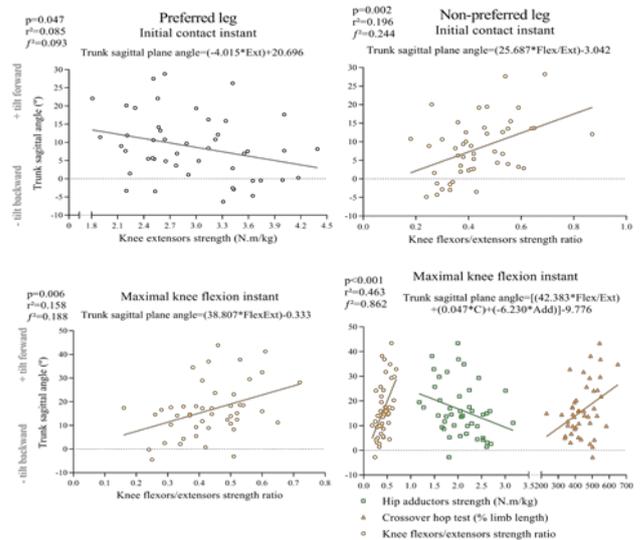

Figure 1: Trunk sagittal plane angles predicted by clinical outcomes.

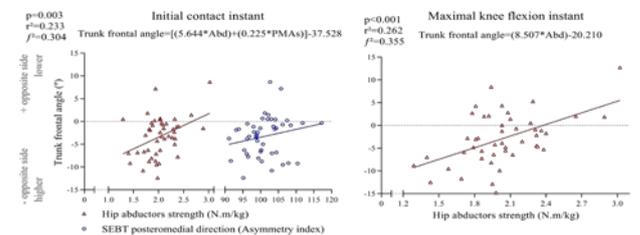

Figure 2: Trunk frontal plane angles predicted by clinical outcomes.

Trunk control during unilateral landings is associated with strength measures. This finding may have important clinical implications.

### Conclusions

Trunk control during landing can be predicted by clinical tests. Knee and hip strength are the strongest clinical predictors of trunk control.

## Hip Range of Motion and Pitching Biomechanics in Adolescent Baseball Pitchers

Maxwell L Albiero, Wesley Kokott, DPT, Cody Dziuk, Janelle A Cross, PhD  
 Department of Orthopaedic Surgery, Medical College of Wisconsin, Milwaukee, WI, USA  
 Email: malbiero@mcw.edu

### Summary

This study examined the relationship between an athlete's hip active range of motion (AROM) and pitching biomechanics. Clinical measurements of hip flexibility and pitching mechanics were recorded. Several significant correlations were discovered between AROM and biomechanical variables. These findings support the influence hip AROM has on pitching biomechanics and suggest greater movement at the hips allows for the kinematic chain to work at its maximal efficiency, increasing pitch velocity potential and decreasing risk for injury.

### Introduction

Baseball pitching is a dynamic task that requires the use of the entire body as a kinematic chain to create upper extremity forces in the throwing arm which are used to release a high velocity pitch. These forces can lead to injury. Previous research has demonstrated the chain begins in the lower extremities and transitions to the upper extremity [1]. Insufficient hip range of motion (ROM) can arrest the throwing mechanics, thereby reducing energy transfer between the lower and upper extremities [2]. A pitcher who is able to more efficiently transfer energy up the chain will create greater forces in the upper extremity resulting in potential for greater ball velocity. However, a lack of proper throwing mechanics can result in these increased forces surpassing a physiologic threshold of the shoulder and elbow joints, creating injury [3]. The purpose of our study was to identify correlations between clinical hip active range of motion (AROM) measurements and pitching biomechanics.

### Methods

Twenty-one adolescent male baseball pitchers ( $16.1 \pm 0.8$  years,  $77.9 \pm 8.3$  kg,  $183.9 \pm 5.2$  cm) from a competitive youth baseball program lacking a history of arm pain or throwing injury participated in this study. A certified physical therapist collected hip AROM measurements via a standardized protocol. A system of 8 Raptor-E cameras (Motion Analysis Corporation, Santa Rosa, CA) were positioned around an artificial mound to capture subjects pitching at 300 Hz. Forty-seven reflective markers were attached to subjects on anatomical landmarks and ten fastball pitches were recorded being thrown into a strike zone net positioned at a regulation distance of 18.4 m from the pitching rubber. The three fastest strikes were analyzed. Marker data was identified then filtered using a 13.4 Hz fourth-order Butterworth low-pass filter in Cortex software (Motion Analysis Corporation, Santa Rosa, CA). Biomechanics were calculated using Visual 3D software (C-Motion, Germantown, MD). SPSS statistical analysis

software (version 26, IBM Corporation, Armonk, NY) was used for data analysis with a significance level of  $p < 0.05$ .

### Results and Discussion

Significant negative correlations were found at foot contact between torso rotation angle and back hip external rotation (ER) AROM, back hip abduction angle and back hip ER AROM, and lead hip abduction angle and back hip abduction AROM (Table 1). Stride length was positively correlated back hip extension AROM. Normalized elbow varus torque (EVT) was positively correlated with lead hip abduction AROM. Stride length and EVT are two commonly investigated variables in pitching biomechanics research. The results from this study demonstrate the impact hip AROM has on both of these, providing a greater understanding of the mechanics effecting these variables. The results also suggest back hip extension may be more vital than back hip abduction in generating a greater stride length due to the transition of the plane of motion seen in the back hip during the pitching motion.

**Table 1:** Significant correlations between pitching biomechanics and hip active range of motion

Kinematics at Foot Contact	r	p-value
Stride length and back hip extension AROM	.446	0.043*
Torso rotation angle and back hip ER AROM	-.468	0.032*
Back hip abduction angle and back hip ER AROM	-.474	0.030*
Lead hip abduction angle and back hip abduction AROM	-.458	0.037*
<b>Kinetics</b>		
Normalized elbow varus torque and lead hip abduction AROM	.435	0.049*

\* Correlation significant at 0.05 level

### Conclusions

Hip AROM has an important influence on pitching biomechanics, and flexibility should be evaluated when training to gain insight on a pitcher's mechanics and injury risk potential.

## Sagittal Plane Kinematics of Partnered and Individual Triple Steps in Swing Dancing

Meredith D. Wells<sup>1</sup>, Feng Yang<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Health, Georgia State University, Atlanta, GA, USA

Email: [mwells19@student.gsu.edu](mailto:mwells19@student.gsu.edu)

### Summary

Despite its increasing popularity, swing dancing has not been thoroughly studied biomechanically, imposing challenges in understanding the movement patterns associated with swing dancing. The purpose of this study was to analyze the kinematics of the triple step to better understand the movement patterns related to swing dance.

### Introduction

Swing dancing today refers to a cluster of dances developed between the 1920s and 1940s to the swing style of music [1]. Swing dancing remains popular today and continues to draw individuals to it with its lively music and social atmosphere [2]. Yet, there is limited research on the kinematics of the swing movements which restricts our ability to understand the demands placed on the body. Although swing dancing is generally performed with a partner, dancing individually also occurs. Therefore, it is of interest to check if the biomechanics differ between individual and partnered conditions.

The purpose of this initial study was to quantify the kinematics of the triple step (one of the most common swing dance elements) in the sagittal plane among recreational swing dancers while dancing individually and with a partner. It was hypothesized that few significant differences in the lower extremity joint positions would be seen between partnered and individual dance conditions.

### Methods

Eight recreational swing dancers who completed at least 50 sessions of swing dancing in the prior year (age:  $30.9 \pm 4.7$  years; height:  $1.73 \pm 0.07$  m; mass:  $73.6 \pm 13.1$  kg; swing dancing experience:  $4.1 \pm 3.1$  years) participated in this study.

Participants completed a 5-minute dance warm-up, and then performed a triple step to the right individually (TSR) and with a partner (TSRP) in a random order. Three trials were collected for each. The triple step involves taking a small step to the side with one foot, bringing the second foot to meet the first, and then taking a larger step to the side with the first foot. Participants performed the dance element on vinyl flooring, to mimic a dance floor, wearing standardized socks.

Three-dimensional lower extremity kinematics were collected via 16 reflective markers using an 8-camera motion capture

system (Vicon, UK). Marker paths were low-pass filtered, and joint centers were calculated from the filtered marker paths and measured anthropometric parameters [3]. Joint angles at the ankle and knee during stance of each of the three steps within the triple step were calculated based on joint center data using inverse kinematics and were compared between dance conditions using paired *t*-tests. The significance level was set as 0.05.

### Results and Discussion

Results from the *t*-test supported our hypothesis, indicating minimal significant differences between dance conditions in the triple step. Differences that were seen at the ankle include: greater peak dorsiflexion (DF) during the stance phase of the first ( $p = 0.025$ ) and third ( $p = 0.031$ ) steps of the TSR individually compared to partnered. Differences observed at the knee include: greater peak flexion during stance of the first ( $p = 0.009$ ) and third ( $p = 0.013$ ) steps of the TSR individually compared to partnered, and greater peak flexion at initial contact during the first ( $p = 0.007$ ) and third ( $p = 0.013$ ) steps of the TSR individually compared to partnered (Table 1).

These findings indicate that recreational swing dancers may move through a greater range of motion when practicing individually. The change in movement pattern when dancing with a partner may be due to the requirement to continuously match the partner's movements, requiring the dancers to be more careful when dancing with a partner to avoid hitting or stepping on them while dancing.

### Conclusions

Results from this study illustrate that there are a few kinematic differences between dancing with and without a partner that need to be considered when planning training and performances. This also needs to be considered when analyzing the dance motion of individuals involved in partnered dances. However, further research with larger sample sizes is required in order to better understand the biomechanics of swing dancing.

## Effects of dissociation on muscle activation and torque during stationary cycling

Milena A. dos Santos<sup>1</sup>, Felipe P. Carpes<sup>2</sup>

Applied Neuromechanics Research Group, Laboratory of Neuromechanics, Federal University of Pampa, Uruguaiana, RS, Brazil  
Email: milena.aguiar2008@hotmail.com

### Summary

To listen to music while exercising indoors can have a dissociation effect on rate of perceived effort (RPE), but its effects on neuromuscular responses are not clear. Here we compared muscle activation and torque output between sessions of indoor cycling while listening or not to music as a dissociation stimulus. We found that exercise and music combined increased RPE, submaximal heart rate, and pedaling cadence, without effects on muscle activation and torque.

### Introduction

Physical exercise can improve cognitive and physical capacities [1,2]. It has been found that dissociation between internal and external focus can influence exercise intensity, heart rate, effort perception, motivation, and pleasure [3]. Additionally, the attentional focus oscillation while listening to music can be a source of distraction [4]. Here we determine whether the music combined to the physical exercise affects neuromuscular activation and torques during cycling.

### Methods

Thirteen health adults, healthy and physically active (6 women and 7 man) visited the laboratory for three times. The first was to determine the maximal power output using a LODE cycle ergometer. The second and third were to complete submaximal cycling trials at 50% of the maximal output. In the submaximal trials the participants listened or not to their preferred music songs in a range of 120-150 beats per minute, using earphones. RPE was quantified every 5 min (6-20 Borg Scale), while heart rate (Polar heart monitor), neuromuscular activation (sampled at 1.5 kHz using DTS Noraxon Inc.), and pedaling torque and cadence (measured every 2° with Lode Excalibur) were continuously recorded. Main effects and interactions considering the music condition (music vs no music) and the exercise time (start, middle, end) were verified using a general linear model ANOVA for repeated measures. Paired comparisons were performed by a dependent t-test or Wilcoxon test.

### Results and Discussion

The music session elicited higher RPE ( $p=0.003$ , figure 1), heart rate ( $p=0.04$ ) and pedaling cadence ( $p=0.04$ , figure 1). Main effects were not found for torque. No music effects were found for RMS and median frequency of the electromyographical signals, despite of a behavior indicating muscle fatigue (RMS increasing, median frequency decreasing along the exercise) for both the submaximal conditions. The higher pedaling cadence may suggest that an involuntary attempt to synchronize the music and the movement frequencies [5]. It may have affected the internal

load resultant of exercise (due to the higher RPE), without increasing exercise duration or external load.

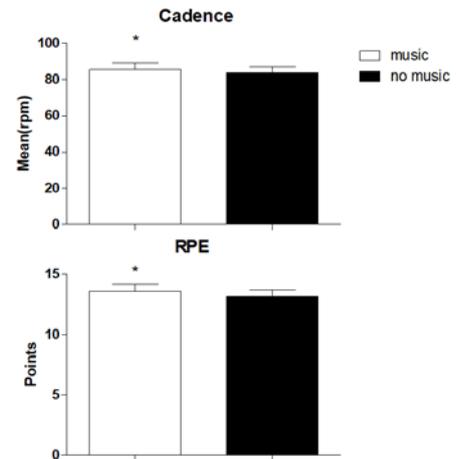

Figure 1. Cadence and RPE in the music and no music sessions. \* $p<0.005$

### Conclusions

Listening to preferred music during indoor cycling can be a strategy to increase internal load, especially cardiovascular demands, without increasing external load as quantified by muscle activation and torque output.

# CLINICAL ESTIMATION OF MOVEMENT BEHAVIOR PREDICTIVE OF GROUND REACTION FORCES DURING ATHLETIC TASKS

RACHEL K. STRAUB,<sup>1</sup> ALEX HORGAN,<sup>2</sup> ADAM J. BARRACK,<sup>1</sup> FRANKLIN ZHUANG,<sup>1</sup> RUBEN CUELLAR,<sup>1</sup> CHRISTOPHER M. POWERS<sup>1</sup>

<sup>1</sup>JACQUELIN PERRY MUSCULOSKELETAL BIOMECHANICS RESEARCH LABORATORY

DIVISION OF BIOMEDICAL & PHYSICAL THERAPY, UNIVERSITY OF SOUTHERN CALIFORNIA, LOS ANGELES, CA, USA

<sup>2</sup>TRINITY COLLEGE, DISCIPLINE OF PHYSIOTHERAPY, SCHOOL OF MEDICINE, DUBLIN, IRELAND

## BACKGROUND

Given that elevated vertical ground reaction forces (vGRF) have been reported to contribute to various lower-extremity injuries,<sup>[1,2]</sup> there is a need for a practical method to characterize movement behavior that is representative of elevated impact forces.

## PURPOSE

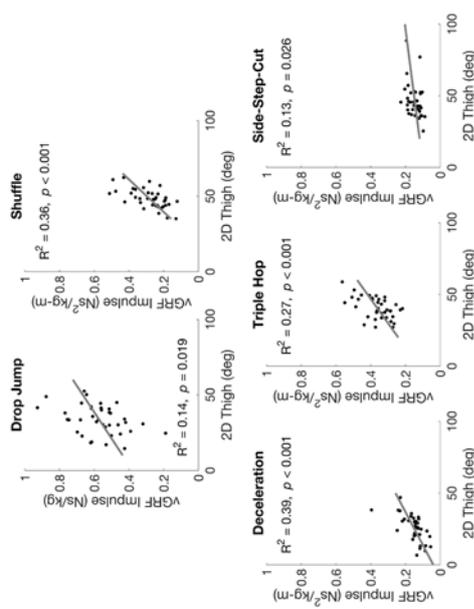

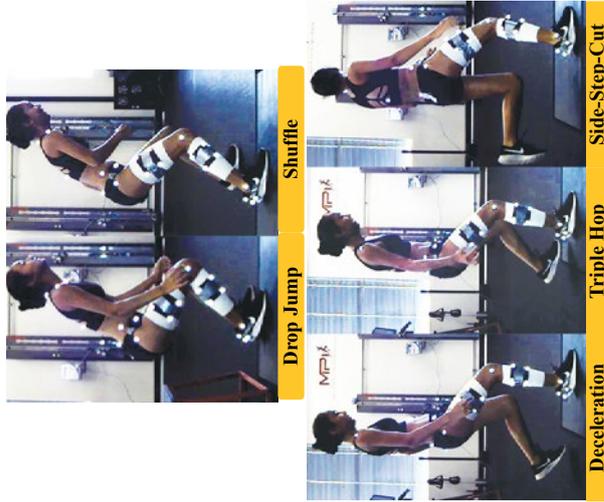

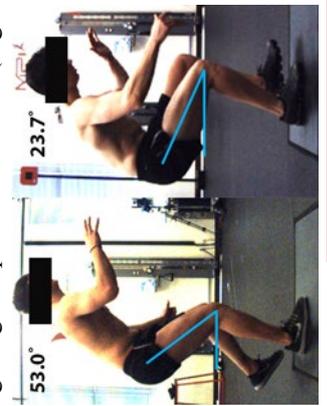

To determine if the thigh angle from 2D video could be used to predict the vGRF during athletic movements.

## METHODS

**Subjects:** 39 healthy athletes (15 males, 24 females)  
**Biomechanical Assessment:** Using a video-based system (Simi Motion), lower-extremity kinematics & kinetics (3D) with video (2D) were collected simultaneously during 5 tasks (Figure).

### Outcomes Variables:

- (1) 1<sup>st</sup> Peak vGRF & vGRF impulses to 1<sup>st</sup> peak
- (2) 2D thigh angle at peak knee flexion (Figure)

## CONCLUSIONS

The findings of the current study indicate that the 2D thigh angle can be used to approximate measures of vGRFs during various athletic tasks. Our findings suggest that the 2D thigh angle may have utility in the screening of athletes thought to be at risk for lower-extremity injury.

## RESULTS

An increased 2D thigh angle predicted higher peak vGRFs for all tasks except cutting (R<sup>2</sup> = 0.17 to 0.47, all p < 0.01). However, an increased 2D thigh angle predicted a greater vGRF impulse for all 5 tasks (R<sup>2</sup> = 0.13 to 0.39, all p < 0.025) (Figure).

E- mail: [reargothyb@gmail.com](mailto:reargothyb@gmail.com)

### Summary (150 palabras máximo)

This study evaluates the neuromuscular profile of the lower limb in Colombian female soccer players, that are in the training school. Fifty-two soccer players participated (age 15.3 years  $\pm$  1.01, weight 54.7 kg  $\pm$  7.6, height 158.7 cm  $\pm$  5.6). The countermovement jump (CMJ) and the isometric hamstring strength test (IHST) were performed using force platforms. The neuromuscular performance data of the CMJ vs Net Force hamstring were correlated with the asymmetry between the lower limbs. No associations were found between asymmetry and neuromuscular performance. A statistically significant association was found between JH, RSI, PP and PPV, which are markers of strength and explosive power of the lower body. According to the literature [1],[2] asymmetry between limbs has not augmented risk of injury, so it is necessary to perform the CMJ and IHST tests and the status of the extensor and flexor muscle chains of the lower body.

### Introduction

Lower body asymmetries in female soccer players and their association with strength and power performance variables have been a subject of study in recent years. Risk factors related to knee and ankle injuries are now relevant, because there is a high rate of overuse injury and high training loads from high impact movements (landings), changes of direction (acceleration and deceleration) and muscle fatigue (hamstrings).

Constant monitoring of physical capacities and sports performance has been established to prevent lesions and identify the variables related to compensations in the body due to training and competition loads. It is currently not clear if risk of lesions is gender dependent or due to load adaptations.

The purpose of this study is to determine the neuromuscular profile of the lower limb of Colombian soccer players in the training process and its association with neuromuscular performance.

### Methods

52 female soccer players in the training process (age: 15.3  $\pm$  1.01 years; weight: 54.7  $\pm$  7.6 Kg; height: 158.8  $\pm$  6.6 cm) were measured in the pre-season stage in this cross-sectional study. Two tests were performed: a) Countermovement jump test (CMJ) using force platforms (one platform for each leg). They performed 5 jumps and the best three were taken. b) Isometric hamstring strength test (IHST) was made in a supine position with 90° knee flexion and 90° hip flexion of the leg. In this position, the athlete applies heel pressure to the force platform for 3 seconds, three times on each leg with

a 30-second rest between each attempt. Correlational analysis was performed between the variables of the IHST and CMJ test using Pearson's correlation (SPSS-V25® software).

### Results and Discussion

We found no correlation between the variables of the IHST vs the CMJ jump test. Likewise, no correlations were found between the asymmetries found in the IHST test, the eccentric and concentric impulse and eccentric asymmetries of the landing in the CMJ. However, there is a correlation between the variables of the CMJ test, such as jump height (JH) with respect to peak power (PP) ( $p = 0.001$ ;  $r=0.001$ ), relative strength index (RSI) ( $p=0.001$ ;  $r=0.001$ ), and the speed at peak power (PPV) ( $p=0.001$ ;  $r=0.001$ ). The PP with respect to JH ( $p=0.001$ ;  $r=0.001$ ), RSI ( $p=0.001$ ;  $r=0.001$ ) and PPV ( $p=0.001$ ;  $r=0.001$ ) and the RSI and PPV with respect to JH ( $p=0.001$ ;  $r=0.001$ ) and PP ( $p=0.001$ ;  $r=0.001$ ).

In our target population the CMJ test reported the neuromuscular profile of the variables JH, PP, RSI, PPV. The asymmetries found in CMJ and IHST were less than 10%, between the lower limbs. Loturco [1] and Bishop [2] found similar rates of asymmetry, on different populations. According to the literature [1],[2] asymmetry between limbs has not augmented risk of injury. Results correlate with previous studies where asymmetries do not correlate with neuromuscular performance.

### Conclusions

Our target population is symmetrical. Asymmetry is not correlated with neuromuscular performance variables. The CMJ and IHST tests did not show associations, indicating that both tests should be performed to determine if there is compromise of extensor and flexor chain in the lower body. CMJ and IHST can be used as an indicator for evaluating overload, muscle fatigue, and hamstring-quadiceps ratio.

This is the first study, as far as we know, that has a target population with women that are in the training process. In this study the variables of JH, PP, RSI and PPV of Colombian female soccer players in the training process, can be the baseline for future investigations that help to demonstrate the associations of lower body injuries and the factors that affect neuromuscular performance under different loads.

## Functional Forearm Fatigue Response to Changing Stride Length in Baseball Pitchers

Ryan L. Crotin<sup>1,2</sup>, Dan K. Ramsey<sup>3</sup>

<sup>1</sup>Sports Performance Research Institute New Zealand, Auckland University of Technology, Auckland, NZ

<sup>3</sup>Department of Health Professions Education, School of Health Professions, D'Youville College, Buffalo, NY

Email: RLCrotin@gmail.com

### Summary

Ulnar collateral ligament injuries are rampant in the sport of baseball where kinetic chain impacts stemming from misappropriation of stride length, or changes that occur in competition due to fatigue have not been evaluated for dynamic elbow stability effects.

### Introduction

Stride length optimization has not been adequately researched in the sport baseball where previous work showed physiologic differences between relatively short and long strides, yet minimal differences in ball velocity [1,2] Maintenance of high velocity pitching demonstrated compensatory adaptation where pitchers have the ability to lengthen or shorten stride length to mitigate fatigue while radar velocity is unaffected and refutes its ability to identify adaptations in mechanics. What is unknown are the functional fatigue impacts on the flexor pronator mass, where stride length compensation may have deleterious effects on medial elbow stability. It was hypothesized that shortening stride length will increase functional forearm fatigue indicated by lowered grip strength after simulated play.

### Methods

A cohort of 19 healthy and skilled competitive pitchers were recruited from collegiate and high school seasonal travel programs from across Western New York. Fifteen threw right-handed and 4 with their left hand (age  $18.63 \pm 1.67$  years, height  $1.84 \pm 0.054$  m, mass  $82.14 \pm 0.054$  kg). Athletes were randomly assigned to throw in two simulated, 80-pitch games delivering the baseball at  $\pm 25\%$  their desired stride. Optical 3D motion capture sampling at 240Hz (Vicon, Denver, CO) integrated with two embedded force plates sampling at 980Hz (Kistler, Amherst, NY) complete with a radar gun and LED display (Jugs Sports, Tualatin, OR) recorded biomechanics and competitive ball velocities.

Bilateral grip strength (Jamar Hydraulic Handgrip Dynamometer, Lafayette Instrument, Lafayette, IN) was tested prior to games and immediately after simulated play. Pitchers had 72 hours of recovery before their second simulated game in the crossover design. Grip data was collected seated with hips, knees and involved elbow bent at

90 degrees with a neutral wrist. Verbal encouragement was provided over a 3 second contraction, followed by 30 seconds rest between 3 repetitions for each arm. Statistical significance, determined *a priori*, was set at  $p \leq 0.05$ . Pairwise t-tests evaluated mean grip strength differences between stride length conditions.

### Results and Discussion

Non-dominant grip strength was unchanged following simulated play indicating the need to evaluate functional forearm fatigue in the dominant arm. Functional forearm fatigue was not detected when strides were lengthened, however, our hypothesis was confirmed in the under-stride condition where strength decreased by approximately 2kg (Table1).

Previous modeling showed that within-subject variability in elbow valgus load can have more injurious impacts under fatigue, where decreased dynamic stabilization of the medial elbow decreased theoretical load capacity of the UCL [3]. Reduced stride length may be adopted to mitigate physiologic fatigue, however baseball pitchers may become less biomechanically efficient and demand more muscular effort from the medial elbow dynamic stabilizers [1].

### Conclusions

Stride length optimization and compensatory stride length evaluation should involve measures of functional forearm fatigue to hallmark the degree of mechanical efficiency in the pitching delivery and thereby better understand stride length adjustment.

### Acknowledgments

## The Effects of Drive-Leg Knee Valgus Angle on Ground Reaction Forces During Baseball Pitching

Anthony W. Fava<sup>1,1</sup>, Jessica L. Downs<sup>1,2</sup>, Hillary A. Plummer<sup>1,3</sup>, Gretchen D. Oliver<sup>1</sup>

<sup>1</sup>Sports Medicine & Movement Lab, School of Kinesiology, Auburn University, Auburn, Alabama, USA

<sup>1</sup>Email: awf0016@auburn.edu, jzd0075@auburn.edu, hplummer47@gmail.com, goliver@auburn.edu

### Summary

This study analysed drive-leg kinematics and ground reaction forces (GRF) from the onset of the windup to follow-through of the pitching motion. Drive-leg knee valgus angle during windup was associated with GRF during the pitch; one GRF correlated with ball speed. At the start of the pitch, drive-leg knee valgus could be a strategy pitchers' use to get into a desired position to generate force and momentum. Following stride foot contact (SFC), drive-knee valgus may enable the foot of the drive leg to remain in position to create a GRF opposite the pitch direction. This can be accomplished by dragging the toe of the drive-leg foot helping to balance the pitcher and assisting the stride leg in decelerating the body's forward momentum.

### Introduction

Sequential movements in baseball pitching allows power and energy to be produced and transferred from the lower extremities, through the trunk, to the distal segments of the arm and ultimately to the ball [1]. Stride-leg kinematic and temporal factors have been linked to improved performance [2]. Following SFC, pitchers with decreased stride-leg knee flexion and increased knee extension angular velocities were associated with higher pitch speeds [2]. Furthermore, pitchers with increased braking GRF following SFC had increased ball velocity [3].

Variations in drive-leg kinematics can influence force production and transfer thus affecting performance [1]. However, previous pitching research has not reported drive-leg kinematics that includes the wind-up motion. This study aimed to analyze drive-leg kinematics and GRF including the wind-up action to determine its effects at latter stages on the pitching motion.

### Methods

Kinematic and GRF data were captured on 21 high school baseball pitchers ( $16.6 \pm 3.1$  yr;  $180.1 \pm 6.1$  cm;  $75.9 \pm 10.5$  kg) throwing fastballs from a mound at regulation distance (18.4 m). The three phases (P1-P3) of the pitching motion that were analyzed were: P1) stride foot lift to peak knee height, P2) peak knee height to SFC, P3) SFC to maximal shoulder external rotation. GRF (vertical, anterior-posterior, medial-lateral) and magnitude of the drive leg were measured using force plates and ball speed was assessed using a radar gun. Multiple regression was used to assess the relationship between drive-leg valgus angle and GRF. Correlation was used to determine the relationship between drive-leg GRF and ball speed.

### Results

During P1, pitchers with increased drive-leg knee valgus angle had an increased anterior and medial drive-leg GRF during P3 ( $r = .686, p = .025$ ) (Figure 1, Table 1). A significant correlation was found between maximum anterior drive-leg GRF during P3 and ball speed ( $r = .434, p = 0.25$ ) (Table 1).

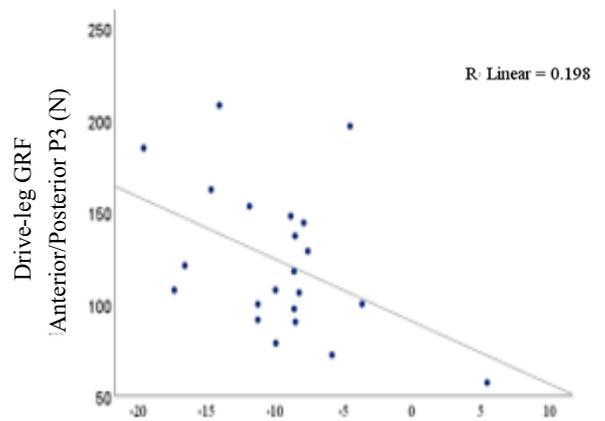

Figure 1: Drive-leg Knee Varus/Valgus Angle P1 (°).

Table 1: Means & St. Deviations; Knee Valgus, GRF, & Ball Speed.

Variable	Mean	SD
Drive Knee Varus/Valgus Angle P1 (°)	-9.62	5.38
Baseline Knee Varus/Valgus Angle (°)	-6.47	5.00
Drive-leg GRF Anterior/Posterior P3 (N)	125.28	39.73
Drive-leg GRF Medial/Lateral P3 (N)	56.23	53.54
Ball Speed (m/s)	31.91	2.75

### Conclusions

The findings of drive-leg knee valgus during P1 (wind-up), resulted in pitchers producing medially directed drive-leg GRF in P3. Medial forces can be useful for stabilizing the lower body when transferring weight to the stride leg in preparing for trunk rotation in P3 (arm cocking). Additionally, an anterior force exerted by the drive-leg foot in P3 opposite to pitch direction may help decelerate the loading of the stride leg. This in turn, could affect temporal factors such as the timing of maximal shoulder external rotation, trunk rotation, and stride-leg knee extension. Pitchers may leverage drive-leg knee valgus to alter kinematics and GRF with the aims of augmenting their throwing technique. Future drive-leg studies should investigate the temporal effects of drive-leg knee valgus on the pitching motion.

## Ground Reaction Force Differences between Two Forms of Squats

Jason Wicke<sup>1</sup>, Joseph Robbins, Sarah Myers

<sup>1</sup>Human Motion Research Lab, William Paterson University, USA

Email: wickej@wpunj.edu

### Summary

Ground reaction forces between the front and back squat were examined. Twenty weightlifters performed three squats at 85% of their specific 1-repetition maximum (1RM), 1) front, 2) back, and 3) bar on back with 1RM of front squat weight. The maximum anteroposterior ( $F_Y$ ) and normalized vertical ( $F_Z$ ) ground reaction forces were measured. Results showed an increased shearing force for the back squat, specifically during the completion of the squat, and a vertical force that decreased during the unweighing phase by approximately 50% of the total weight. These results suggest that weightlifters should initiate unweighing to stop the upward movement of the bar sooner, to reduce the larger shearing and ‘bouncing’ that appears to occur at the end of the lift.

### Introduction

Squats are one of the most typical weight training exercises to build lower extremity strength. Front squats, where the bar is placed on the anterior of the body, result in a posterior lean, requiring greater muscles forces on the anterior portion of the legs. Conversely, back squats (bar on back) result in an anterior lean that places greater forces on the muscles of the posterior leg [1]. Significantly lower compressive forces and extensor moments were found at the knee during the front squat compared as compared to the back squat [2]. This study examined the maximum anteroposterior (shear) and vertical ground reaction forces while performing a front and back squat.

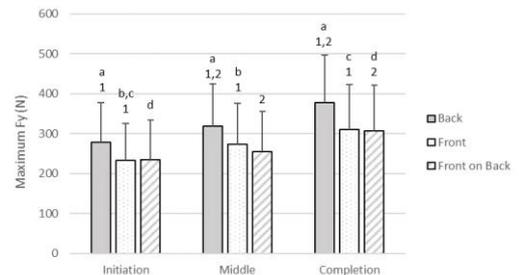

### Methods

Twenty healthy college-aged males who were experienced weightlifters participated in the study. Prior to participation, an informed consent approved by the institutional review board was signed. Three trials in randomized order were performed: a front squat with a load of 85% of the participant’s one repetition maximum (1RM), a back squat with a load of 85% 1RM, and finally a back squat with the load of 85% of the participant’s front squat 1RM (FonB). Ground reaction forces in the anteroposterior direction ( $F_Y$ ) and vertical direction ( $F_Z$ ) were recorded on two Bertec<sup>TM</sup> force plates. The  $F_Z$  data were normalized to the combined weight being lifted and the body weight of the participant. The dependent variables for this study were the maximum ground reaction force measures ( $F_Y$  and  $F_Z$ ) and the independent variables were three phases of the squat (initiation, middle, completion) and the squat methods.

### Results and Discussion

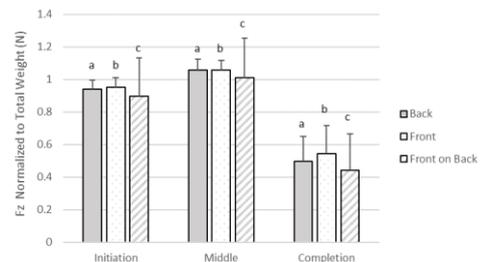

The max shearing forces ( $F_Y$ ) were significantly greater during the completion phase of the back squat (Figure 1), though peak shear forces at the knees occur at 85-105° of

flexion [2]. Furthermore, max  $F_Y$  within each phase was significantly greater during the back squat and can be attributed to the larger weight, indicating that shearing forces at the feet are more dependent on the weight rather than the location of the bar.

**Figure 1:** Max  $F_Y$  forces. letters =  $p < 0.05$  within a squat across the phases / numbers =  $p < 0.05$  between squats within each phase.

The normalized maximum  $F_Z$  were similar between squat methods (Figure 2), indicating that  $F_Z$  is primarily related to the total weight lifted. What was most surprising was the significantly lower  $F_Z$  (unweighing) that was produced right at the completion of the squat. For all three squats this unweighing reached approximately 50% of the total weight. It would be expected that with experienced lifters, deceleration of the bar to slow the ascent would be more gradual to avoid such large unweighing values at the completion of the lift.

**Figure 2:** Max  $F_Z$  normalized to total weight. letters =  $p < 0.05$  within a squat across the phases.

### Conclusions

Shearing and vertical forces produced during a squat were examined. Absolute values indicated only slight differences between squats. A more gradual ascent may minimize bouncing at the completion of a lift, improving performance, and thus reducing the chance of injury.

# The Influence of Sports-Related Concussion on Cognition and Landing Biomechanics in Collegiate Athletes

Jason M. Avedesian<sup>1</sup>, Tracey Covassin<sup>2</sup>, Shelby Baez<sup>2</sup>, Jennifer Nash<sup>3</sup>, Ed Nagelhout<sup>4</sup>, Janet S. Dufek<sup>1</sup>

<sup>2</sup>Department of English, University of Nevada, Las Vegas, Las Vegas, NV, USA  
 Email: jason.avedesian@unlv.edu

## Summary

Collegiate athletes with and without a history of sports-related concussion (SRC) performed an unanticipated jump-landing task and neuropsychological testing. Group-based statistics and predictive models were performed to compare group differences on biomechanical and neuropsychological measures. Collegiate athletes with a history of SRC demonstrated significantly less knee flexion during the landing task compared to the control cohort. Knee flexion and neuropsychological variables related to attention and working memory were identified as the strongest predictors of SRC injury history.

## Introduction

Athletes who sustain an SRC are at an approximately two times greater risk for lower extremity (LE) injury, often several months beyond full unrestricted return-to-sports [1,2]. However, the biomechanical and neuropsychological mechanisms associated with LE injury risk post-SRC have yet to be firmly elucidated.

This investigation sought to determine differences in landing biomechanics and neuropsychological performance in collegiate athletes with a history of SRC compared to matched controls. Additionally, various predictive models were performed to determine history of SRC based upon biomechanical and neuropsychological performance.

## Methods

A total of 40 National Collegiate Athletic Association Division 1 athletes (20 SRC, 20 controls) performed biomechanical and neuropsychological testing. Each athlete in the SRC group was matched to one control athlete, controlling for sport, position, sex, and age ( $\pm 1$  year).

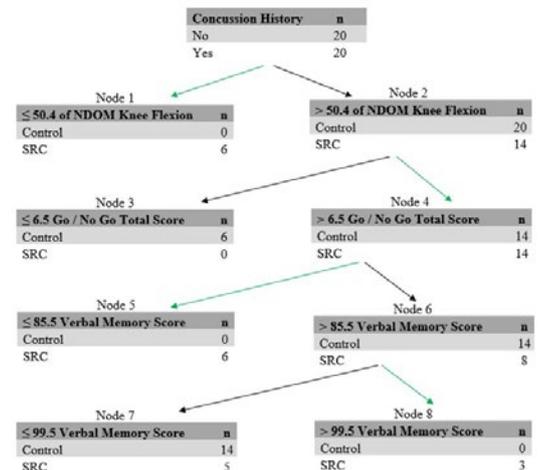

Sport participation for the 20 athletes in the SRC group (age:  $20.5 \pm 1.3$  years; time mean time since last SRC:  $461 \pm 263$  days) and the 20 athletes in the control group (age:  $19.8 \pm 1.3$  years; were as follows: football (n = 6), volleyball (n = 4), men's soccer (n = 3), women's soccer (n = 3), rowing (n = 2), field hockey (n = 1), and women's diving (n = 1)

Athletes completed unanticipated land-and-cut tasks on the dominant (DOM) and non-dominant (NDOM) limbs. Select kinetic and kinematic variables associated with LE injury risk were measured during biomechanical testing. Athletes performed two neuropsychological assessments: Immediate Post-Concussion Assessment and Cognitive Testing and Senaptec Sensory Station.

## Results and Discussion

Group-based statistics revealed that the SRC group performed the landing task with significantly decreased knee flexion on both the DOM (SRC: 54.1 deg, control: 60.2 deg) and NDOM (SRC: 54.0 deg, control: 60.3 deg) limbs compared to controls. No other group differences were observed for biomechanical and neuropsychological variables.

Binary logistic regression (Multiple Object Tracking and NDOM knee flexion) and C5.0 decision tree algorithm (Verbal Memory, NDOM knee flexion, and Go / No Go total score) identified multiple biomechanical and neuropsychological predictors of SRC group membership (Figure 1).

**Figure 1:** C5.0 decision tree identified NDOM knee flexion  $\leq 50.4$  deg, Go / No Go  $\leq 6.5$ , and Verbal Memory  $\leq 85.5$  and  $\geq 99.5$  as significant indicators of prior SRC injury history.

## Conclusions

Collegiate athletes with a history of SRC display biomechanical movement patterns at the knee that may suggest a greater risk for LE injury. Biomechanical and cognitive performance may uniquely identify prior SRC history.

## Inertial measurement unit for determining elbow torque during baseball pitching

Janelle A. Cross, PhD<sup>1</sup>, Cody Dziuk, BS<sup>1</sup>, Jessica M. Fritz, PhD<sup>1</sup>

<sup>1</sup>Department of Orthopaedic Surgery, Medical College of Wisconsin, Milwaukee, WI, USA

Email: jacross@mcw.edu

### Summary

This study examined the use of an inertial measurement unit (IMU) sensor for determining elbow torque during baseball pitching. An optical motion capture system was used as the gold standard. An IMU sensor was placed near the subject's medial epicondyle on the throwing arm. The three fastest pitches thrown for a strike were analyzed. The resultant accelerations and calculated torques were compared between the motion capture and IMU systems. Significant positive correlations were found between the systems: medial elbow marker acceleration and resultant IMU acceleration, and elbow varus torque and IMU calculated torque. The IMU sensor could be an alternative to performing a full biomechanical analysis when concerned with elbow injury risk in pitchers.

### Introduction

Overuse and improper pitching mechanics lead to increased elbow torque, and consequently increased risk of ulnar collateral ligament (UCL) injury and reconstruction [1,2]. The ability to quantify elbow torque daily throughout a throwing session, and cumulatively throughout an entire season would allow for more accurate tracking of UCL injury risk correlated with increased elbow torque. The purpose of this study was to examine an IMU sensor for determining elbow torque during baseball pitching.

### Methods

Nineteen adolescent male baseball pitchers participated (16.0 ± 0.8 years, 77.4 ± 9.0 kg, 182.2 ± 5.3 cm). Each pitcher had at least 4 years of pitching experience with no current complaint of arm pain or history of throwing arm surgery. All subjects signed assent forms, and informed consent was obtained from their guardians prior to data collection. Eight Raptor-E cameras (Motion Analysis Corporation, Santa Rosa, CA) were positioned around an artificial mound to capture motion at 300 Hz. Forty-seven reflective markers were attached at specific landmarks. A Blue Trident IMU sensor (Vicon Motion Systems, Ltd.; Oxford, UK) was attached to the subject's throwing arm forearm, 4 cm below the medial epicondyle. IMU data was recorded using Vicon CaptureU software (Vicon Motion Systems, Ltd., Oxford, UK). Ten fastball pitches were recorded being thrown into a strike zone net positioned at a regulation distance of 18.4 m from the pitching rubber. The three fastest strikes were analyzed.

Marker data was identified then filtered using a 13.4 Hz fourth-order Butterworth low-pass filter in Cortex software (Motion Analysis Corporation, Santa Rosa, CA). Kinetics were calculated using Visual 3D software (C-Motion, Germantown, MD) [23]. Custom Python code was used to

extract and process the IMU data. The magnitude of the acceleration signal was calculated using the X, Y, and Z component signals. Forearm and hand lengths and masses were used to calculate a moment of inertia for each subject. The moment of inertia was used to calculate the torque using the resultant acceleration of the IMU. SPSS Statistics software (version 26, IBM Corporation, Armonk, NY) was used to analyze the data. Due to the difference in the scale of the acceleration magnitudes between the two systems, statistical analyses were focused on correlation tests. Associations examined were linear; thus, two-tailed Pearson correlation coefficients were used to determine correlations between the motion system and IMU metrics. A significance level of  $p < .05$  was chosen.

### Results and Discussion

The mean and standard deviations of the four key metrics compared are presented in Table 1. Significant positive correlations were found for both the medial elbow marker acceleration and resultant IMU acceleration ( $r = 0.356$ ,  $p = .007$ ), and the elbow varus torque and IMU calculated torque ( $r = 0.559$ ,  $p < .001$ ). The results from this study demonstrate that the Blue Trident IMU sensor could be an alternative to performing a full biomechanical analysis when concerned with elbow injury risk in pitchers. The acceleration metrics had a low to moderate positive correlation and the torque metrics had a moderate to strong positive correlation.

**Table 1:** Motion capture system and IMU mean and standard deviations

Elbow Marker Acceleration (deg/s <sup>2</sup> )	367.6	±	39.4
IMU Acceleration (deg/s <sup>2</sup> )	1333.7	±	487.1
Elbow Varus Torque (Nm)	60.8	±	16.2
IMU Calculated Torque (Nm)	60.0	±	22.3

### Conclusions

The positive correlations between the motion capture system and IMU suggest the IMU sensor is reliable for coaches and athletes who do not have access to a motion capture system and has the advantage of daily use throughout a throwing season to cumulatively assess elbow torque while pitching.

## Body Composition and Segmental Sequencing in Trained Softball Athletes

Kenzie B. Friesen<sup>1</sup>, Gretchen D. Oliver<sup>2</sup>

<sup>1</sup>College of Kinesiology, University of Saskatchewan, Saskatoon, Canada

<sup>2</sup>Sports Medicine and Movement Laboratory, School of Kinesiology, Auburn University, Auburn, USA

Email: [kenzie.friesen@usask.ca](mailto:kenzie.friesen@usask.ca)

### Summary

Segmental angular velocities of the trunk, shoulder, elbow, and wrist significantly differed between pitchers with a healthy body fat percentage (BF%) and a high BF%. While increased mass is often considered beneficial in pitching, differences in movement patterns exist according to body fat presence and should be further studied to understand how body composition can influence both performance and injury.

### Introduction

Softball pitchers regularly present above-average body sizes despite reports that larger athletes are more susceptible to injury [1]. The windmill pitching motion is a sequential movement that requires proper coordination of segments to affect performance [2] and distal segment stress [3].

The purpose of this study was to examine the difference in segmental angular velocities of the trunk, shoulder, elbow, and wrist, between two groups of pitchers: 1) those with a healthy BF% (<32%) and 2) those with a high BF% (≥ 32%).

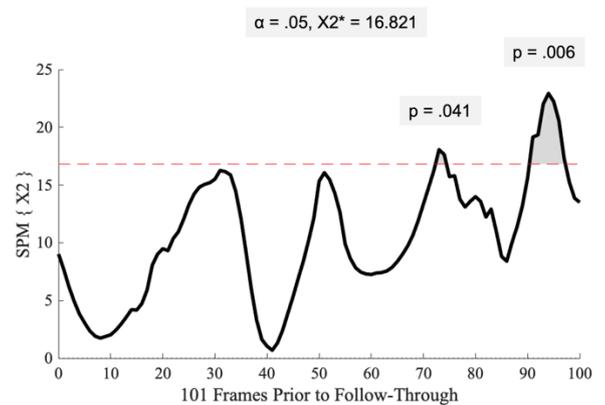

### Methods

Forty high-school and college softball pitchers completed body composition testing via dual-energy x-ray absorptiometry and were placed into pitcher BF% groups. Kinematic data were captured at 240 Hz using an electromagnetic motion capture system synced with motion analysis software. Trunk rotation, shoulder flexion, elbow flexion, and wrist flexion angular velocities were defined according to ISB recommendations [4] and extracted over the final 101 frames prior to follow-through (defined as 100 ms following ball release). Statistical parametric mapping (SPM) was employed using MATLAB to complete a multivariate analysis of variance (MANOVA) over the 101 frames of data. Pitch velocity was also collected using a calibrated radar gun. An independent samples t-test was used to compare pitch velocity between the two groups of pitchers.

### Results and Discussion

The SPM MANOVA {X<sub>2</sub>} was statistically significant and showed that the two groups of pitchers differed at 74-75% and 92-99% of this portion of the movement (SPM{X<sub>2</sub>}<sub>1,4</sub> = 16.821, *p* = .041 and .006). The t-test revealed pitch velocity did not differ between pitcher groups, *t* = 1.484, *p* = .145.

Research notes larger athletes can possess increased segmental mass moments of inertia which can influence joint moments and angular accelerations [5]. Therefore, increased BF% may explain altered movement patterns during the windmill softball pitch. This has implications for performance, as research notes elite pitchers have better proximodistal sequencing [2]. Similarly, segmental sequencing differences between BF% groups may offer insight to pain and injury as research reports larger athletes have higher rates of injury [1].

**Figure 1:** SPM analysis of the combined multivariate dependent variable (segmental angular velocities) during 101 frames of data prior to follow-through of the pitch. X<sub>2</sub>\* = SPM critical threshold.

### Conclusions

Segmental sequencing differed between pitcher groups while pitch velocity did not. Therefore, the authors suggest that pitchers adopt different movement strategies to accommodate their physical characteristics and still reach comparable pitch outcomes. More research is needed to examine whether these sequencing differences are beneficial (increased pitch velocity) or detrimental (increased injury risk) to pitchers.

Pitcher Groups	Age (years)	Height (cm)	Mass (kg)	BF%	Pitch Velocity (mph)
Healthy BF%	16 ± 2	169.8 ± 6.9	64.8 ± 9.3	27.6 ± 2.5	56 ± 5
High BF%	15 ± 2	171.3 ± 5.9	83.5 ± 15.6	39.8 ± 5.1	54 ± 5

## Should Major League Baseball Adjust the Mound Distance?

Megan S. Stewart<sup>1,2</sup>, Alek Diffendaffer<sup>1</sup>, Jon Slowik<sup>1</sup>, Glenn Fleisig<sup>1</sup>

<sup>1</sup>The American Sports Medicine Institute, Birmingham AL, USA

<sup>2</sup>Concordia University of Chicago, River Forest, Illinois, USA

Email: megan.s.stewart19@gmail.com

### Summary

With a decrease in runs scored, Major League Baseball (MLB) commissioned the American Sports Medicine Institute to conduct a biomechanical study looking at a potential change to distance of the pitching mound.

### Introduction

Moving the mound backwards, farther from homeplate has also been suggested for increasing offense<sup>1</sup>. The theory is that increased pitch velocity in today's game has reduced the time for the ball to reach homeplate, thus, lowering the ability for the hitter to react to the baseball. Therefore, increasing the distance between the pitching mound and homeplate may provide the hitter with an increase in time to see the baseball, swing, and make good contact. While an increase in the pitching distance may increase the offense, the effect on joint kinetics, pitching biomechanics, and injury risk must be determined. Therefore, the primary purpose of this research study was to determine the effect of pitching distance on adult baseball pitching biomechanics.

### Methods

The research study was approved by the Institutional Review Board at St. Vincent's Health System (Birmingham, AL, USA). There was a total of 26 healthy, active collegiate pitchers (10 Division 1, 2 Division 2, 11 Division 3, 3 Junior College) were recruited to participate in this study. All of the testing was completed in an indoor biomechanics laboratory.

Anthropometric measures were collected and 38 retro-reflective markers were attached the participant at previously described<sup>10,16,17</sup>.

Three-dimensional motion data of each pitcher were tracked with a 12-camera motion capture system sampling at 240 Hz with a three-dimensional residual threshold set at  $0.45 \pm 0.20$  mm (Raptor System, Motion Analysis Corporation, USA). Ball kinematics were measured for the final 21 participants using a PITCHf/x system (SportsMEDIA Technology, Fremont, CA, USA). The first three pitches of each condition were excluded from the analysis to allow the pitcher to fully adapt to the pitching distance. The participant was unaware that these pitches would be excluded. Pitcher biomechanics and ball kinematics were calculated for the final five pitches for each mound condition.

Thirty-seven pitcher kinematic and kinetic variables were calculated as previously described<sup>13,15,17</sup>. The initial ball velocity was measured at a location of 10ft in front of the pitching rubber. The final ball velocity was measured as the baseball crossed the front of homeplate. The length of ball

flight was defined as the total time it took the baseball to travel between these two abovementioned locations. Horizontal break of the baseball was defined as the maximum horizontal deviation from an imaginary straight-line path between the release point and the point where the pitch crossed the back tip of home plate. Vertical break of the baseball was defined as the maximum vertical deviation from an imaginary straight-line path between the release point and the point where the pitch crossed the back tip of home plate. For each pitching distance, strike percentage was calculated as the number of pitches within the PITCHf/x strike zone divided by the total number of pitches. For all of the pitching distances, the magnitudes of all parameters were averaged for each participant. A repeated measures analysis of variance (ANOVA) was utilized to detect significant differences among the pitching distances. When a significant difference ( $p < 0.05$ ) was found, pairwise differences were analysed with a Tukey post-hoc test ( $p < 0.05$ ).

### Results and Discussion

The pitchers were (mean $\pm$ SD) 19.7 $\pm$ 1.2 years old, 73 $\pm$ 2 in tall, and had a weight of 205 $\pm$ 19 lbs. There were no significant differences seen for ball velocity, movement, or spin when pitching from the four mound heights for both the curveball and fastball. The mean ball velocity for the fastball and curveball was 88.4 $\pm$ 6.06 mph and 70.2 $\pm$ 5.95 mph respectively. There were twelve biomechanical variables (seven kinematic variables and five kinetic variables) that were found to be significantly different when comparing the mound height for the fastball pitches. When comparing mound height and curveballs, there were eight kinematic variables shown to be significantly different.

### Conclusions

A moderate (up to 3.2 ft) increase in pitching distance will have no statistically significant effect on pitching kinematics or kinetics. The duration of ball flight increased with pitching distance, supporting the concept that moving the mound back would benefit hitters with more time to decide and execute their swing. However, the magnitudes of horizontal and vertical break also increased with pitching distance, potentially benefitting pitchers.

### Acknowledgments

We would like to acknowledge Major League Baseball.

# Correlation of Glenohumeral Internal Rotation Deficit, Total Range of Motion, and Retroversion to Shoulder Kinetics in Collegiate Baseball Pitchers

Hannah L. Stokes<sup>1</sup>, Marc Duemmler<sup>1</sup>, Nigel Zheng<sup>1</sup>, Koco Eaton<sup>2</sup>

<sup>1</sup>Department of Mechanical Engineering and Engineering Science, University of North Carolina at Charlotte, NC, USA

<sup>2</sup>Tampa Bay Rays and University of South Florida, FL, USA

Email: [nzheng@unc.edu](mailto:nzheng@unc.edu)

## Summary

The study included 109 collegiate baseball pitchers and investigated correlations between shoulder rotational properties and shoulder kinetics during pitching. Pearson correlation tests were performed using SPSS. Retroversion had the most significant correlations to shoulder kinetics.

## Introduction

Glenohumeral internal rotation deficit (GIRD), total range of motion (tROM), and retroversion (bony external range of motion) are related to shoulder injuries [1]. Higher joint loading has been shown to lead to more injury incidences [2]. GIRD and tROM are commonly assessed by team clinicians. The purpose of this study is to quantitatively investigate shoulder rotational properties related to GIRD, tROM, and retroversion and shoulder kinetics during baseball pitching. If correlations are found, this could improve the way shoulder rotational properties are monitored in order to reduce potential injuries from excessive forces and torques. We hypothesized that GIRD, tROM, and retroversion would have no significant correlation to shoulder kinetics.

## Methods

The study included 109 collegiate baseball pitchers (height: 186±8 cm and weight: 85±9 kg). The study was approved by an institutional review board and all pitchers gave informed consent. All pitchers were healthy during biomechanical testing. The shoulder rotational test measured the end-point angle (EPA) and resistant onset angle (ROA) using a custom-made wireless device [3]. The test measured internal and external angles on both the throwing and non-throwing arm. tROM is defined as internal plus external EPA. Bilateral difference internal EPA is related to GIRD and bilateral difference external ROA is related to retroversion.

Pitching motion data was collected at 240 Hz with sixteen reflective markers using a motion capture system [4]. The ball speed was measured during pitching. A custom MATLAB program was created to use an inverse dynamics model to calculate anterior/posterior, superior/inferior forces, and internal/external rotation, horizontal adduction/abduction torques. Pearson correlation tests were performed using SPSS with an alpha set to 0.05.

## Results and Discussion

Shoulder rotational properties had significant correlations with shoulder forces and torques (Table 1). Bilateral external ROA difference had significant correlations with superior/inferior forces, and internal rotation and horizontal adduction

torques. tROM had significant correlations with anterior force, external rotation and horizontal abduction torques. Bilateral internal EPA difference did not have any significant correlations. The shoulder rotational properties were not significantly correlated with ball speed.

**Table 1:** Pearson correlation values for shoulder rotational properties (ext: external, int: internal, bilat diff: bilateral difference) and shoulder kinetics, where \* indicates  $p < 0.05$ .

	Forces			
	Anterior	Posterior	Superior	Inferior
<b>Bilat Diff Int EPA</b>	0.126	-0.087	0.089	-0.051
<b>tROM</b>	0.222*	-0.013	0.019	-0.113
<b>Bilat Diff Ext ROA</b>	-0.110	0.133	-0.291*	0.257*
	Torques			
	Internal	External	Horizontal Adduction	Horizontal Abduction
<b>Bilat Diff Int EPA</b>	0.028	0.099	0.036	-0.107
<b>tROM</b>	0.131	0.254*	-0.029	-0.166*
<b>Bilat Diff Ext ROA</b>	-0.259*	-0.016	-0.201*	-0.034

Findings emphasize that shoulder rotational properties should be monitored quantitatively in order to ultimately, improve performance and reduce injury. Correlations between GIRD and tROM with shoulder kinetics align with previously reported findings [5]. Further investigation is needed to determine if these correlations to kinetics are related to injury and surgery incidences.

## Conclusions

GIRD, tROM, and retroversion are correlated with shoulder kinetics in college baseball pitchers. The bilateral difference in external ROA (retroversion) had the most significant correlations and should be closely monitored.

## Acknowledgments

This study is funded by a Clinical Research Grant from Major League Baseball.

## Are Distal Throwing Arm Kinematics Predictive of Maximum Elbow Valgus Torque in Youth Baseball Pitchers?

Tessa C. Hulburt<sup>1</sup>, Garrett S. Bullock<sup>1</sup>, Arnel L. Aguinaldo<sup>2</sup>, Kristen F. Nicholson<sup>1</sup>

1. Department of Orthopaedic Surgery, Wake Forest School of Medicine, Winston Salem, NC, USA

2. Department of Kinesiology, Point Loma Nazarene University, San Diego, CA, USA

Email: [thulburt@wakehealth.edu](mailto:thulburt@wakehealth.edu)

### Summary

The purpose of this study was to determine if distal throwing arm kinematics calculated from fastball (FB), breaking ball (BB) and off-speed (OS) pitches are predictive of elbow valgus torque (EVT) in younger (13-15 years) and older youth athletes (16-18 years). Motion capture data and a generalized linear model with Lasso regularization found that kinematics from OS pitches thrown by younger youth pitchers were most association with EVT.

### Introduction

Motion capture biomechanics has emerged as a vital tool to understand injury risk patterns and efficient mechanics in baseball pitching [1]. Biomechanics studies have investigated the lower extremity, trunk, and upper throwing arm, but little attention has been given to the distal throwing arm, particularly in youth pitchers [2]. The purpose of this study was to determine if distal throwing arm kinematics calculated from three pitch types are predictive of EVT in youth athletes aged 13-15 and 16-18 years.

### Methods

Motion capture analyses were conducted on 52 pitchers aged 13-15 years (age:  $14.8 \pm 0.65$  years, height:  $1.78 \pm 0.07$  m, weight:  $71.5 \pm 11.6$  kg) and 52 pitchers aged 16-18 years (age:  $16.7 \pm 0.5$  years, height:  $1.85 \pm 0.07$  m, weight:  $83.1 \pm 11.5$  kg). A 41 reflective markerset and twelve-camera motion analysis system (Qualisys AB, Göteborg, Sweden) were used to collect pitching mechanics data. Ball velocity (BV) was recorded with a Trackman device (Trackman, Scottsdale, Arizona). Distal throwing arm kinematics were calculated with Visual3D (C-Motion, Inc. Germantown, Maryland). Pitching models were defined using the PitchTrak model [3], and segment coordinate systems were defined according to ISB recommendations [4]. EVT was normalized by body weight (N) and height (m). A generalized linear model with a Lasso regularization method was chosen due to multicollinearity within the kinematics dataset and the non-normal distribution of EVT data. This model calculated if 12 kinematic predictor variables were prognostic of EVT response variable by weighting each variable coefficient. Larger coefficients indicated a stronger association with EVT.

### Results and Discussion

Kinematics from OS pitches thrown by youth players aged 13 to 15 years were most associated with EVT. Wrist flexion angle at maximum shoulder external rotation (MER) and ball release (BR) from this age group and pitch-type had a negative

and positive relationship with EVT, respectively. Forearm pronation at MER from younger youth OS pitches had a positive relationship with EVT. Both 10ms and 100ms after BR, ulnar deviation angle from younger youth OS pitches had predictive value for the response variable EVT. The only variable related to EVT in the older youth age group was wrist flexion at 10ms after BR in FB pitches. Younger youth player kinematics data from OS pitches may be associated with EVT because the OS pitch is often the last pitch-type learned after FB and BB pitches. Lack of skill and coordination with this pitch type may lead to potentially injurious elbow mechanics. Further, the average OS pitch ball speed for younger and older youth players was 73.6mph and 79.9mph, respectively. Despite the higher ball velocity, older youth player OS pitch kinematics were not associated with EVT, potentially indicating that older youth players develop the skill and coordination to throw OS pitches more safely.

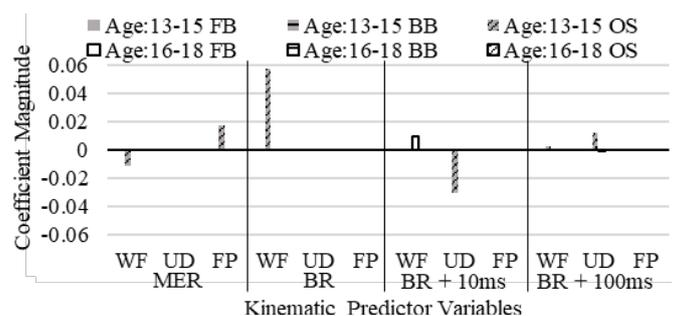

Figure 1. Kinematic coefficients associated with EVT for younger and older youth pitchers. Kinematic variables are wrist flexion angle (WF), ulnar deviation angle (UD), and forearm pronation angle at timepoints maximum external rotation (MER), ball release (BR), 10ms after ball release (BR + 10ms), and 100ms after ball release (BR + 100ms).

### Conclusions

Distal throwing arm kinematics from OS pitches thrown by younger youth pitchers were most related to EVT. Proper mechanics should be emphasized to younger youth pitchers when throwing OS pitches to avoid increased stress to the medial elbow. Future work should include an analysis of distal throwing arm angular velocities and torques and comparison to skilled adult pitchers.

# Limb Symmetry During a Cutting Task in Athletes With and Without a History of Sports-Related Concussion

Warren O. Forbes<sup>1</sup>, Jason M. Avedesian<sup>1</sup>, Janet S. Dufek<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Nutrition Sciences, University of Nevada Las Vegas, Las Vegas, NV

Email: warren.forbes@unlv.edu

## Summary

Twenty athletes with a history of sports-related concussion (SRC) and twenty matched control athletes performed a land-and-cut task with their dominant and non-dominant limbs. An independent t-test was used to compare kinematic and kinetic variables prospectively linked to lower extremity (LE) injury risk between the dominant limb and the non-dominant limb during the task. Although there were no significant differences in limb asymmetry, there were differences in frontal plane kinetics at the knee joint that may predispose athletes in each cohort to increased LE injury risk.

## Introduction

Athletes who sustain SRCs may have alterations to neuromuscular control that increase their risk of future non-contact LE injury [1]. The exact mechanisms of the relationship between SRC, altered neuromuscular control, and LE injuries are currently unknown.

A link between SRC history and limb asymmetry has been observed in elite athletes that may increase the risk of non-contact LE injury [2]. The Limb Symmetry Index Dominant/Non-Dominant (LSI-D/ND) has been used as a measure to quantify asymmetry between limbs (LSI-D/ND = dominant limb/non-dominant limb x 100) [3]. LSI-D/ND values should be greater than 90% to minimize the risk for sustaining an LE injury. The purpose of this study was to analyze the differences in LSI-D/ND between SRC athletes and a matched control group.

## Methods

College athletes with a history of SRC (n = 20) and a control group of healthy athletes matched by sport, position, sex, and age (n = 20) were recruited for this study.

Athletes performed an unanticipated land-and-cut task. The task consisted of each athlete standing on a 60 cm box with a visual stimulus (FITLIGHT Corp., Aurora, Ontario, CA) positioned three meters away from the athlete. Various colors (eg, green, pink, blue, and red) were presented as the visual stimulus. Athletes were instructed to only respond to a green or red light. When a red or green light was presented, athletes were instructed to step off the box, land on both limbs and perform a 45-degree cutting movement to the left or right, respectively. A trial was considered successful if the athlete obtained full foot contact on the force platform and performed the correct land-and-cut maneuver in the direction corresponding to the color stimulus.

The kinetic and kinematic dependent variables of interest for the dominant (defined as the preferred limb for their respective sport) and non-dominant limbs were vertical ground reaction force (vGRF), peak knee extensor moment

(pKEM), peak knee abduction moment (pKAM), peak ankle dorsiflexion angle (pDF), peak knee flexion angle (pKF), and peak knee abduction angle (pKA). Separate independent t-tests were performed to compare LSI-D/ND for each dependent variable between the SRC and control groups.

## Results and Discussion

There were no significant differences in LSI-D/ND between the SRC and control groups for vGRF, pKEM, pKAM, pDF, pKF, and pKA (p > .05).

Results indicated no significant differences in limb asymmetry between the SRC group and the control group. Every dependent variable, apart from pKAM, were within the acceptable LSI-D/ND range indicating minimized risk of LE injury. The LSI-D/ND for pKAM was 219% and 213% respectively for SRC and the control group. This indicates that the dominant limb, on average, had a peak knee abduction moment two times greater than that of the non-dominant limb. Further testing would be needed to assess the potential for frontal plane mechanics that could lead to LE injury.

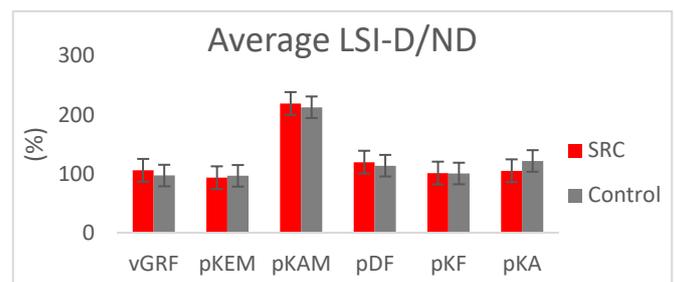

Figure 1. Limb Symmetry Dominant/Non-Dominant

## Conclusions

Although LSI-D/ND was not significantly different between the SRC and control group, further research regarding limb asymmetry in athletes with an SRC history is necessary. While this study failed to identify any limb asymmetries between groups, analyzing each dependent variable individually may provide further insight regarding potential LE injury risk.

## Sprinting with prosthetic versus biological legs: an unfair advantage?

Owen N. Beck<sup>1</sup>, Paolo Taboga<sup>2</sup>, & Alena M. Grabowski<sup>3,4</sup>

### Summary

Due to the world-class 400m running performances of athletes with prosthetic legs, many people assume that running-prostheses provide users an overall advantage over non-amputees during sprint races. These assumptions have caused athletics governing bodies to effectively prohibit the use of running-prostheses from sanctioned competition. Here, we show that no athlete with prosthetic legs, including the fastest such athletes, exhibit a single 400m performance metric that is superior to those achieved by elite non-amputees. Hence, the use of prosthetic legs during 400m running races cannot be considered unequivocally advantageous compared to the use of biological legs.

### Introduction

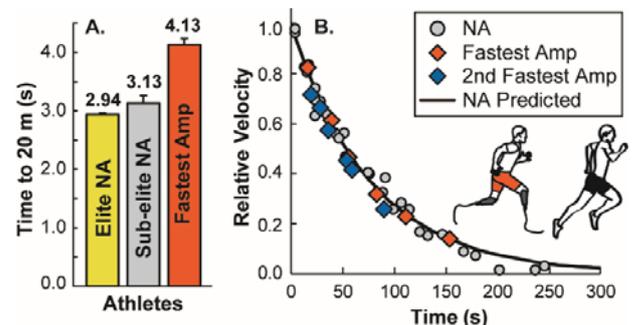

Exceptional athletes with bilateral prosthetic legs have run 400m faster than the Olympic track and field qualifying standard. Yet, the potential for these athletes to race alongside non-amputee Olympians has been stifled by policymakers who assume that running-prostheses provide users an overall advantage versus non-amputee competitors. This assumption has been ill informed by the scientific literature, because there is no consensus regarding the *net effect* of running with prosthetic versus biological legs. Thus, we sought to determine whether athletes with bilateral prosthetic legs have inherent advantages versus non-amputees during 400m races by comparing athlete 400m performance metrics: initial race acceleration, maximum straight and curve running velocity, velocity at aerobic capacity, and sprint endurance. We reasoned that if an athlete with prosthetic legs exhibits a 400m performance metric that is superior to that achieved by elite non-amputees, prosthetic legs likely confer specific advantages to their users versus athletes with biological legs.

### Methods

We quantified each 400m performance metric from the fastest male athlete with bilateral prosthetic legs (400m personal record (PR): 44.38 s) and compared his metrics to those of other elite male athletes with and without prosthetic legs. Statistically, we deemed athletes with prosthetic legs to exhibit a different 400m performance metric than non-amputees if they achieved a value outside the non-amputee range, and/or when our statistical tests revealed  $\geq 95\%$  confidence that their best 400m performance metric was different from the mean of the comparison non-amputee cohort ( $p < 0.05$ ).

### Results

The fastest initial acceleration out of the starting blocks through 20 m from an athlete with prosthetic legs was 40% slower ( $>59$  SDs) than the average of elite non-amputees (Fig. 1A) [1]. The fastest treadmill-running velocity achieved by athletes with prosthetic legs (11.4 m/s) was similar to, but not faster than that achieved by non-amputees (11.7 m/s). Athletes with prosthetic legs are estimated to slow  $\geq 1.3\%$  more than non-amputees on an outdoor track curve versus on a straightaway. Notably, at a mutual running velocity (10 m/s), the fastest athlete with prosthetic legs exhibited similar ground reaction forces and stride kinematics as non-amputees ( $<8\%$  &  $<2$  SDs) [2]. The fastest  $\dot{V}O_{2peak}$  from athletes with prosthetic legs (5.0 m/s) is nearly identical to that of non-amputee 400m athletes (PR:  $\leq 48.03$  s; Avg  $\pm$  SD:  $4.9 \pm 0.04$  m/s) [2] and 19% ( $>3$  SDs) slower than that of 10 km non-amputee distance-runners (PR:  $<32$  min). The sprint endurance profile of the two fastest athletes with prosthetic legs was nearly identical to that of non-amputees ( $<3\%$  &  $<1$  SD; Fig. 1B) [2].

**Figure 1.** A. Avg  $\pm$  SD time to sprint from the starting blocks to 20 m for elite non-amputees (NA) [1], sub-elite NA [1], and the fastest athlete with prosthetic legs (AMP). B. The time that NA [2], as well as the two fastest AMP could sustain a treadmill running velocity relative to their maximum velocity [2].

### Conclusions

Currently, no athlete with bilateral leg amputations using running-prostheses, including the fastest such athletes, has ever been reported to have a lab-tested 400m performance metric that is superior to that achieved by non-amputees. Therefore, the use of prosthetic legs during 400m running races cannot be considered unequivocally advantageous compared to the use of biological legs.

# CONCURRENT CHANGES IN MEDIAN NERVE DEFORMATION AND DISPLACEMENT DURING GRIPPING

Aaron M. Kociolek<sup>1</sup>, Gabrielle Racine<sup>1</sup>, Michael W. R. Holmes<sup>2</sup>

<sup>1</sup>Biomechanics and Ergonomics Lab, School of Physical and Health Education, Nipissing University, North Bay ON, Canada

## Summary

We investigated median nerve (MN) deformation and displacement in concert to elucidate carpal tunnel dynamics during forceful gripping. Twelve participants performed 3 different grip types (power, chuck, pulp) while ramping force up from 0% to 50% of maximal voluntary effort (MVE) and ramping force down from 50% to 0% MVE. Ultrasound of the transverse carpal tunnel demonstrated time-dependent changes in loading (ramping force up) versus unloading (ramping force down) for both MN deformation and displacement metrics. These results indicate that MN deformation is linked to its displacement during forceful gripping and may further suggest a viscoelastic effect due to strain of surrounding tissues, including the subsynovial connective tissue within the carpal tunnel.

## Introduction

Finger exertions cause the flexor tendons in the carpal tunnel to displace palmarly, thus decreasing the distances between the flexor tendons and transverse carpal ligament [1]. Tendon displacement may, in turn, influence passive carpal tunnel structures, including the MN. Cowley et al. [2] showed the MN deformed during forceful gripping tasks, with the MN becoming more circular due to shortening in the radioulnar axis and lengthening in the palmar-dorsal axis. However, it remains unclear to what extent MN deformation is related to tendon dynamics. We evaluated MN deformation and displacement relative to the flexor tendons throughout loading and unloading of forceful gripping tasks to better elucidate tissue interactions within the carpal tunnel.

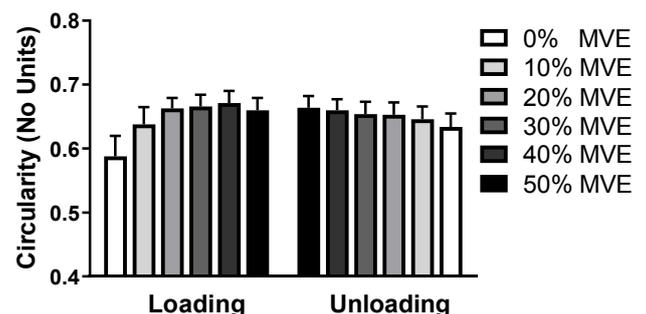

## Methods

Twelve right-handed participants ramped isometric force up from 0% to 50% of MVE before ramping force down from 50% to 0% MVE for 3 different grip types (power, chuck, pulp). Grip forces were measured with a digital dynamometer (MIE Medical) at 1000 Hz in a custom LabVIEW program (National Instruments), which also provided participants with the force ramp matching profiles via visual display. The transverse carpal tunnel was imaged at the distal wrist crease using ultrasound (Vivid Q, 12L, General Electric) with an acquisition frequency of 13 MHz and a sample rate of 30 Hz. MN images were extracted from 0–50% in 10% increments of MVE during both the loading (ramping force up) and unloading (ramping force down) phases. Images were analyzed in Image J (National Institutes of Health) to determine MN cross-sectional area, circularity [ $4\pi(\text{Area}/\text{Perimeter}^2)$ ], width (radioulnar axis), and height (palmar-dorsal axis) as well as the relative displacement between the MN and flexor digitorum superficialis tendon of

the middle finger (FDS-M). Three-way repeated measures ANOVAs tested the effects of grip type (power, chuck, pulp), grip force level (0%-50% in 10% increments of MVE) and ramp direction (loading versus unloading) on all deformation and displacement outcome variables ( $\alpha = 0.05$ ).

## Results and Discussion

We found a force level by ramp direction interaction on MN circularity ( $F_{5,55}=3.18$ ,  $p=0.014$ ). During loading, the MN became more circular from 0%-20% MVE, with no further change from 20%-50% MVE. These results fit a quadratic relationship. During unloading, there was a gradual decrease from 50%-0% MVE, which fit a linear relationship (Fig 1). Interestingly, MN displacement profiles during loading and unloading mirrored the deformation results. For example, the MN displaced ulnarly and dorsally relative to the FDS-M during the loading phase, but only up to 20% MVE with very little change thereafter. Conversely, the MN displaced radially and palmarly during unloading; however, displacement occurred gradually throughout the entire unloading phase from 50-0% MVE.

**Figure 1:** Mean ( $\pm$  standard error) median nerve circularity while ramping up (loading) and ramping down (unloading) grip force.

## Conclusions

MN deformation and displacement both changed in a time-dependent manner, including differences in loading versus unloading. Therefore, the results indicated that deformation of the MN was linked to its displacement relative to the flexor tendons. Time-dependent changes may also suggest a viscoelastic effect due to strain of the surrounding subsynovial connective tissue within the carpal tunnel.

# In-Vivo Measurement of Wrist Angles During the Dart-Throwing Motion Using Inertial Measurement Units

Gabriella Fischer<sup>1,2</sup> and Michael A. Wirth<sup>1</sup>, Simone Balocco<sup>3</sup>, Maurizio Calcagni<sup>1</sup>

<sup>1</sup>Division of Plastic Surgery and Hand Surgery, University Hospital Zurich, University of Zurich, Zurich, Switzerland

<sup>2</sup>Institute for Biomechanics, ETH Zurich, Zurich, Switzerland

<sup>3</sup>Dept. Mathematics and Informatics, University of Barcelona, Barcelona, Spain

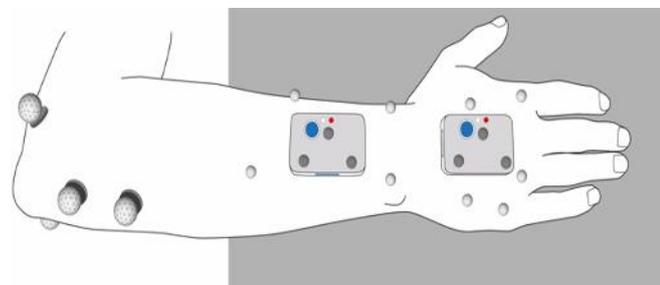

Email: Gabriella.Fischer@usz.ch

## Summary

This study investigates the clinically relevant dart-throwing motion (DTM) by comparing an inertial measurement unit based system (IMU) previously validated for basic motion tasks (BMT) with an optoelectronic motion capture system (OMC). Ten healthy volunteers performed the DTM equipped with both systems. Results of both systems were comparable, but bigger differences between the systems were found than in BMT and different possible reasons were identified in this study. Its easy applicability makes the IMU interesting for clinically measuring DTM range of motion (ROM).

## Introduction

Movements in the wrist during activities of daily living often occur in an oblique plane from flexion-radial deviation to extension-ulnar deviation, this movement is referred to as DTM. The DTM is clinically relevant but its ROM is not usually clinically measured with goniometers due to the complexity of the movement [1] and systems like OMC capable of capturing this movement are very complex to use and require a laboratory setting. We investigated an easy to use IMU previously validated for motion analysis of BMT in the flexion/ extension and radial/ ulnar deviation planes [2] for this more complex movement by comparing it to the motion analysis gold standard, an OMC [3].

**Figure 1:** Sensor (IMU), skin marker (light grey, OMC1) and sensor marker (dark grey, OMC2) placement

## Methods

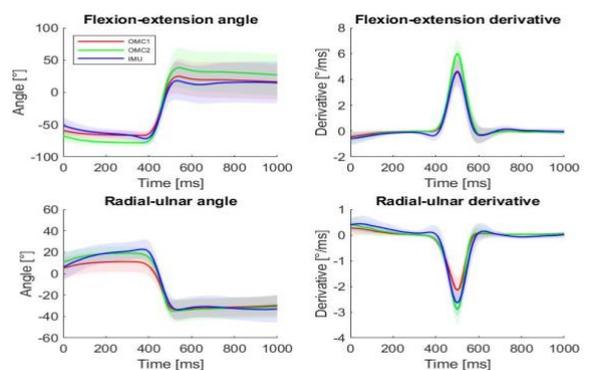

Ten healthy volunteers were equipped with both OMC skin markers and IMU on their right hands as depicted in Figure 1 and performed the DTM a total of 10 times on two different days.

The kinematic evaluation of the OMC was based on marker clusters [4] and a functional determination of the wrist joint centre and flexion axis. Joint rotations were calculated according to an established protocol [5]. The kinematic evaluation of the IMU was carried out by the software included in the DyCare® system. The resulting mean  $\pm$

standard deviation angle curves over all trials and subjects were aligned and compared. Absolute ROM in both movement axes were calculated for both systems as well as mean absolute differences (MAD) between the two systems.

## Results and Discussion

We found ROM values of 99° for both systems in the flexion/ extension plane with a MAD of 7°. A ROM of 47° for the OMC1 and 62° for the IMU with a MAD of 17° in the radial- ulnar deviation plane was calculated. The calculated angle and velocity curves are depicted in Figure 2. The results show lower agreement between the systems than we found for BMT in an earlier study [1], possible explanations being a differently calculated orientation of the DTM plane for both systems and skin movement artefacts due to the weight of the sensors and skin markers at high velocity movements.

**Figure 2:** Wrist movement angles and movement speeds in the flexion/ extension and radial/ ulnar deviation plane during DTM

## Conclusions

This study shows the challenge of comparing results of different kinematic motion capture systems for complex movements. Further investigations regarding calculation of the orientation of the DTM plane, probably using an imaging technique, would be helpful. Nevertheless, IMU are promising for future clinical application as they allow for measurement of dynamic and coupled wrist movements.

### Summary

High-intensity eccentric exercise can damage and weaken a muscle, and ‘the repeated bout effect’ (RBE) attenuates these impairments following a subsequent bout. It is unclear how the RBE influences torque production across a range of stimulation frequencies (i.e., the torque-frequency relationship). Nine males completed two bouts of high-intensity eccentric elbow flexions, separated by 4 weeks. A torque-frequency relationship was constructed 30 min to 7 days after both bouts. Indirect measures inferred the attenuation of damage in the second bout. Low and high frequencies recovered earlier than middle frequencies and there were no between-bout differences in torque at any frequencies. Therefore, there is not a RBE on the torque-frequency relationship of the elbow flexors.

### Introduction

Unaccustomed high-intensity eccentric exercise damages and weakens a muscle, marked by decreased isometric strength and increased serum creatine kinase (CK) and self-reported soreness. Following the exercise, adaptations occur, then when an identical bout is performed several weeks later, damage and weakness are attenuated. This phenomenon is termed the repeated bout effect (RBE) [1,2]. Muscle damage can differentially affect low (~10 Hz) and high-frequency (~50 Hz) torque production, contributing to prolonged low-frequency force depression [1]. However, results in this area have been equivocal [3,4], and the RBE’s influence on torque across a range of stimulation frequencies is unclear.

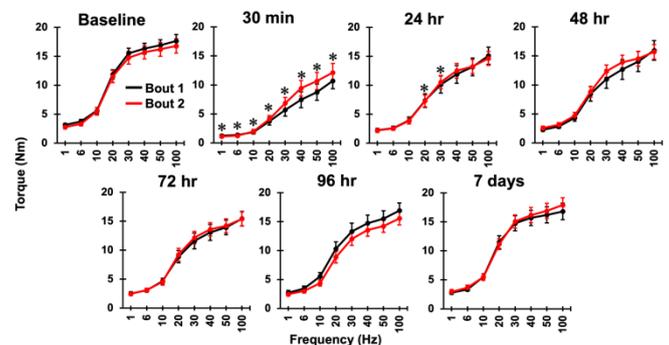

### Methods

Nine recreationally active males ( $24 \pm 2$  years,  $74.7 \pm 13.8$  kg,  $177.4 \pm 6.6$  cm) were recruited. Visits were split between Bout 1 and 2, 4 weeks apart. On a dynamometer at a  $110^\circ$  elbow angle, the current that elicited optimal twitch torque by percutaneous stimulation of the elbow flexors was first determined. An isometric maximal voluntary contraction (MVC) of the elbow flexors was then performed. A torque-frequency relationship was then constructed through tetanic stimulations (1000- $\mu$ s pulse width, 1-s duration) at 1, 6, 10, 20, 30, 40, 50, and 100 Hz. Participants then performed the eccentric exercise, which was 5 sets of 30 maximal isokinetic eccentric elbow flexions from  $50^\circ$  to  $140^\circ$  at  $180^\circ/s$ .

All baseline (BL) mechanical measures were repeated 30 min, 24, 48, 72, and 96 hr, and 7 days after the eccentric exercise. Serum CK (from the antecubital vein of the forearm) and self-reported soreness (visual analog scale) were also measured at baseline and throughout recovery. Data in figures are mean  $\pm$  standard error ( $n=9$ ).

### Results and Discussion

Serum CK, soreness, and MVC torque inferred the RBE’s attenuation of damage in Bout 2, with 820%, 19%, and 18% peak between-bout differences, respectively. A three-way ANOVA (bout[1-2]  $\times$  time[BL-7 days]  $\times$  frequency[1-100 Hz]) revealed a time  $\times$  frequency interaction ( $P<0.01$ ) for tetanic torque, but no bout  $\times$  time  $\times$  frequency interaction ( $P=0.12$ ). Hence, recovery was similar in both bouts, with Sidak-corrected t-tests showing lower (1-10 Hz) and higher frequencies (40-100 Hz) recovered by 24 hr, and middle-range frequencies (20-30 Hz) recovered by 48 hr (Figure 1).

**Figure 1:** Recovery of the torque-frequency relationship following Bout 1 and 2. \*Difference from baseline ( $P<0.05$ )

Contrary to our results, previous studies observed protection of 10, 15 and 100-Hz torque by the RBE 1-2 days post-exercise, albeit in lower-limb muscles [3,4]. Therefore, the RBE may affect the torque-frequency relationship of upper and lower-limb muscles differently. Future studies should explore peripheral mechanisms that may contribute to the longer lasting impairment of middle-range frequency torque production.

### Conclusions

Elbow flexor torque production at middle-range frequencies experienced longer lasting impairment by eccentric exercise-induced weakness than at low and high frequencies. The RBE does not seem to mitigate these impairments.

## Effects of localized muscle fatigue on muscle activation during a multi-joint repetitive task

E. Renda<sup>1,2</sup>, C. Yang<sup>1,2</sup>, J.N. Côté<sup>1,2</sup>

<sup>1</sup>Department of Kinesiology and Physical Education, McGill University, Montreal, Canada

<sup>2</sup>Occupational Biomechanics and Ergonomics Laboratory, Michael Feil and Ted Obelfed/CRIR Research Centre, Jewish Rehabilitation Hospital, Laval, Canada

Email: erika.renda@mail.mcgill.ca

### Summary

The objective of this study was to evaluate the effects of localized fatigue at different arm and trunk joints on electromyographical characteristics recorded during a multijoint, standing repetitive pointing task (RPT) performed with the dominant arm. We recruited 17 young adults. The activation amplitude (RMS), variability (SD) and mean power frequency (MnPF) were calculated for each of the pre-fatigue and post-fatigue RPT trials. Results show that activation of shoulder muscles was greater in all fatigue conditions. Results suggest that agonist (i.e. for the RPT: shoulder) muscles compensate by increasing their involvement during the arm task when either they, or other muscles, are locally fatigued.

### Introduction

Previous research on musculoskeletal disorders identified muscle fatigue as one of the risk factors for its development [1]. Muscle fatigue can be defined as a decrease in the maximal force or power one produces for submaximal and/or dynamic contractions [2]. Only a few studies investigated the impact of localized muscle fatigue (i.e. induced by localized efforts of individual muscles involved in a multi-muscle task) on patterns of whole-body tasks [3]. Of those, studies which used electromyography (EMG) measures only evaluated the coordination and co-contraction of the fatigued trunk muscles during a task where the trunk was an agonist [3]. It is not clear how the activity patterns of various muscles involved in a multi-joint task would adapt when fatigue is induced locally at any muscle more or less involved in producing the task.

### Methods

Seventeen young adults (8 males) without history of upper body injuries were recruited. Surface EMG electrodes were placed on: upper trapezius, pectoralis major, anterior and middle deltoid, biceps and triceps brachii, and left and right erector spinae. Subjects held a 0.7 kg weight and performed a Repetitive Pointing Task (RPT) in a standing position, moving the dominant index forward and backward at 1 Hz for 30 seconds (non-fatigued RPT (NFRPT)). Afterwards, they completed one shoulder, one elbow and one lower back fatiguing protocol in randomized order, separated by at least 30 minutes, where they held fixed weights and/or postures until exhaustion. Then, they performed the RPT again (after shoulder fatigue: SFRPT, after elbow fatigue: EFRPT, after trunk fatigue: TFRPT). RMS, SD and MnPF were calculated for each muscle during each RPT trial. The Least Significance Difference tests were applied between condition for each EMG variable for each muscle. To correct for type one errors, the Benjamini-Hochberg procedure was implemented.

### Results and Discussion

**SFRPT:** Muscle activation was greater in middle deltoid (MD) compared to the other conditions (NFRPT:  $p < 0.001$ , EFRPT:  $p = 0.024$ , TFRPT:  $p = 0.0032$ ), and in anterior deltoid (AD) compared to NFRPT condition ( $p = 0.0032$ ). This demonstrates that when the shoulder muscles are fatigued, the prime movers mainly increased their muscle activation, likely by recruiting more and bigger motor units to keep up with the required pace and maintain the elevated arm posture and the movement performance. SD was greater in anterior deltoid (NFRPT:  $p < 0.001$ , EFRPT:  $p = 0.0021$ , TFRPT:  $p < 0.001$ ) and middle deltoid (NFRPT:  $p = 0.0015$ , EFRPT:  $p < 0.001$ , TFRPT:  $p < 0.001$ ) in SFRPT in comparison to the other three conditions. The increase in variability suggests that these muscles may be searching for new movement patterns to preserve performance in the presence of fatigue at that joint.

**EFRPT:** Upper trapezius variability in this condition was greater than in NFRPT ( $p = 0.0024$ ), suggesting that this task's shoulder stabilizer was also searching for more motor unit rotation strategies to adapt to the elbow fatigue condition.

**TFRPT:** Middle deltoid activation amplitude was significantly greater compared to NFRPT ( $p < 0.001$ ). A reason for this may be that since the trunk muscles are fatigued, the trunk is likely reducing its motion. With less trunk motion, a compensatory strategy would be to further engage the shoulder movers to move the arm from one target to the other.

### Conclusions

Muscle activation adaptations to fatigue differ depending on which joint is locally fatigued during the multi-joint task. However, in all fatigued condition, the shoulder muscles compensate by increasing their involvement in the task. Results highlight compensatory strategies in muscles not fatigued, suggesting higher-level processes when adapting to fatigue to coordinate a multi-muscle task.

## Effect of Thumb IP Joint Posture on CMC Joint Movement during Thumb Opposition

Hiroshi Kurumadani<sup>1</sup>, Kazuya Kurauchi<sup>1</sup>, Shota Date<sup>1</sup>, Toru Sunagawa<sup>1</sup>

<sup>1</sup>Analysis & Control of Upper Extremity Function, Graduate School of Biomedical & Health Sciences, Hiroshima University, Hiroshima, Japan  
Email: hkuruma@hiroshima-u.ac.jp

### Summary

We examined whether the thumb interphalangeal (IP) joint posture affected the carpometacarpal (CMC) joint movement during thumb opposition. Twenty healthy adults conducted a thumb opposition task with two postural conditions: thumb IP joint extension and flexion. We recorded the three-dimensional thumb movement during tasks and then analyzed the thumb's joint angles and postural synergy in the conditions. The CMC joint angle and posture had become larger and more opposition in the thumb IP joint extension than the thumb IP joint flexion, respectively. We found that the thumb IP joint posture affected the CMC joint movement.

### Introduction

The CMC joint of the thumb has a crucial role in thumb opposition; the evaluation of the CMC joint movement in thumb opposition is clinically important [1,2]. For the CMC joint evaluation, it has been discussed that the thumb IP joint posture affects the CMC joint movement in thumb opposition [3]. This study aimed to quantitatively examine the effect of the thumb IP joint posture on the CMC joint movement during thumb opposition.

### Methods

Twenty healthy adults conducted a thumb opposition task with two conditions: thumb IP joint extension and flexion. We used the Kapandji test, which opposed the thumb at 11 positions (from 0 to 10 positions) [1,2], as the thumb opposition task.

We recorded the thumb movements during the task using a three-dimensional motion capture system. We computed the

flexion/extension, abduction/adduction, and pronation/supination angles of the CMC joint. Furthermore, we obtained the postural synergy of the thumb using principal component analysis. We compared the CMC joint angles and the postural synergy between the two conditions.

### Results and Discussion

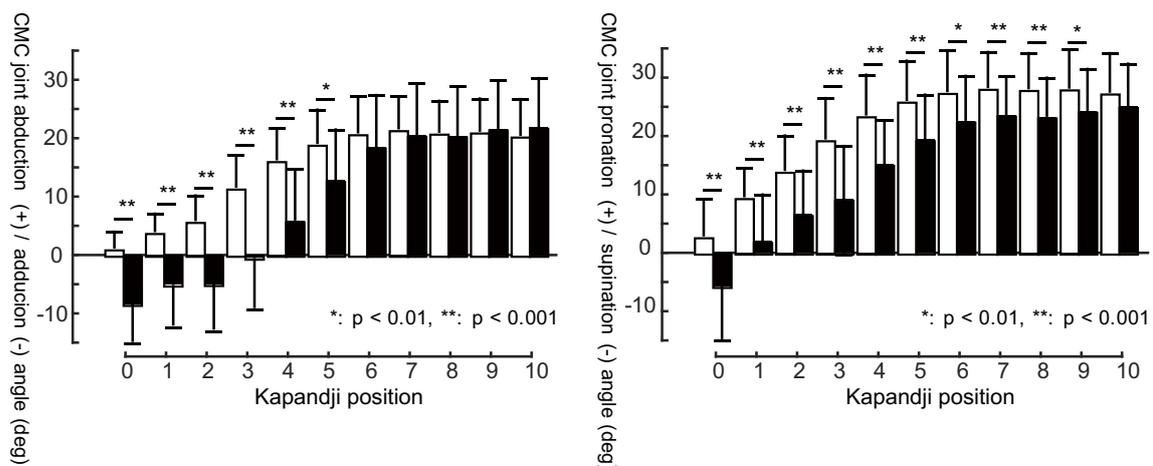

The CMC flexion angle had no differences between the thumb IP conditions at most Kapandji positions. The CMC abduction and pronation angles had significant differences between the thumb IP joint conditions; the CMC joint angles in the thumb IP joint extension were more abducted and more pronated than those in the thumb IP joint flexion (Figure 1). Postural synergy showed that thumb posture in the thumb IP joint extension had become more opposition than that in the thumb IP joint flexion. The adduction moment in the flexor pollicis longus muscle would be associated with these differences in the CMC joint movement. [4].

### Conclusions

The thumb IP joint posture affects the CMC joint movement; thus, thumb opposition should be evaluated with thumb IP joint extension.

## Carpal bone arch changes in response to carpal bone rotation

Andrew S Michalski, Jocelyn Hawk, Zong-Ming Li

Hand Research Laboratory, Departments of Orthopaedic Surgery and Biomedical Engineering

University of Arizona, Tucson, USA

Email: lizongming@arizona.edu

### Summary

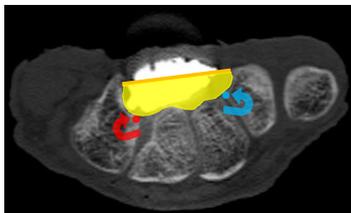

The hamate and trapezium were independently rotated to assess the influence of carpal bone motion on the carpal bone arch morphology. Carpal bone internal rotation decreased the carpal arch width. Hamate internal rotation reduced the cross-sectional area of the bone arch, but changes were small (<1.5%) at 10 degrees of rotation. The area remained invariant (-0.8% to 1.5%) in the 30 degree trapezium rotation range. These data suggest the space at the bone portion was relatively insensitive to carpal bone rotation within 10 degrees from the initial position.

### Introduction

Carpal tunnel syndrome (CTS) is a peripheral nerve entrapment syndrome affecting hand function. CTS symptoms are minimized by reducing the compressive pressure on the median nerve accomplished through carpal tunnel release surgery or compressing the distal wrist to narrow the carpal arch [1]. Carpal arch narrowing has demonstrated improvements to median nerve compression attributable to the increased area of the ligament arch [2]. However, it is unknown how carpal bone rotation associated arch narrowing affects the bone arch space. The purpose of this study was to investigate how internal rotation of the hamate and trapezium would influence the dorsal bone arch of the carpal tunnel. We hypothesized internal rotation of the distal carpal bones would decrease the carpal arch width and decrease the cross-sectional area of the bone arch.

### Methods

The carpal tunnel contents were evacuated from one cadaveric hand, and a medial balloon was inserted and pressurized to 10 mmHg using a solution of water and CT contrast agent. The complete hand was scanned using a clinical CT scanner. An axial slice at the distal tunnel, including the hook of hamate and ridge of trapezium (Figure 1), was identified for analysis.

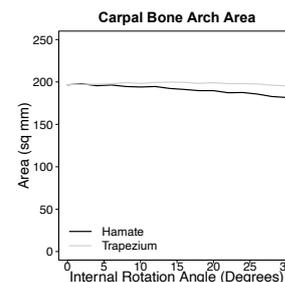

**Figure 1:** Carpal tunnel CT cross-section. Orange line is the carpal arch width. The yellow region is the carpal bone arch area. Hamate (red dot) and trapezium (blue dot) rotation occurs at 2-degree intervals about the point (arrows).

The carpal bones (hamate, capitate, trapezoid and trapezium) were manually segmented. Landmarks were manually identified on the hamate and trapezium surfaces, corresponding to the dorsal transverse carpal ligament insertion points, identified by the intersection of the carpal tunnel balloon and carpal bones. The line between these

landmarks corresponds to the carpal arch width (Figure 1, orange line). The other set of landmarks corresponds to the rotation points on the hamate (Figure 1, red point) and trapezium (Figure 1, blue point), identified by the innermost point on the carpal arch surface of each bone. The hamate or trapezium was independently and iteratively rotated 30 degrees about the rotation point at 2-degree intervals. Carpal bone arch area was defined as the area contained by the carpal bones' inner surfaces and the arch width line. The carpal arch width and area were measured at each rotation.

### Results and Discussion

As the hamate or trapezium was internally rotated by 2-degree intervals, the carpal arch width progressively decreased. The arch width decreased by 4.5 and 3.1 mm at the 30-degree rotation of the hamate and trapezium. As the rotation angle of the hamate bone increased, the carpal bone arch area decreased, but the decrease was small (<1.5% at 10 degrees). As the trapezium was internally rotated, the carpal bone arch area varied within 1.5% (Figure 2).

**Figure 2:** Measured carpal bone arch area with increasing internal rotation of the hamate (black) or trapezium (gray).

Narrowing of the carpal arch width has been shown to increase the ligament arch area [2-4], and this study showed that narrowing the arch by rotating the carpal bones within 10 degrees had a relatively small influence on the bone arch area. Our data suggests that internally rotating the distal carpal bones decreases the carpal arch width and does not affect the bone arch area. Further investigation is needed to understand the implications to the total carpal tunnel area.

### Conclusions

Little change in the carpal bone arch area was observed with rotational perturbation to the carpal bones. These findings suggest that the carpal tunnel space is relatively insensitive to carpal bone motion, and the carpal ligament arch may play a more significant role in increasing the carpal tunnel cross-sectional area and decompressing the median nerve.

# INTER- AND INTRA-PARTICIPANT UNIFORMITY OF MUSCLE ACTIVATION DURING WRIST MOTION

**Oluwalogbon O. Akinnola<sup>1</sup>**, Vasiliki Vardakastani<sup>1</sup>, Angela E. Kedgley<sup>1</sup>  
<sup>1</sup>Department of Bioengineering, Imperial College London, London, UK  
 Email: o.akinnola16@imperial.ac.uk

## Summary

The activity of seven forearm muscles were recorded during wrist flexion-extension, radial-ulnar deviation, and dart thrower's motion. Inter- and intra-participant comparisons showed people perform tasks with a consistent muscle activity pattern unique to them. The presence of co-contraction indicates that stability, not energy efficiency, may be a priority at the wrist.

## Introduction

Electromyography (EMG) has been used to diagnose pathology and validate musculoskeletal models [1, 2]. Muscle activation patterns have been found to be similar for people performing the same task in the lower limb [3]. Standard activation patterns have not been reported for the upper limb, but it has been found that finger contact forces and moments are similar between people performing prehensile tasks [4]. This study seeks to establish if muscle activation patterns for fundamental and functional motions of the wrist are consistent both within and between people.

## Methods

23 participants ( $1.71 \pm 0.08$  m,  $68.26 \pm 12.66$  kg,  $28.6 \pm 4.60$  years) took part in this study. Each participant performed three sets of five cycles of wrist flexion-extension (FE) radial-ulnar deviation (RUD), pronation-supination (PS), and dart throwing motion (DTM) with their dominant hand. The muscle activity of extensor digitorum communis (EDC), extensor carpi radialis (ECR), extensor carpi ulnaris (ECU), flexor digitorum superficialis (FDS), flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), and pronator teres (PT) were recorded using surface EMG sensors (Delsys, Natick, MA). Statistical Parametric Mapping (SPM) non-parametric Multivariate ANOVA (MANOVA) was used to test for differences between the muscle activation patterns. The mean Pearson Correlation Coefficient (PCC) between the participants also calculated.

## Results and Discussion

No difference was found within participants between the muscle activation patterns for each set of cycles. Activation

patterns for different motions performed by the same participant differed ( $p < 0.01$ ). Post-hoc analysis found that activation patterns for all participants differed from all other participants in every motion ( $p < 0.0002$ ). Qualitative comparison showed different levels of co-contraction (Figure 1). Mean PCCs varied between 0.40 – 0.66.

People showed a consistent muscle activation pattern when performing a specific motion repeatedly, but this pattern differed from one individual to another. Moderate correlation across participants for all the muscles was seen. Muscles have specific anatomical functions, so some correlation is expected but it was not strong. This could be different neuromuscular strategies or a consistent strategy applied to different physiology. Co-contraction was consistent in a participant across motions but varied across them. This ranged from co-activation of multiple synergistic agonists to activation of only a select few muscles. Literature showed extended activation increases metabolic cost [5] and proposed that co-activation of the antagonist muscles in the upper limb is adopted to manage unstable interactions with the environment [6]. Thus, wrist stability during motion may be more important than conserving energy to allow for precise manipulation. This has implications for the level of subject-specificity required for the development of musculoskeletal models of the wrist.

## Conclusions

Our data indicate that physiological differences may lead to varying levels of co-contraction to achieve stability. The presence of co-contraction indicates that minimising energy expenditure is not a priority at the wrist.

### Summary

Change of direction (COD) ability predicts sport performance and COD movement strategy is associated with sport injury.[1] Nevertheless, current laboratory-based testing methods lack ecological validity. Inertial measurement units (IMU) may assist practitioners to assess individual on-field COD movement patterns.

### Introduction

A more acute COD cut angle increases tissue stress and strain that are thought to increase injury risk and these movements occur readily in soccer. IMUs provide the possibility of on-field COD analysis. However, there is no consensus on the relevant IMU signal features. Peak resultant acceleration is a commonly used feature in IMU based movement detection in sports.[3] The aim of this study was to analyze the individual within-season variability of accelerometer features in a COD test.

### Methods

U15-U17 soccer players (n=7 females, n=12 males) performed two soccer-specific COD tests separated by two months.

Two bi-directional maximal effort COD maneuvers were performed at 3 cut angles (180°, 135° and 90°) and value from last trial was used. IMU sensors (Shimmer 3 IMU) were placed on both lower limbs and lower back. Trials were video recorded, tagged in Dartfish (Dartfish Live S) and synced with IMU data.

The penultimate foot ground contact (PFC) and final foot ground contact (FFC) were tagged for each limb. Peak resultant acceleration for PFC and FFC, time to peak acceleration, time between PFC and FFC and shock attenuation were extracted and used for analysis.

### Results and Discussion

As a representative example of the variability observed in the outcome measures, intra-subject variability was found to be substantial for FFC peak acceleration (Figure 1). This was supported by poor to moderate intraclass correlation (ICC 3,1) coefficients between tests (ICC = 0.66, range for all

measures = -0.3 to 0.66) regardless of sensor placement. There were no systematic group changes observed that could be explained by the timing of the two tests.

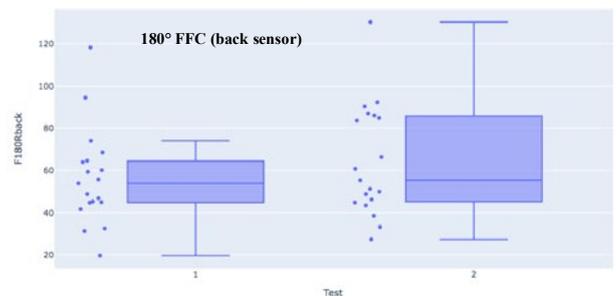

Figure 1: Individual Change in Peak Resultant Acceleration

### Conclusions

As COD movement strategies are associated with sport injury, our data highlights the use of IMU technology to detect individual in-season change in COD patterns so that targeted training interventions can be applied to increase performance or decrease injury risk. A more thorough assessment of the reliability of the IMU signal features over a shorter time frame is needed. This would help practitioners to determine the stability of the measures, the number of tests that should be performed to establish the COD movement pattern, and relevant measures for sport performance and injury risk detection.

### Acknowledgments

## Classification of High Knee Flexion Postures Using Feature and Time-Series Based Distance Approaches

Annemarie F. Laudanski<sup>1</sup>, Arne Küderle<sup>2</sup>, Felix Kluge<sup>2</sup>, Bjoern M. Eskofier<sup>2</sup>, and Stacey M. Acker<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada

<sup>2</sup>Department of Computer Science, Friedrich-Alexander Universität, Erlangen, Germany

Email: annemarie.laudanski@uwaterloo.ca

### Summary

Childcare workers spend a significant portion of their working hours adopting high knee flexion postures, despite their association with increased risk for musculoskeletal injury development. This study compared means of identifying these postures based on the classification of inertial data using both feature and time-series based distances, in order to identify a classifier capable of providing objective data on the demands of this occupation. Results suggest that comparing inertial based ankle, knee, and hip flexion angle estimates using Dynamic Time Warping distances as inputs to a  $k$ -Nearest Neighbor classification algorithm offers a promising means of identifying high flexion postures in childcare settings.

### Introduction

Occupational exposures to high knee flexion postures, such as kneeling or squatting, result in increased risk of joint tissue degradation and osteoarthritis development [1]. Despite this association, frequent pain reporting, and a limited understanding of work-related exposures in childcare, few guidelines and little quantitative data exist to manage the adoption of these postures in workplace settings [2]. The objective of this study was therefore to compare classification approaches for inertial measurement unit (IMU) data in order to determine the most suitable means of identifying high knee flexion postures in occupational childcare settings.

### Methods

Twenty participants completed 3 repetitions of 8 high flexion and 2 upright postures, frequently adopted in childcare, which were grouped into 6 movement categories (Table 1). Each participant was instrumented with 4 IMUs, attached to the base of the sacrum, the lateral aspect of the right upper and lower leg, and the superior aspect of the right mid-foot.

IMU signals were calibrated based on a 10-m walk and two isolated joint motion trials, consisting of rotations about the hip and the knee respectively, and flexion angles for the ankle, knee, and hip were subsequently estimated [3,4]. Two variations of a  $k$ -Nearest Neighbor (kNN) cross-validated classifier were developed and compared in order to determine the most robust approach for the identification of childcare related postures. In the first, time-domain features (maximum, minimum, mean, and standard deviation) for each flexion angle were extracted from consecutive windows of 500 ms, with a 50% overlap. These 12 features were combined with movement labels to create an ( $n \times 13$ ) training dataset containing  $n$  trial windows, which were compared and classified based on Euclidean distances. The second classifier relied on a time-series based approach, where the training dataset was composed of movement labels and the

corresponding flexion angles, scale normalized between -1 and 1, combined tip to tail. Dynamic Time Warping (DTW) based distance metrics for classification were calculated between each of the ( $n \times 344$ ) consecutive 2 s windows. For both training sets, a 5-fold cross validated nearest neighbor classifier ( $k = 1$ ) was developed using 80% of the training data while the remaining 20% was withheld for testing.

### Results and Discussion

Overall accuracies of 41.1% and 79.8% were reached when classifying postures through feature and time-series based kNN approaches respectively. Movement sensitivity and specificity can be found in Table 1. The highest rates of misclassification in the DTW-based approach were observed between unsupported and supported kneeling, suggesting that these postures could potentially be grouped into a single kneeling category if their separate study was not of interest.

**Table 1:** Sensitivity and specificity (%) for childcare postures classified using feature and time-series based kNN approaches.

Classifiers	Sensitivity		Specificity	
	Feature based kNN	DTW based kNN	Feature based kNN	DTW based kNN
Movement Categories				
Unsupported Kneeling (dorsiflexed, plantarflexed)	44.8	78.2	84.31	93.0
Supported Kneeling (single and double hand supported)	38.4	72.7	83.3	91.6
Squatting (flatfoot, heels-up)	42.5	84.9	86.4	96.0
Sitting on a child-sized and adult-sized chair	39.9	81.1	88.7	96.2
Standing still	45.3	83.3	97.6	99.4
Walking	33.8	95.5	95.4	99.3

### Conclusions

While classification results must be validated in continuous data, as would be collected in childcare settings, the DTW-based nearest neighbor classification of time-series data offers promise for the identification of high flexion postures.

## Validation of a wearable sensor OpenSense model for evaluating motor variability in gait

Christopher A. Bailey<sup>1</sup>, Julie Nantel<sup>1</sup>, Ryan B. Graham<sup>1</sup>

<sup>1</sup>School of Human Kinetics, University of Ottawa

Email: cbailey2@uottawa.ca

### Summary

Stride-to-stride variability in gait is a factor associated with falls in older adults. Currently, there is no known inexpensive and opensource method available for evaluating variability of the underlying joint motions outside of the lab and clinic. We propose an inertial measurement unit (IMU) OpenSense model of joint angle variability. Trunk-down joint angles were estimated from optoelectronic and IMU motion capture, and variability was quantified by conventional and dynamical systems metrics. In a preliminary evaluation, IMU modelled variability patterns approximated optoelectronic patterns, with similar mean standard deviation (meanSD), statistical persistence ( $\alpha$ ), and maximum Lyapunov exponents ( $\lambda_{\max}$ ). Preliminary findings suggest that the IMU-OpenSense model measured both the magnitude and dynamics of joint angle variability accurately during treadmill gait.

### Introduction

Motor variability, the existing variability in sensorimotor actions like joint motions, is a control principle of gait linked to fall risk. Measurements include the inter-stride standard deviation to quantify the magnitude of variability [1] and dynamical systems metrics to quantify quality of stride-to-stride control [2]. Current kinematic evaluation methods select a non-portable evaluation of joint motion [1] or a portable but limiting evaluation of variability in segment motion [3]. An approach is still needed for a robust and portable evaluation of stride-to-stride joint control in gait. One potential approach is simulating inverse kinematics from segment-worn IMUs, which can estimate joint angles to  $\sim 3^\circ$  of error [4]. Since many variability measurements are not limited by initial posture estimations by IMUs, there is high potential for accuracy. Thus, the objectives of this study were to test the validity of an IMU-driven model of joint angle variability in gait and the sensitivity of the model to varied gait conditions.

### Methods

Young adults (N = 16, 8 females) will be recruited; data are available for one young male (aged 29 years). Motion data were acquired optoelectronically (Vicon Vantage) and by IMUs (Xsens Dot). Markers were placed according to the Rajagopal full body model [5] and IMU sensors were placed on the trunk, pelvis, thighs, shanks, and feet. The participant completed five 7-minute trials of treadmill gait under varied conditions: preferred speed (1.16 m/s), 70% preferred speed, 130% preferred speed, active arm swing at preferred speed, and arms-held at preferred speed. Optoelectronic and IMU motion data were input into the full body OpenSim model to simulate lower limb joint angles [5], using the OpenSense tool kit for IMU-to-segment calibration and inverse kinematics. Joint angles were partitioned into individual strides and synchronized between methods by the foot velocity profile.

Variability outcomes were the meanSD, scaling exponent  $\alpha$  of range of motion, obtained via detrended fluctuation analysis,

and  $\lambda_{\max}$  of the continuous timeseries for each joint angle degree of freedom. IMU outcome validity (relative to optoelectronic) will be tested by established metrics and methods (e.g. root mean square error, intraclass correlation coefficients, Bland-Altman plots), and sensitivity will be analyzed by Condition\*Method ANOVAs.

### Preliminary Results

IMU variability patterns appeared to approximate optoelectronic patterns across lower limb joints in normal speed gait (e.g. left ankle dorsiflexion/plantarflexion in Figure 1).

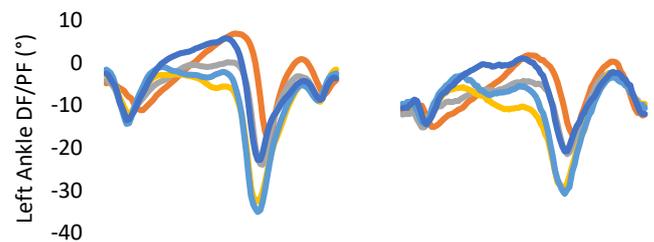

Figure 1. IMU (left) and optoelectronic-modeled (right) dorsiflexion/plantarflexion (DF/PF) in five consecutive, matched strides.

MeanSD,  $\alpha$ , and  $\lambda_{\max}$  of left ankle dorsiflexion/plantarflexion were similar between the IMU and optoelectronic models, which was a consistent observation across joints and degrees of freedom (Table 1). This suggests that the IMU model accurately measured joint variability magnitude, persistence, and local dynamic stability in the young male. Further data acquisition is needed to verify this initial observation and to evaluate whether measurements are sensitive to changes across conditions and to interindividual differences.

Table 1. Left ankle dorsiflexion/plantarflexion variability outcomes.

	meanSD (°)	$\alpha$	$\lambda_{\max}$
IMU	2.17	0.54	1.837
Optoelectronic	2.00	0.87	1.843

### Summary

Increase in the use of accelerometers to analyze gait variables, such as ground contact time, provides the potential for greater insight into real-world environments. However, care must be taken to avoid generalizing laboratory-based results to real-world conditions. This study sought to determine the reliability of ground contact time between an indoor track and outdoor run over the course of 3 days. Results showed that inter-day reliability for each condition was excellent, but intra-day reliability between conditions demonstrated only moderate agreement.

### Introduction

Most studies using accelerometry to analyze “overground” running are performed on controlled surfaces (i.e. indoor tracks), whereas most runners exercise outdoors. Thus, research is warranted on whether data derived from controlled conditions can be reliably translated to less controlled, outdoor environments. Ground contact time (GCT) is a metric frequently used in biomechanical research and has been shown to be a valid predictor of running performance [1]. The aim of this study was to determine whether GCT measured by a back-mounted tri-axial accelerometer is reliable when measured across several days in either a controlled indoor run or an outdoor overground run.

### Methods

Nine recreational runners (4F, 5M; age =  $24.22 \pm 4.12$  yrs) completed 3 testing sessions on 3 separate days within a 21-day period. Each session involved two experimental protocols following a 5-minute warm-up: one 2km indoor run (200m track) and one 2km outdoor run, each at a self-selected speed (indoor =  $3.15 \pm 0.28$ , outdoor =  $3.06 \pm 0.37$  m/s). The order of conditions was randomized each day.

During each session, an inertial measurement unit (IMU) containing a tri-axial accelerometer (Shimmer3®; Shimmer Inc., Ireland: 200 Hz) was securely attached to the low back between L3-L5 vertebrae with orthogonal axis -x, y and z aligned in the mediolateral, vertical and anteroposterior directions.

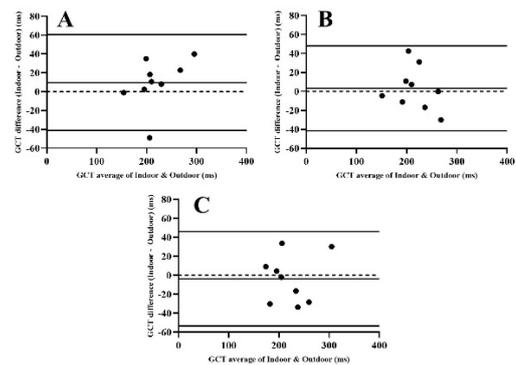

Acceleration data were low pass filtered at 10 Hz and data were analyzed from the first 5-minute epoch of each condition, excluding the initial 30 seconds to account for the acceleration phase. GCT was calculated as the time difference between the initial contact and toe off for each stride and averaged across the 5-min epoch according to methods described by Benson et al. [2].

Between-session reliability for each condition was evaluated by intraclass correlation coefficients (ICC 2,k) calculated. Values of <0.5, 0.5-0.75, 0.75-0.9 and >0.9 were interpreted as poor, moderate, good, and excellent, respectively [3]. Between-condition reliability was evaluated using Bland-Altman limits of agreement (LoA)

for each day, and a two-way repeated measures ANOVA ( $\alpha=0.05$ ) condition [indoor vs outdoor]  $\times$  day [1 vs 2 vs 3].

### Results and Discussion

When GCT was compared across all three sessions, ICCs were 0.908 and 0.951 for the indoor and outdoor conditions, respectively, demonstrating excellent between-day reliability. This result suggests that GCT estimated from tri-axial accelerometers mounted on the low back is reliable over time when conditions are similar. For intra-day, between-condition analysis, there was no significant condition  $\times$  day interaction ( $P=0.528$ ) or significant main effects for condition ( $P=0.526$ ) or day ( $P=0.951$ ). LoA for each day are shown in Figure 1. Although no significant differences were detected between days or conditions via ANOVA, only moderate agreement between conditions (mean bias=5.52 ms; LoA range 44.81-50.87 ms) can be observed. Thus, caution is warranted in presuming agreement for GCT across conditions.

**Figure 1:** Bland-Altman LoA plots of GCT for (A) day 1, (B) day 2, and (C) day 3. Mean bias and 95% limits of agreement are represented by the solid lines.

### Conclusions

GCT derived from a single, back-mounted tri-axial accelerometer demonstrated excellent between-day reliability within surface condition, but only moderate between-condition reliability. These results should be considered in future studies when extrapolating indoor accelerometry data to outdoor overground conditions, as well as by manufacturers of wearable devices that report this metric.

## Summary

Youth athletes wore an IMU on their lower back while completing a neuromuscular training warm-up program with concurrent video recording. The videos were evaluated to determine if athletes completed the prescribed exercise volume. Algorithms were developed to quantify exercise volume from the IMU signal. Excellent algorithm accuracy suggests that IMUs may be used to quantify exercise volume during a neuromuscular training warm-up program.

## Introduction

Sport injuries among youth can have long-term consequences, such as the increased risk of osteoarthritis [1]. Neuromuscular training (NMT) warm-up programs are effective in preventing injuries in youth sports [2]. Ensuring that the athletes are performing the NMT warm-ups as prescribed is critical to achieve the benefits of NMT warm-up programs [3].

Monitoring exercise volume through direct observation or video recording is time consuming and difficult to conduct in a team setting. Inertial measurement units (IMUs) may be effective at measuring the volume of some exercises by leveraging their ability to record impacts and changes in orientation. The purpose of this study was to evaluate the accuracy of using IMUs to measure exercise volume during a NMT warm-up in basketball and soccer.

## Methods

Participants were female and male youth basketball and soccer players performing single leg jumps (front to back), double leg jumps (in place), Nordic hamstring curls, and/or single leg balance exercises as part of a NMT warm-up prior to their typical practice. Video of the exercises was recorded, and participants wore an IMU on their lower backs. A physiotherapist evaluated the videos and determined if each

participant performed the prescribed exercise volume for each exercise. Algorithms were developed for each exercise to count the number of repetitions based on the IMU signal. The repetitions counted using the algorithms were compared to the gold standard from the physiotherapist evaluation in terms of accuracy, precision, and recall.

## Results and Discussion

A total of 91 (39 female, 52 male) youth athletes performed at least one of the four warm-up exercises. There was greater than 0.94 accuracy, precision and recall for all exercises except single leg balance which had accuracy of 0.889, precision of 0.897 and recall of 0.956. The single leg jump algorithm classified all sets correctly (Table 1). The high classification accuracy is consistent with other algorithms that use IMUs to count repetitions during gym exercises [4].

## Conclusions

IMUs may be used to quantify exercise volume for exercises that involve both impact during landing and changes in orientation during rotations. Using IMUs to monitor exercise volume could be used to explore the association between exercise volume during a NMT warm-up and injuries.

# Validation of In-Shoe Force Sensors for Measuring Ground Reaction Forces During Walking

Kaleb Burch<sup>1</sup>, Sagar Doshi<sup>1</sup>, Erik Thostenson<sup>1</sup>, Jill Higginson<sup>1</sup>

<sup>1</sup>University of Delaware, Newark, Delaware, USA

## Summary

Fabric-based nanocomposite pressure sensors [1] placed in shoes were validated for measurement of ground reaction forces (GRF). A detailed calibration and validation approach is presented. The sensors exhibit good agreement with force plate (FP) measurements for six subjects walking at 3 speeds.

## Introduction

Quantification of GRF, particularly maximum vertical GRF, offers clinical value for applications such as detecting overloading during a partial weight-bearing regimen [2]. Consequently, wearable sensors such as pressure-sensitive shoe sensor (SS) systems [3] have been designed with the goal to continuously record GRF during daily life. This study seeks to introduce a simple SS system and validate it against FP measurements for quantification of peak and absolute maximum GRF during walking.

## Methods

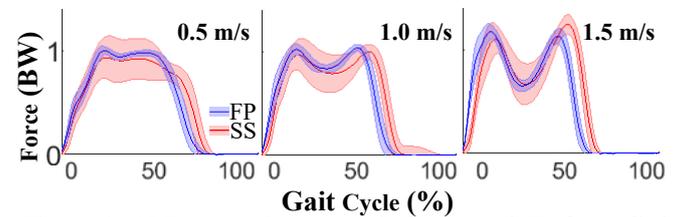

Ten subjects (age:  $23.3 \pm 2.5$  years, mean  $\pm$  std; mass:  $75.2 \pm 18.2$ ; 5 male and 5 female) performed calibration trials and then walking trials on an instrumented treadmill (Bertec Corp, Worthington, OH, USA). FPs recorded GRF (2000 Hz) and an Arduino Uno Rev3 (mean frequency of 28Hz) recorded resistance from sensors on the hindfoot and forefoot. Calibration trials involved 3 repetitions of shifting one's body weight (BW) onto and off of individual sensors. Six total 30-second walking trials were conducted with 2 repetitions each of 3 speeds (0.5 m/s; 1.0 m/s; 1.5 m/s); order was randomized.

The loading phase of the calibration trials was used to calibrate sensor resistance to force. Walking trials were evaluated using cross validation, where all 8 subsets of data that include 1 trial each at all 3 speeds were considered. Within each subset, the following process was carried out. The two FP peak forces from 12 gait cycles (GCs) per trial were extracted, as well as both SS forces at those times. SS forces were scaled to approximate FP force using the least-squares method. Then, 12 steps from each of the 3 trials not used for calibration were used to compare SS with FP using the Bland-Altman method. This analysis was performed on 2 sets of data: (1) both GRF peaks (2PK) in each GC and (2) the maximum GRF (MAX) in each GC. Results were evaluated

in terms of mean of difference (MoD) and reproducibility coefficient (RPC).

## Results and Discussion

GRF of the SS system closely matched the FP in shape and magnitude (Figure 1). The Bland-Altman results showed varying levels of agreement across subjects (Table 1). Results varied depending on whether 2PK or MAX was considered. Under the 2PK assessment, the MoD was less than 2% for all but one subject. Likewise, RPC was less than 24% for all but one subject. Under the MAX assessment, the MoD was less than 4% for all subjects. RPCs ranged from 8.5 – 33.8%; most subjects were around 10%. This is comparable to another SS study [3] that obtained an estimated RPC of 10.4%.

**Figure 1.** GRF curves (mean  $\pm$  std) for SS and FP from all 6 subjects over all GC at each speed. Results from a representative subset of data, identified by proximity to mean RPC, are used.

We expect that these sensors could be useful for providing feedback on overloading for patients prescribed with a partial weight-bearing regimen [2].

## Conclusions

This sensor system offers reasonable maximum force measurements for walking at 3 different speeds.

### Summary

Inertial measurement units (IMUs) are promising to evaluate quality of movement during activities of daily living (ADL) of subjects with Parkinson's Disease (PD). Here we introduced a classifier to identify ADL. In total 179555 observations were analyzed. Classifier reached an accuracy higher than 99%. Therefore, the classifier has potential to support monitoring of PD subjects using IMUs.

### Introduction

Inertial measurement units (IMUs) are promising to evaluate quality of movement during activities of daily living (ADL) performed by people with movement disorders, particularly people with Parkinson's Disease (PD), due to their accuracy, ubiquitousness, unobtrusiveness, and low cost [1][2][3]. IMUs applications comprise detection and monitoring of motor fluctuations. However, most studies reported in literature have limitations related monitoring during free living conditions where ADL are performed. Therefore, we introduced a classifier to identify ADL performed by subjects with PD which could be helpful to support monitoring using IMUs.

### Methods

To build the classifier and to test its ability to detect ADL, it was necessary to register movement data of six common ADL performed on one session during on medication state of PD subjects. Four IMUs shimmer3 (Shimmer Research Ltd, Dublin, Ireland) were used to collect data at a sampling frequency of 50Hz. IMUs were located on foot, thigh, pelvis, and wrist. Free-living environment conditions were simulated at the Hospital. Five PD subjects participated in the study (mean age: 63.5±2.6 years, mean Hoehn-Yahr score: 2). Movement data of six common ADL tasks were recorded in random order. IMU data were filtered using a lowpass 2nd order Butterworth filter with a cutoff frequency of 5 Hz. IMU data was smoothed using a moving average filter with a window size of 6.4 s. Institutional research and ethics committees approved the measuring protocol. All subjects and parents gave their informed consent. WKNN classifier was calculated using 13 predictors based on accelerometer, magnetometer, and gyroscope data on each single axis (X, Y,

Z) and 3D resultant. WKNN classifier training and evaluation was done in MATLAB R2019a (Natick, MA, USA) leaving out 50% of data.

### Results and Discussion

In total 179555 observations were analyzed. WKNN classifier was validated using leaving out 50% of data. WKNN classifier reached an accuracy, precision, sensitivity, and specificity higher than 99%, a false negative rate and a false discovery rate <1%, and an area under the curve higher than 0.99, see Table 1.

**Table 1:** Confusion Matrix

		Predicted Class					
		1	2	3	4	5	6
True Class	1	14021	8	10	3	12	0
	2	13	11761	7	4	1	2
	3	9	2	7279	12	4	1
	4	4	4	4	12767	12	6
	5	2	0	8	4	33922	6
	6	1	0	2	4	4	9978

### Conclusions

The introduced a classifier has potential to identify ADL performed by subjects with PD which could be helpful to support monitoring using IMUs.

## Use of an inertial sensor for anaerobic resistance tests

Andrés Cervantes V.<sup>1,2</sup>, Julieta del C. Díaz de la G.<sup>2</sup>, Domingo Rangel M.<sup>1</sup>

<sup>1</sup>Centro de Física Aplicada y Tecnología Avanzada, Universidad Nacional Autónoma de México, Querétaro, México

<sup>2</sup>Licenciatura en Fisioterapia, Facultad de Medicina, Universidad Nacional Autónoma de México, Ciudad de México, México

### Summary

This study shows the development of an anaerobic power test, using its own inertial device for its implementation. The test consisted of carrying out one minute of continuous countermovement type jumps (CMJ), following the vertical jumps specifications of Bosco's protocol. The results obtained in the evaluation were able to correspond with the variables sought by the continuous jump resistance tests [1], taking into account that the presented system has a considerably lower cost when compared to laboratory instruments commonly used for this type of tests. The acceleration data of the developed system were previously validated, using as a reference the MetaMotion R sensor, from the company MbiEntLab, obtaining a significant correlation ( $r = 0.9389$ ;  $p < 0.0001$ ). This study presents us with an alternative for the application of this test, where it is possible to obtain the fatigue indices sought by the original protocol, using a lower cost equipment.

### Introduction

The importance of biomechanics in sports analysis lies in the comparison of quantitative movement data [2]. In the search to achieve quantitative measurement of body mechanics in its most natural way without significantly interfering with movement, biomechanics has worked to describe certain sports gestures based on information from inertial sensors, this implies not having the spatial trajectory in coordinates, but only with the linear acceleration and/or the angular velocity of a body segment, and thus have the facilities that an inertial system provides in the measurement process [3].

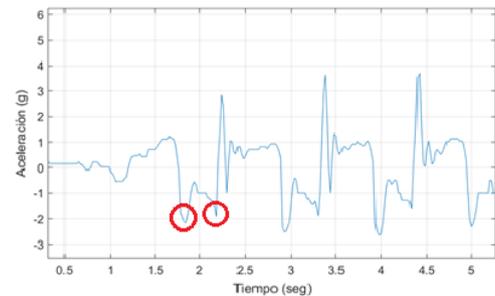

The continuous jump test for one minute is an anaerobic endurance test, which uses Bosco's protocol of vertical jumps and measures mainly anaerobic power levels through increased contact times, and resistance to fatigue to through the decrease in flight times over the minute [1].

### Methods

The presented system was placed on the subject's lower back, at the level of the sacrum. Starting in an upright position on both feet with hands on hips, the subject received the start and end signal of the test, performing countermovement jumps (CMJ) at maximum effort from start to finish, carrying out the full movement indicated by Bosco's protocol of the CMJ jump, with hands on hips at all times, and knees straight in the air. The system worked with the preset parameters, which are 50Hz sample rate and +/- 16g range on all three accelerometer axes.

### Results and Discussion

Using the data series obtained in the test, a data handling was carried out using the magnitude of the acceleration, oriented with the signs measured by the vertical axis of the system. Finally, the jump takeoff and landing points were identified (Figure 1), using the corresponding acceleration peaks. In this way, by measuring the time intervals between the peaks, it was possible to obtain the flight time, contact and total times of the test, from which the fatigue resistance parameters are determined.

**Figure 1:** Acceleration vs. time data graph of the continuous jump test, with the identification of peaks signaled, corresponding to takeoff and landing of the jump.

Using the flight time values, the percentages of decrease of this were obtained, in intervals of 10 seconds (Table 1), with respect to the maximum value.

Time intervals	10 (s)	20 (s)	30 (s)	40 (s)	50 (s)	60 (s)
ToF decrease parameter	0.94	0.9	0.87	0.79	0.63	0.42

**Table 1:** Table of parameters for the reduction of flight time during the test, corresponding to the fatigue resistance indices.

In the same way, it was possible to obtain the contact times, total jump time and acceleration peaks for take-off and landing for each of the jumps.

### Conclusions

This application method allows us to obtain functional results, comparable with those of the original protocol [1], using tools that allow the test to be applied in any condition and which are inexpensive.

## Comparisons Between Researcher-Placed and Subject-Placed Wearable Sensors

Matthew C. Ruder<sup>1</sup>, Michael Hunt<sup>2</sup>, Dylan Kobsar<sup>1</sup>

<sup>1</sup>Department of Kinesiology, McMaster University, ON, Canada; <sup>2</sup>Department of Physical Therapy, University of British Columbia, BC, Canada

Email: matthew.ruder@gmail.com

### Summary

Wearable sensors allow research to move out of the lab and collect data in the real world. One potential application for these sensors could be to monitor disease progression of knee osteoarthritis. The subject-placement of sensors may become useful in such applications, but this may influence the reliability of these data. Therefore, this study assessed the reliability of outcome measures from researcher-placed sensors and subject-placed sensors within and between sessions. The results suggest that the subject-placed sensors have comparable reliability to researcher-placed sensors for most metrics. Future research should evaluate if reliability could be further improved with new post-processing methods.

### Introduction

Knee osteoarthritis affects more than 5 million Canadians and over 32 million Americans, making it one of the most common musculoskeletal diseases. Knee joint loading has been used to assess disease state and progression, along with the presence of a varus thrust (i.e., abrupt lateral knee motion or peak frontal plane angular velocity during stance) [1,2]. Wearable sensors offer the ability to collect similar data in more ecologically valid, real-world settings and over longer periods of time. While this may further support the monitoring of disease states and progression, it may often require the self-placement of sensors. Additionally, given the ongoing shift to remote data collections with COVID-19, there is a need to better understand the effect of subject sensor placement on the reliability of wearable sensor metrics.

Therefore, the purpose of this study was to assess the reliability of wearable sensor metrics between a researcher-placed sensor and a subject-placed sensor within and between two in-lab data collections. It was hypothesized that vertical (V) and resultant (R) acceleration impact peaks would display excellent reliability with researcher-placed and subject-placed sensors for both within- and between-session reliability. However, we expected to observe reduced between-session reliability for other axis-specific metrics such as anteroposterior (AP) and mediolateral (ML) accelerations impact peaks, as well as frontal plane angular velocity peaks, especially in subject-placed sensor conditions.

### Methods

Nine healthy, pain-free young adults were recruited for this study. Each participant attended two data collection sessions with 5-7 days between collections. During each session, the participant was instructed to place a 9-axis IMU (Shimmer 3, 100Hz, Shimmer Sensing, Dublin, IE) on their left shank at the medial inferior tibial tuberosity. Following participant placement of the sensor, an experienced researcher carefully placed another sensor at the same location on the right shank. Participants were then instructed to complete ten 8m over-ground walking trials. Participants walked at their preferred gait speed and all trials were within  $\pm 10\%$  of this speed.

The variables of interest were V, ML, AP, and R acceleration impact peaks and frontal plane angular velocity peaks during stance. Within-session reliability was assessed by comparing the average from all steps in the first 5 trials to those in the last 5 trials within session 1. Between-session reliability was assessed by comparing the average from all steps in the first 5 trials in session 1 to the first 5 trials in session 2. An ICC (2,k) was used to assess reliability, with <0.5, 0.50-0.75, 0.75-0.90, and 0.90+ defined as poor, fair, good, and excellent reliability.

### Results and Discussion

V and R acceleration impact peaks displayed good to excellent reliability (ICC: 0.87-0.96) in all cases. Similarly, all other researcher-placed sensor metrics displayed excellent reliability (ICC: 0.91-0.94). For subject-placed sensors, only ML impact peaks displayed excellent between-session reliability (ICC=0.96), while AP impact peaks and frontal plane angular velocity peaks were fair (ICC: 0.68-0.74), possibly due to a misalignment between axes. See Table 1.

### Conclusions

The between-session reliability for subject-placed sensors appears to be comparable to that of an experienced researcher for measuring V and R impact peaks, as well as ML impact peaks. However, lower levels of reliability may be present in other metrics, such as angular velocity used as an estimate of varus thrust. Future research is needed to evaluate if the reliability of subject-placed wearable sensors can be improved through an automated post-processing alignment correction.

## Examining the association of backward walking velocity with forward balance control in healthy adults

Kirat Shukla<sup>1</sup>, Joel Lanovaz<sup>1</sup>, Jonathan Farthing<sup>1</sup>, Gary Linassi<sup>2</sup>, Alison Oates<sup>1</sup>

<sup>1</sup>College of Kinesiology, University of Saskatchewan, Saskatoon, Canada

<sup>2</sup>College of Medicine, Department of Physical Medicine and Rehabilitation, University of Saskatchewan, Saskatoon, Canada

Email: kirat.shukla@usask.ca

### Summary

The association between backward walking velocity and balance control measures in forward walking was examined in healthy adults. The results demonstrated that specific measures of balance control in forward walking were significantly correlated with backward walking velocity.

### Introduction

Gait velocity during forward walking is one of the most frequently reported outcomes and has been used to assess balance control and predict the risk of falls, recurrence of falls, and cognitive decline with increasing age [1,2]. Backward walking velocity, while not a common measure, has been shown equal to or better in identifying individuals with a history of falls compared to commonly used measures such as the timed up and go test [3]. In addition to using backward walking as a rehabilitation exercise [4], studies report it as a clinically useful test of balance to discriminate fallers from non-fallers [3,5], individuals with Parkinson's disease from healthy controls [6], and to highlight gait dysfunction in children with cerebral palsy [7]. The purpose of this study was to explore the relationship between backward walking velocity and balance control during normal forward walking and a challenging task of forward tandem walking. The primary hypothesis was that backward walking velocity would positively correlate with the magnitude of forward balance control measures and negatively correlate with variability of those same measures.

### Methods

Thirty-five healthy adults (28.4±8.8 years) performed five trials each for forward, backward, and tandem walking along a 10-m walkway in a lab environment. Trials were completed in random order at the participants' preferred speed. Kinematic data were collected using a motion capture system (fs = 100 Hz, Vicon Motion Systems, Denver, CO) and low pass filtered at 8 Hz using a 4<sup>th</sup> order Butterworth filter. Processing and calculation of outcome variables were completed offline using custom-written scripts (MATLAB R2019b; MathWorks, Natick, MA). Balance control during forward and tandem walking was characterized using margins of stability (MOS) in the anteroposterior (AP) and mediolateral (ML) directions (average and variability) over a stride and variability of step length and step width during normal forward walking. Variability of MOS and stepping measures were calculated as the standard deviation (SD) of the mean. An increase in the MOS magnitude and a reduction in the variability of the MOS and stepping measures were interpreted as increased balance control. Data were examined

for normality using the Shapiro-Wilk test. Balance control measures were correlated with backward walking velocity using Pearson's  $r$  for normally distributed data and Spearman's  $\rho$  for non-normal data ( $\alpha=0.05$ ).

### Results and Discussion

Backward walking velocity was positively correlated with the magnitude of the MOS in the AP direction during normal walking ( $r = .710, p < .001$ ) and negatively correlated with the variability of the MOS in the AP direction during tandem walking ( $\rho = -.451, p < .05$ ). The results suggest individuals with a higher backward walking velocity are more stable in the sagittal plane during forward and tandem walking. This relationship warrants further investigation into individuals with a higher risk of falls. The significant correlations from this study are in line with previously published results in which backward velocity was significantly correlated with performance on clinical tests of balance [8]. The lack of relationships between backward walking velocity and forward balance control in the ML direction ( $p > .05$ ) and the variability of stepping measures ( $p > .05$ ) may be due to the nature of the population (healthy) and should be examined further since balance control in the ML direction has shown to be a predictor of falls [9].

### Conclusions

The primary purpose of this study was to examine the relationship between backward walking velocity and balance control in healthy adults. Participants with faster backward walking velocity had better AP dynamic balance control in forward and tandem walking. These results provide further evidence for the utility of backward walking as a clinical test of balance. Backward walking could be useful as a dynamic balance control measure for researchers and clinicians.

### Acknowledgments

Funding was provided by the College of Graduate and Postdoctoral Studies and College of Kinesiology (University of Saskatchewan).

We would like to thank all the participants who volunteered for the study.

## Summary

Femoroacetabular impingement (FAI) is increasing in diagnosis amongst athletic populations and is a highly estimated cause of hip pain of the general population. Increased GRFs as well as altered ROM have been associated with impingement morphologies. These are seen through alteration of landing mechanics and heights. Healthy subjects completed unilateral drop tests from 30 and 50-cm heights. Female participants demonstrated increased peak GRF (pGRF), peak hip joint force (pHJF), hip ROM in the frontal and sagittal plane compared to males, suggesting gender-based risk factors. Height also increased pGRF, pHJF, and ROM, similarly to gender-based differences.

## Introduction

FAI diagnoses have been rapidly increasing amongst adolescents and adults. With an estimated 22-55% of all hip pain caused by these impingement pathomorphologies, incidence rates are as high as 10-15% of the general population. Traditionally associated with aging populations, strong links have emerged with athletic participation [1,2]. Increased risks of injury potential have been associated with modified landing mechanics such as single leg and cutting tasks, as well as increased landing height [3]. As height increases, BW normalized GRF increases, with more energy absorption necessary from the lower body [4]. With unilateral and cutting task landings, the largest kinematic differences are related to frontal plane motion at the hip and knee [5].

## Methods

Eighty-three recreationally active subjects ages 18-35 participated in the study. Inclusion criteria included at least 30 minutes of exercise and one jumping related exercise performed per week, with no history of lower extremity surgery, no injury in the past 6 months, and no condition that impaired the ability to jump or land. 3D marker coordinate data (200 Hz, Vicon, Centennial, CO, USA) and kinetic data (2000 Hz, Bertec, Columbus, OH, USA) were collected using single retro-reflective markers placed on the skin over anatomical landmarks as well as rigid four-marker cluster plates, serving as tracking markers.

A successful trial consisted of the participant dropping off a 30-cm and 50-cm box without the contralateral limb contacting the ground, landing with their entire intended foot on the force plate without hopping or jumping, and maintaining arms crossed high across the chest.

Visual3D as well as OpenSim were used for creating subject specific models and calculating discrete and continuous kinematic and kinetic variables. A 2x2 analysis of variance was performed in SPSS for each discrete variable while

continuous variables were compared using ensemble curve analyses.

## Results and Discussion

	Males	Females	30-cm	50-cm
<b>Peak Force (BW)</b>				
pGRF #*	3.47 ± 0.49	3.66 ± 0.52	3.28 ± 0.43	3.85 ± 0.43
pHJF #*	9.26 ± 2.34	10.18 ± 1.98	8.79 ± 1.91	10.65 ± 2.11
<b>Loading Rate (BW/s)</b>				
pGRF #*	58.97 ± 12.76	62.59 ± 13.23	53.87 ± 10.45	67.69 ± 11.76
<b>ROM<sub>i</sub></b>				
Hip Flexion #*	6.94 ± 3.18	8.48 ± 3.89	7.08 ± 3.35	8.34 ± 3.80
Hip Adduction #*	4.70 ± 2.44	6.45 ± 2.96	4.08 ± 2.00	7.08 ± 2.78
Hip Rotation *	6.41 ± 3.35	5.72 ± 2.84	5.40 ± 2.88	6.73 ± 3.21
Ankle Dorsiflexion #*	32.39 ± 9.26	32.93 ± 8.49	31.91 ± 9.05	33.41 ± 8.66
<b>ROM<sub>L</sub></b>				
Hip Flexion *	17.31 ± 8.76	19.23 ± 10.24	15.53 ± 8.12	21.01 ± 10.11
Hip Adduction #*	13.04 ± 5.65	18.86 ± 8.15	11.46 ± 5.00	20.80 ± 6.65
Hip Rotation #*	10.87 ± 5.47	8.86 ± 3.54	8.75 ± 3.79	10.97 ± 5.26
Ankle Dorsiflexion *	44.32 ± 1.60	45.20 ± 7.94	43.23 ± 9.18	46.30 ± 9.32
# Significant main effect for sex (p<0.05)				
* Significant main effect for landing height (p<0.05)				

**Table 1:** Group means and STD for discrete variables.

Significant differences between continuous forces and landing heights were identified for GRF between 1-29%, and HJF between 14-25% and 77-100% of the landing phase. Significant main effects for sex and height were identified for pGRF, pHJF, GRF loading rate, ROM initial contact (ROM<sub>i</sub>), hip flexion and adduction, ROM<sub>i</sub> ankle dorsiflexion, and ROM landing (ROM<sub>L</sub>) hip adduction and rotation. Females landed with +0.19 BW pGRF, +0.92 BW pHJF, and +3.62 BW pGRF loading rate compared to males. Landings from 50-cm incurred +0.57 BW pGRF and +1.86 BW pHJF, with loading rates +13.82 BW/s pGRF and +28.46 BW/s pHJF compared to 30-cm landings. All ROM<sub>i</sub> angles except ankle dorsiflexion were greater for 50-cm than 30-cm landings as well as all ROM<sub>L</sub> angles. These results might suggest that modified landing mechanics can place added stress associated with FAI development in athletic populations.

## Conclusions

In conclusion, females demonstrated increased pGRF and pHJF, increased hip ROM flexion and adduction compared to their male counterparts. Increases in landing heights yielded similar increases in pGRF and pHJF.

### Summary

The purpose of this systematic review was to identify the most commonly used tasks when determining unrestricted return – to-activity (RTA) following an anterior cruciate ligament reconstruction (ACLR) in paediatric patients. The literature was reviewed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines (PRISMA). A total of 25 articles met all criteria for review; of which, strength (14/25 studies) and hopping (9/25 studies) tests were the most commonly used RTA tasks. Current RTA criteria have focused on easily collected metrics such strength and hopping distance, despite limited evidence supporting their use in a paediatric population.

### Introduction

Anterior cruciate ligament (ACL) rupture is a debilitating knee injury associated with sequela such as joint degeneration [1]. Unfortunately, following an ACL reconstruction (ACLR), rates of either ACL graft failure or contralateral ACL rupture ranges from 17-30% in paediatric patients [2]. A contributing factor to the high re-injury rate in this population may be the lack of consensus regarding the appropriate criteria for allowing RTA post-operatively. By reviewing the literature, future interventions can build more effective RTA assessments through the validation of current RTA criteria and the implementation of new criteria according to identified literature gaps. Thus, the purpose of this systematic review was to determine the most commonly used criteria when assessing RTA readiness post-ACLR in paediatric patients.

### Methods

Following PRISMA guidelines, a systematic search was performed of Medline/PubMed, Cochrane, Embase, CINAHL, and SPORTDiscus electronic databases. Studies were included if they specified the criteria used to determine RTA following an ACL reconstruction and included paediatric patients ( $\leq 18$  years old). The quality of each study was assessed using the validated Methodological Index for Non-Randomized Studies. The primary outcome of interest was the RTA task(s) used by each study when determining clearance to full activities.

### Results and Discussion

A total of 25 articles met all criteria for review. Strength (14/25 studies) and hopping (9/25 studies) tests were the most commonly used tasks when deriving RTA criteria (Table 1). A limb symmetry index of  $>90\%$  was the most common

threshold for determining RTA. In addition, only 2/25 studies used an objective assessment of movement quality before RTA.

**Table 1:** Frequency of tasks reported in the literature when accessing RTA in adolescents

Task	No. of Studies
Isokinetic Strength	9
Anterior Hop	7
Triple Hop	6
Cross Hop	4
Timed-Hop	2
Isometric Strength	2
Single Heel Raise	2
Single Leg Dip	2
Tuck Jump	2
Shuffle T-Test	2
Sprint/Cutting T-Test	2
Vertical Jump	1
T-Balance Test	1
Shuttle Run	1
Sprint and Back Paddle	1
Sprint Stop and Go	1
Cutting 90°	1
Side Shuffle 90°	1

### Conclusions

Despite the high rate of ACL re-injuries in paediatric and adolescent patients, there is substantial variability in the use and reporting of paediatric RTA criteria following an ACLR. With limited available evidence to support paediatric RTA decision making, it is not surprising there is no consensus on the appropriate criteria for determining RTA. Current criteria have focused on easily collected metrics such strength and hopping tests, despite evidence suggesting they are ineffective at reducing the risk for re-injury [3]. Although infrequently used in the current literature, clinicians may benefit from the inclusion of patient reported outcome measures and lower-limb kinematics in their RTA assessments.

### Summary

Rotator cuff repairs (RCRs) are common orthopedic procedures which require the application of suture anchors [1]. The humeral head, where the suture anchors are inserted, is of low density particularly when osteoporosis is present, resulting in failure of the suture anchor due to low pullout strength [2]. This study aims to improve fixation of suture anchor in RCR by utilizing a swelling co-polymeric material [3] integrated into a unique suture anchor design. By controlling the swelling characteristics of the material, the swelling suture anchor (SSA) provides better fixation and promotes osteointegration for improved long-term anchor fixation.

### Introduction

With a swelling anchor, swelling strain can be utilized for effective anchor fixation as opposed to the tradition shear strain of screws which is low in low density bone. By allowing the material to swell after implantation the SSA can affix itself within low density bone without damaging it. Additionally, the SSA has a refixation capability as compared to a traditional suture anchor [3].

The purpose of this study is to develop and evaluate a SSA optimized for osteointegration and fixation into low density bone. The swelling and mechanical properties of the material, such as strength and porosity, were characterized.

### Methods

Cylindrical samples of the swelling material with varying diameters of 4, 5, and 8 mm were created. The swelling characteristics were evaluated by placing the samples in saline solution and allowing them to swell for 33 days. During this time the weight and volume increase was periodically measured. Then the samples were removed from the saline solution and mechanically tested. Mechanical testing consists of compression under cyclic load followed by testing to failure.

### Results and Discussion

Within the initial 24 hours the material nearly reached its peak swelling capability as seen in Fig. 1. After the 33-day swelling period the average percent change in diameter of the samples was 6.24% and the average percent change in weight was 9.99%. The swelling material has a dry compressive strength of 120 MPa and a wet compressive strength of 47 MPa. The dry modulus of the material is 1.7 GPA and the wet modulus is 0.9 GPA. As a reference, the average compressive strength of cancellous bone is 10-20 MPa and the modulus is 0.2-0.5 GPA. As can be seen from these results (Fig. 2), the swelling co-polymer losses a significant amount of its mechanical

properties while become more ductile. In the swelling state the mechanical properties match well those of cancellous bone thus minimizes stress shielding as oppose to a metal anchor.

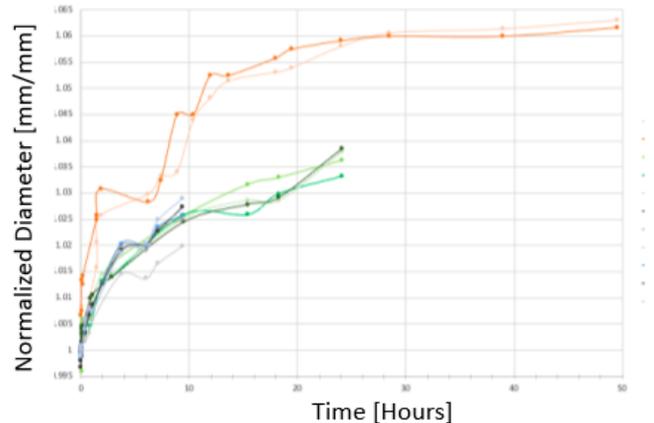

Figure 1: Swelling characterization of the material

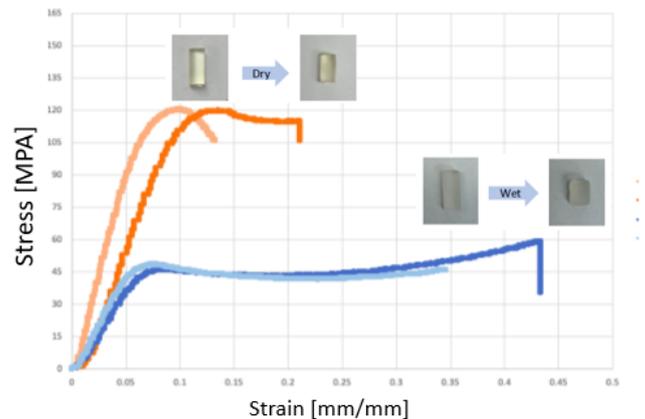

Figure 2: Mechanical characterization of swelling material

### Conclusions

The unique properties of the swelling co-polymer makes it a good candidate for implementation in suture anchors that improve fixation to cancellous bone and promote osteointegration.

## Increased postural threat alters control of dynamic stability in response to external perturbations that induce a step

Noah J. Rosenblatt<sup>1</sup>, Shirali Shah<sup>1</sup>, Marco Avolos<sup>1</sup>

<sup>1</sup>Center for Lower Extremity Ambulatory Research, Rosalind Franklin University of Medicine and Science, North Chicago, USA

Email: [noah.rosenblatt@rosalindfranklin.edu](mailto:noah.rosenblatt@rosalindfranklin.edu)

### Summary

The mechanisms by which fear of falling increases fall risk are poorly understood. While increased anxiety in response to postural threat affects postural control during standing and following non-stepping perturbations, the effect on stepping responses remains unknown. We compared dynamic stability when healthy young adults utilized a step to regain stability in response to an external perturbation applied while standing overground (OG) versus a raised platform. Regardless of stepping direction, participants initiated a step significantly earlier and under significantly less instability while on the platform. Participants also took significantly shorter recovery steps on the platform. Under conditions of increased postural threat, healthy young subjects adopt a cautious strategy in which they are less willing to allow instability, triggering steps prior to conditions that would otherwise do so.

### Introduction

FoF affects ~35% of adults >60 years of age and increases fall risk. FoF can lead to avoidance of activities and in turn deconditioning, which can precipitate falls. Older adults with FoF may also perceive everyday environmental challenges, e.g., small obstacles, as more threatening than would a non-fearful older adult, which may incite excessive anxiety and impact postural posture and balance [1]. One way to isolate the extent to which psychological versus physiological changes may negatively impact posture and balance, and in turn fall risk, in older adults with FoF is to have young adults perform tasks under conditions of increased postural threat. i.e., standing on a raised surface. When standing at a height, young adults impart greater volitional control over posture [2]. In general, increased threat alters neuromuscular control of standing postural [3]. While altered postural control may increase the likelihood of balance loss, falls ultimately occur due to an inappropriate recovery response, most often in the form of a step to extend the base of support. The purpose of this study was to evaluate the effects of postural threat on the compensatory stepping response in healthy young adults.

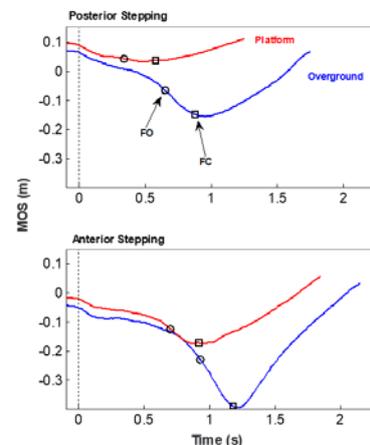

### Methods

Ten healthy young adults participated. Passive reflective markers were placed on bony landmarks and postural perturbations were applied in the anterior and posterior directions using a waist mounted spring scale while participants stood OG and on 1m raised platform (PF). The spring was pulled to a set load while the participant resisted. At random intervals the load was released, and the participant was instructed to avoid stepping. If successful, the load was increased; otherwise, the load was repeated. Loading ceased after steps were taken on two consecutive trials at a given load, which defined the stepping threshold. For the two trials at the stepping threshold, we extracted the following from motion capture data and averaged across trials: i) time to recovery

foot off (FO); ii) margin of stability (MOS) at recovery foot off relative to the mean MOS for the 100ms prior to load release ( $MOS_{FO}$ ); iii) MOS at recovery foot contact ( $MOS_{FC}$ ) taken relative to the stepping limb; iv) recovery step length and time. Two-way repeated ANOVAs (factors of stepping direction and surface - OG vs PF) and correlations were used to assess effects and relationships among variables.

### Results and Discussion

Posterior, but not anterior stepping thresholds were significantly lower PF vs OG. However, the between surface loading differences were unassociated with any other between-surface changes. Regardless of stepping direction, participants reacted more quickly during PF; time to FO was significantly reduced and  $MOS_{FO}$  was significantly greater (Figure 1), with a strong association between the two ( $r=-0.825$ ;  $p<0.001$ ). Posterior steps during PF were taken before instability ensued ( $MOS_{FO}=4.1\pm 3.8$  cm). Participants took significantly shorter recovery steps during PF, but step time was unaffected. Increased stability during the recovery step for PF resulted from an extrapolated center of mass that remained closer to the border of the stance foot, contributing to a significantly greater  $MOS_{FC}$  despite the shorter step.

**Fig 1:** Weighted group average MOS curves for non-stepping limb

Under increased postural threat, healthy young adults adopt a cautious strategy. While this could be protective against falls in older adults with FoF, it may also have unintended negative consequences, e.g., reduced processing time, altered attentional demands. Additional work is needed.

### Conclusions

The control of dynamic stability following a postural perturbation eliciting a step is affected perceived postural threat.

### Summary

Degenerative Disc Disease is a musculoskeletal disorder often surgically operated using fusion implants and associated with high failure rates. The aim of this study was 1) to compare the sacropelvic parameters, usually measured preoperatively in 2D, and their 3D measurement from pelvis and sacrum bone reconstruction; 2) understand the correlation between the bone shape and the sacropelvic parameters. Calculated 3D angles were not statistically different to the 2D measured angles. The distances calculated from a 3D perspective were statistically different to the ones measured in 2D. Sacrum shape has a moderate correlation with pelvic incidence.

### Introduction

Degenerative Disc Disease is a major musculoskeletal disorder often surgically operated using fusion implant devices. The International Spine Study Group has reported that the success of the surgery relies on the optimal values of sacropelvic parameters [1]. Quantitative measurements of the sacropelvic parameters are usually performed on 2D sagittal/frontal X-rays pre surgery. The information obtained from the projection of 2D angles are supposedly limited compared to the parameters calculated in 3D. Therefore, the aim of this study were to 1) compare sacropelvic parameters measured in 2D and 3D and 2) understand the correlation between sacropelvic parameters and bone shape.

### Methods

De-identified CT scans (Siemens, Munich, Germany) from 79 healthy adult participants were collected (43 F, 45 ±6 y.o.) with sacrum and pelvis segmented using Mimics (Materialise, Belgium). An orthopaedic surgeon measured 2D sacropelvic parameters: anterior pelvic angle (AP), pelvic incidence (PI), sacral table angle (STA), projection angle (PA), femorosacropelvic angle (FSPA), pelvisacral angle (PSA), crest pubic distance (CPD), crest sacrum distance (CSD), inlet (ID) and outlet distances (OD) on the sagittal and frontal slices of the CT scan images. Each bone surface were fitted to template meshes and assigned the ISB coordinate system [2]. A Python code was used to find each pelvic and sacrum landmarks needed to calculate the 3D aforementioned sacropelvic parameters automatically from the fitted meshes. The comparison between 2D and 3D measurements was done using a dependent t-test on each of the angles.

A Principal Component Analysis (PCA) was performed on each bone using a python library [3] to understand the shape variation of the pelvis and sacrum. Pearson correlation coefficient (R) were determined from the PCA projected weights and the calculated 2D sacropelvic parameters.

### Results and Discussion

Sacropelvic parameters of the calculated 3D measurements and measured 2D angles and distances are shown in Table 1. No statistically significant difference were found between 2D and 3D angles measurements while the crest-pubic, crest-sacral and inlet distances showed significant differences. This difference is likely due to two reasons. First, the SSM calculated distances are taken in 3D space which will always be larger than when projected onto a 2D plane. Second, the 2D calculated distances highly depends on the CT scan slice chosen for measurements. These results look promising to be able to use the SSM with a regression algorithm to predict clinical angles without the need for extensive scans. The first and second principal components (PC) for the sacrum and pelvis described 1) bone height and 2) bone width variation. The third PC described the iliac width in the pelvis and superior articular process shape variation in the sacrum. The R-value between sacrum's width (PC2) and PI shows a moderate correlation (0.537). However, no significant correlation were observed between the other sacropelvic angles and pelvic/sacrum bone shape.

### Conclusions

We found statistical differences in the 2D versus 3D measurements of crest-pubic, crest-sacral and inlet distances but no significant differences in angle measurements. We also found that sacrum width is moderately correlated with the pelvic incidence angle.

### Acknowledgement

### Summary

Anterior cruciate ligament (ACL) injuries are immediately disabling, and require long rehabilitation periods, in order to return to the previous level of competition. Addressing the prevention through musculoskeletal modelling (MSM) allows for the estimation of variables not otherwise measurable.

The present work aims to define knee ligaments geometry in a musculoskeletal model, focusing on ACL injury prevention.

### Introduction

The majority of knee and ACL injuries are often identified as non-contact injuries [1]: they occur when forces applied to the ligament are greater than the loads it can withstand [2] – in order to be effective, screening methods should be linked to ACL mechanical etiology [2]. MSM has already been successfully applied in clinic to assess musculoskeletal disorders [3]. A musculoskeletal model with enhanced degrees of freedom (DOF) at the knee and knee ligaments has been identified in literature [4], although not specifically developed for deep flexion tasks. Some works [5,6] have been identified reporting rotations on the frontal and transverse plane [5], and ligaments elongation and spatial orientation [6] in relation to passive knee flexion up to 130 degrees.

The present contribution aims to define the 3D ligaments geometry in a musculoskeletal model having enhanced DOF at the knee, focusing on high knee flexion tasks simulation.

### Methods

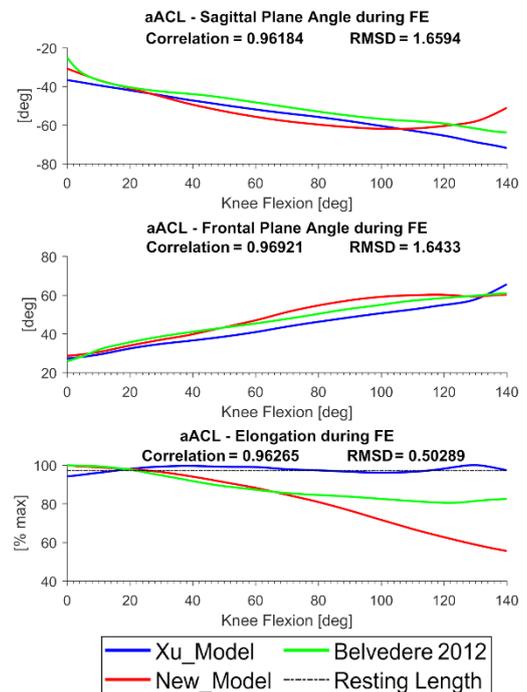

Once digitalized the data published in [5,6], the insertions of 11 ligament bundles have been redefined through an iterative algorithm: 1. once simulated the knee flexion as in [5], the models' ligaments 3D geometry and elongation are compared with [6] by means of RMSD and Pearson's correlation; 2. comparison are performed only when ligament elongation is higher than its resting length. 3. a tentative insertions cloud is then computed and a simulation run for each combination of tentative insertions. 4. breaking condition are set as the best insertions combination result, equal to the insertions combination given as input. 5. the optimization procedure is performed several times for each bundle, restarting the process with slightly different initial conditions, to avoid for suboptimal solutions, and the best overall solution is stored with the corresponding parameter values.

### Results and Discussion

Ligaments geometry optimization results (Fig. 1) showed good compliance with [6] geometries and elongation rates,

both in terms of correlation and RMSD, when the ligament elongation was higher than its resting length.

The repositioned ligaments geometry and the elongation pattern showed good compliance with [6] throughout the knee flexion. Both ligaments lever arms end force exertion are affected by these parameters during MSM simulations, hence by adopting the proposed methodology outcomes would be in line with knee physiology in simulating high knee flexion tasks.

**Figure 1:** ACL anteromedial bundle - frontal and transverse plane projection of the angle formed against the vertical tibial axis, and ligament elongation trough knee flexion.

### Conclusions

The proposed knee model could be adopted for knee injury prevention screening in high knee flexion tasks and support the clinical decision making in readmitting an injured athlete to trainings and competitions.

### Summary

No consensus exists on how to model human articulations within musculoskeletal models (MSKM). We propose to evaluate a joint model based on their anatomical consistency (AC), i.e. by quantifying ligament and cartilage deformation associated to its motion: to be consistent with articular physiology this deformation should be minimum. We compared AC of three ankle joint models with increasing personalisation and showed that a higher personalisation better complies with the expected physiological behaviour.

### Introduction

MSKM are widely adopted to estimate muscle and joint forces during motion tasks. Many different joint models and kinematic chains (KCs) have been proposed, from simple spherical or revolute joints to complex parallel mechanisms or coupling equations between the joint degrees of freedom. Guidelines for the definition of MSKM were proposed [1], but no consensus exists on the best KCs, mainly due to validation complexity. Rather than validation, we propose to use the concept of AC to compare different KCs. In agreement with articular physiology, a common assumption in MSKM is that joints are workless [1]. For this to hold true, no significant tissue deformation should occur within the joint during motion. AC can thus be determined by quantifying the ligament and cartilage deformation associated with joint motion. This concept was tested by computing the internal forces associated with tissue deformation for three different ankle models, characterised by an increasing level of personalisation. Through dynamic simulations of gait, the effect of these internal forces on the output of the three analysed models was also quantified.

### Methods

Gait analysis and medical resonance imaging (MRI) were collected from 10 juveniles (1:9 m:f,  $11.6 \pm 3.1$  y.o.,  $45.2 \pm 17.9$  kg,  $1.44 \pm 0.15$  m) as part of the MD-Paedegree project. For each subject, three lower-limb MSKM were built, differing from each other for the definition of the ankle model. The first model (scaled generic, SGJ) was obtained from marker-based scaling of the generic OpenSim model gait2392 [2]. The second one (morphological fitting-based, MFJ) was identified via morphological fitting of a cylinder to the MRI-segmented talar surface [3]. The third one was a 1-degree of freedom joint with a spatial floating-axis, defined by optimising the transmission of contact forces, i.e. maximising joint congruence (MCJ) [4]. Attachment regions of the tibio-calcaneal (TiCa) and fibulo-calcaneal (FiCa) ligaments were identified on MRI and were represented by their single most isometric fibre [5] with a bilinear elastic characteristic. Cartilages were modelled with the elastic foundation approach. Ligament elongation and cartilage co-

penetration associated with the ankle motion were computed for each model over the ankle range of motion. A standard inverse OpenSim pipeline, including Static Optimisation and Joint Reaction Analysis, was run to estimate ankle moment, muscle forces and joint forces. The pipeline was run first ignoring (scenario 1, S1) and then considering (scenario 2, S2) the ankle joint internal forces resulting from tissue deformation. Differences in maximum ankle moment (normalised by body mass and height), and amplitude of ankle contact forces (normalised by body weight, BW) between S1 and S2 were investigated for the three models.

### Results and Discussion

SGJ exceeded 30% of ligament elongation for both FiCa and TiCa (Table 1), above the physiological isometric threshold of 5% [5]. MFJ and SGJ showed non-physiological cartilage co-penetration. Internal forces due to tissue deformation (S2) caused a dramatic alteration of ankle moment and contact forces in SGJ (Table 2). MFJ and MCJ ankle moments were in line with average values reported in a previous work for the same cohort [3], but MFJ failed to provide reasonable values for contact forces under S2. Differences between S1 and S2 should be minimum to comply with ankle physiology. These differences provide a good indication of the AC of a joint model.

Table 1: Maximum tissue deformation across the cohort

	MCJ	MFJ	SGJ
FiCa elongation [%]	3.5	8.2	50.7
TiCa elongation [%]	5.9	17.9	32.6
Cartilage co-penetration [mm]	-0.5	-2.4	-5.4

Table 2: Maximum difference between S1 and S2 across the cohort

	MCJ	MFJ	SGJ
Plantarflexion moment [N/kg]	0.0	0.2	13.3
Ankle contact force [BW]	0.8	6.8	120.8

### Conclusions

Quantification of AC provides a solid criterion for the comparison of different joint models and personalisation strategies. A low AC raises concern about MSKM outputs credibility. When investigating specific subjects, a level of AC similar to the one of MCJ is recommended.

### Acknowledgments

Email: dssiitb@gmail.com

### Summary

Orthopaedic training is typically based on passive joint assessment; however, postoperative patient satisfaction depends on successful outcomes during active functional tasks. This study aimed at introducing cadaveric simulators to surgical fellows to provide quantitative and dynamic assessment of the joint following total knee arthroplasty (TKA). Significant differences observed in postoperative joint kinematics between passive and active tasks indicated the benefits of integrating joint simulators in orthopaedic training.

### Introduction

Orthopaedic training sessions, although vital for surgeons to understand postoperative joint function, are primarily based on passive and subjective joint assessment. However, cadaveric knee simulators, commonly used in orthopaedic research [1], could potentially benefit surgical training by providing quantitative kinematic assessment of the joint for active functional motions. The integration of cadaveric simulators in orthopaedic training was explored with recipients of the European Knee Society Travelling Fellowship visiting our institution in 2018 and 2019. The aim of the study was to introduce the fellows to a knee joint simulator in order to observe the surgical impact of TKA on the dynamic joint behaviour.

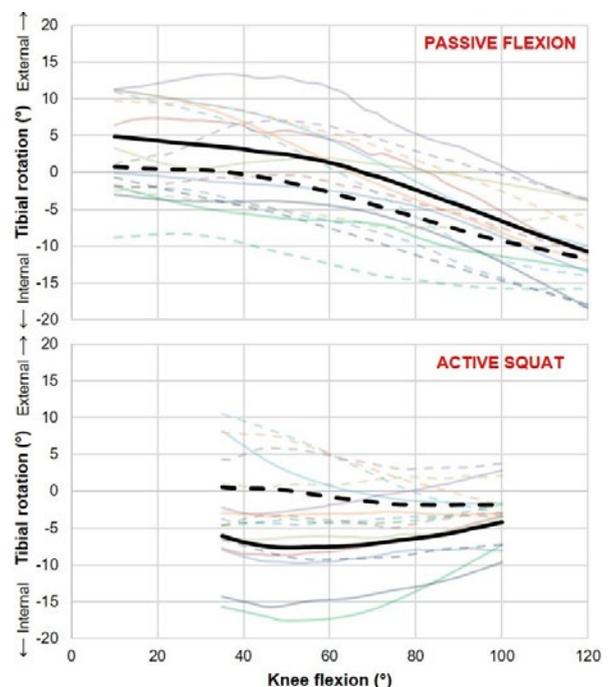

### Methods

Eight fellows were assigned a fresh-frozen lower limb each to plan and perform posterior-stabilised TKA using patient-specific instrumentation. Specimens were tested in the native and postoperative conditions on a validated knee simulator [2]. All fellows participated in the *in vitro* testing protocol, which included passive flexion (0°-120°), active squatting (35°-100°) and varus-valgus laxity tests (at 0° and 90°). Tibiofemoral kinematics were recorded with an optical motion capture system and compared between native and postoperative conditions using a linear mixed model ( $\alpha$ :  $p < 0.05$ ). The detailed kinematic analysis was also discussed with the fellows.

### Results and Discussion

Postoperative tibial abduction was closer to neutral than the native condition during squatting, although differences were not statistically significant ( $p > 0.28$ ). Passive flexion resulted in higher tibial internal rotation post-TKA ( $p < 0.05$ ), while squatting resulted in lower internal rotation post-TKA ( $p < 0.033$ ) (Figure 1). Postoperative joint stiffness was greater in extension ( $1.4 \pm 1.2^\circ$ ) than in flexion ( $4.4 \pm 2.0^\circ$ ) for a joint moment of 10 Nm.

*In vitro* experimental testing on the knee simulator provided the fellows with new quantitative parameters for postoperative joint assessment. Although trained at different institutions, all fellows followed certain standard intraoperative guidelines while performing TKA, such as achieving neutral tibial abduction and avoiding internal tibial rotation [3], albeit at a static knee flexion angle. However, postoperative tibiofemoral kinematics exhibited differences for passively and actively loaded motions (Figure 1). Thus, traditional orthopaedic training could be further enhanced by the inclusion of cadaveric simulators replicating functional joint motions, as was also the unanimous opinion of all participating fellows in their positive feedback.

**Figure 1:** Tibial rotation during passive flexion and active squatting in native (solid) and postoperative (dotted) states. Data shown for each specimen (light colours) and mean across specimens (black).

### Conclusions

Postoperative joint kinematics differed significantly for active squatting as compared to passive flexion, thereby indicating the potential contribution of cadaveric joint simulators in objectifying and improving surgical training.

## Summary

This study is part of a larger investigation aimed at developing a novel dynamic custom Ankle-Foot Orthosis (AFO) to improve function and comfort in patients not satisfied with standard solutions. Within this aim, a setup capable to replicate the biomechanical conditions characterizing the AFO in gait was developed. The setup allows to simulate the dorsi/plantar flexion an AFO is subjected to in the stance phase of walking. The setup was tested in a sample of standard and custom AFOs made of fiber-glass reinforced polyamide. Finite Element Analysis (FEA) was used to assess the stress distribution in the custom AFOs using the same boundary conditions. The setup showed high repeatability in assessing AFO stiffness and appeared flexible to adapt to different sizes and dimensions. The stiffness of the custom AFOs was consistent with that of similar-size off-the-shelf AFOs and the maximum Von Mises stress was lower than the material's yield strength.

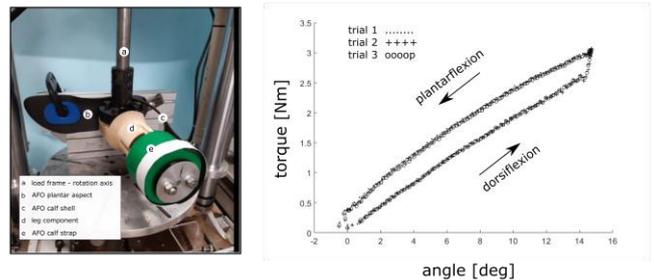

## Introduction

AFOs are prescribed to address a deficit of the main ankle dorsiflexor muscles in drop-foot patients. While standard-size off-the-shelf AFOs are suitable to support the foot and ankle, these do not account for subject-specific morphology for ankle deficit and functional demand, and do not address concomitant morphological and postural alterations of the foot. Measuring the mechanical properties of AFOs is a key element to provide each patient with the right AFO [1]. However no standard setup for testing AFOs is currently available [2, 3]. In this study, a setup capable to replicate the AFO flexion during the stance phase of gait was developed. The setup has been tested for intra-sample repeatability and sensitivity to inter-sample difference in measuring AFO stiffness of custom and off-the-shelf orthoses.

## Methods

A setup based on a servo-hydraulic testing machine (Biaxial Mini Bionix 858, MTS) capable to replicate the biomechanical conditions characterizing the AFO during the stance phase of walking was developed (Fig.1). Within the apparatus, the plantar aspect of AFO is fixed, while the calf shell is free to rotate about the load frame axis, which is aligned with the ideal ankle joint axis according to anatomical proportions. In order to allow physiological dorsi/plantarflexion, the calf strap constrains the upper border of the calf shell on a plastic cylinder free to slide along and to rotate around the "leg" axis. The rotational actuator applies 15 deg under angular displacement control while the torque cell (axial-torsional load cell 662.20D, MTS) measures the AFO resisting torque to flexion. Stiffness of the AFO [Nm/deg] is determined as the average slope of the torque/angle curve (fig 1, right) across five test repetitions. In the present study, two AFOs

were designed and manufactured via Selective Laser Sintering of fiber-glass reinforced polyamide powder (Windform GT, CRP Technology, Modena) customised for two drop-foot patients, and 6 standard polyethylene AFOs (*Molla di Codivilla*, Ottobock) – two samples for each small, medium, and large sizes – were tested for mechanical properties with the proposed setup. FEA was used to assess Von Mises stress in the regions subjected to the larger deformations and the overall stiffness of each design under the same boundary conditions of the bench testing.

**Figure 1:** Left, one of the custom AFOs in the testing rig. Right, torque/angle scatter plots in three 0-15-0 deg deformation-controlled dorsi/plantarflexion cycles.

## Results and Discussion

For all AFOs, torque/angle plots were highly repeatable across the five test repetitions. For each size, the measured stiffness of the *Molla di Codivilla* AFOs was consistent between left and right samples. Small and medium sizes presented a similar stiffness of about 0.17 Nm/deg, whereas the large size showed the largest average stiffness (0.28 Nm/deg). The two custom AFOs showed an average stiffness of 0.18 Nm/deg and 0.26 Nm/deg. FEA confirmed that Von Mises stress was lower than the yield strength of the material (56.2 MPa) at 15 deg flexion.

## Conclusions

While confirmation on a larger sample of AFOs is required, the present setup appears capable to characterize AFOs mechanical properties in realistic biomechanical conditions. The mechanical characterization will allow to accurately measure the stiffness of current off-the-shelf orthoses and to verify if the stiffness of the laser sintered custom AFOs is consistent with the nominal design values.

### Summary

The biomechanical data of human body was measured using inertial measurement unit (IMU) sensors for *The Timed Up and Go* (TUG) test. The test was recorded using a simple RGB camera and the video was analyzed using a machine learning (ML) approach. This study aims to evaluate the accuracy of biomechanical data estimated from 2D video source using machine learning method against data measured using 3D IMU's sensors.

### Introduction

Commonly used system for motion tracking is marker based optical systems using stereoscopic cameras, these systems are commonly used in indoor environment. Wearable sensors based on IMUs using a biomechanical model are comparatively fast systems and are capable of working in outdoor environment. These systems are expensive and skilled persons are required for their operation. ML techniques for estimation of kinematics of human body using computer vision algorithms and neural networks developed over past few years have proven to be revolutionary for data collection. Machine learning techniques using single RGB 2D camera source are gaining attraction due to their accessibility and minimal cost. *OpenPose* is a pose estimation technique consisting of neural networks, which is utilized, and output is processed to obtain kinematic data [1]. A large set of biomechanical data can be obtained for motion capture in clinical and sports kinematic analysis. The accuracy of kinematic data estimated using these techniques is questionable due to less reported comparison with physically measured data using either an optical system or sensor-based system.

### Methods

The TUG test is commonly used to assess mobility of a person and require both static and dynamic balance. The TUG test was selected to compare results of inertial measurement system and machine learning approach. Human body kinematic data was measured using inertial measurement system containing 17 IMUs (XSENS MVN Awinda), the system measures kinematics of 23 body segments. A single RGB camera synchronized with IMU's was used to record videos.

The test was performed on 15 healthy subjects and ten trials of each subject were recorded. The displacement (horizontal and vertical) of three body segments (head, sternum and pelvis) measured by inertial system was used as reference to compare with ML technique. The video data was parsed into

frames, which were processed through a multistage Convolutional Neural Network (CNN), converting the feature maps of the input frame into the part confidence maps and part affinity fields which were further processed to obtain the required location of the segments for each frame. The location was assimilated into position of segments from the frame after scaling to physical dimensions of the setup.

CNN was trained using the *Body25* Caffe model with high accuracy flags. The neural networks were deployed on an ubuntu-based Linux server utilizing Tesla T4 GPUs, however, potentially can be scaled for locally and commercially available server execution. The estimated kinematic data was compared with reference data and accuracy evaluation was conducted on the basis of the Mean Absolute Error (MAE).

### Results and Discussion

The horizontal and vertical position was represented as  $x$ -axis and  $z$ -axis respectively. The MAE for three segments for a single subject is presented in Table 1. The maximum MAE of three segments in horizontal and vertical position was 0.1370 m and 0.0878 m respectively. The errors in horizontal direction are comparatively high due to perspective and fisheye effect. The horizontal and vertical position of head using both systems is shown in Figure 1. The distinguishing characteristics of the kinematic displacement graphs were considerably conserved for kinematic analysis in both  $z$ -axis and  $x$ -axes.

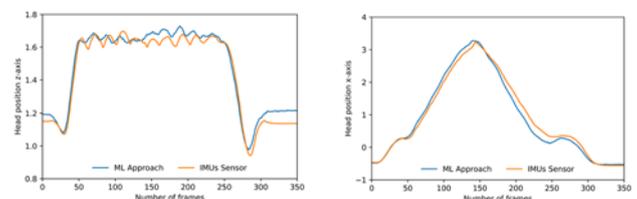

Figure 1: Head position  $z$ -axis (left) and  $x$ -axis (right)

### Conclusions

The results of ML technique are in good agreement with inertial measurement system with a maximum MAE of 0.1370 m. The use of this technique is very cheap compared to using IMUs systems. The results of this study can be used for accurate assessment of clinical biomechanics especially TUG test.

### Summary

The emergence of deep neural networks has enabled kinematic analysis outside of a lab and without expensive equipment. A method from computer science, pose estimation, can be used to detect body landmarks via a process called supervised learning, which requires “training” images to be manually labelled. Several open-source algorithms exist for this purpose but they are not tailored to the needs of biomechanists: the training data were labelled via crowdsourcing, so the body parts that they detect are not always relevant or accurate. This in turn results in poor kinematic estimates. One solution is to use custom models, which allow the “marker set” to be chosen. In this work I compare 2D joint angles computed using pre-trained and custom models, demonstrating the superiority of the latter.

### Introduction

The emergence of deep neural networks has enabled joint angles to be computed without expensive cameras or reflective markers. Markerless detection of human body landmarks is achieved using an approach from computer science called “pose estimation”. With additional post-processing, joint angles can then be computed. Several open-source algorithms allow body landmarks to be detected in real-time [1,2], but the landmarks that they detect often do not coincide with those typically used in biomechanical motion analysis. As an alternative, it is possible to train a custom model (e.g. using DeepLabCut [3]) where the specific marker set can be chosen. In this work I compare joint angles obtained using pre-trained and custom models, as well as manual analysis, for a range of human movements.

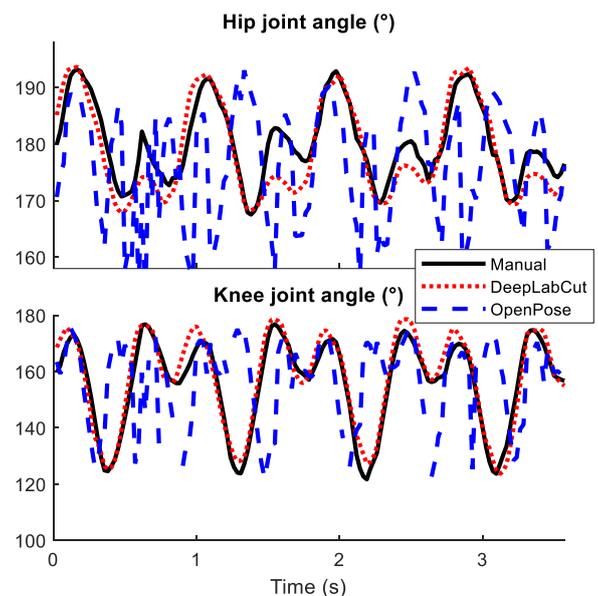

### Methods

Various common movements were examined from 8 participants (mean age: 26±3 females) including running on a treadmill and clinical tests that allow for a stationary camera position (e.g. sit-to-stand, lower limb ab/adduction, lumbar side flexion). Videos were processed in 3 ways: manual analysis, with an OpenPose pre-trained model [1] and with a custom model developed in DeepLabCut and a marker set that more closely resembled those used in biomechanics studies. Primarily single plane movements were chosen for simplicity, and because the use of pose estimation for markerless 3D joint angle prediction is still in its infancy (see [4]).

### Results and Discussion

Compared to manual analysis, a custom DeepLabCut model yielded more similar joint angle estimates than the OpenPose

pre-trained model (Figure 1). For all movements, across a whole repetition or stride, mean differences in hip angle were 10.1° (control vs. OpenPose) and 6.2° (manual vs. DeepLabCut). Corresponding values for knee angle were 15.8° and 5.1° respectively.

**Figure 1:** Hip and knee joint angles during running computed using 3 methods: manual analysis (Manual), a pre-trained model (OpenPose) and a custom model (DeepLabCut).

### Conclusions

Accurate markerless motion analysis requires neural network models trained in accordance with the needs of biomechanists. For 2D analysis, this can be achieved using custom models combined with transfer learning to minimise the required volume of training data.

## Improved Balance Analysis Accuracy using a Functional Base of Support Model

Matthew Millard<sup>1</sup>, Lizeth Sloot<sup>1</sup>, Katja Mombaur<sup>2</sup>

<sup>1</sup>Optimization, Robotics and Biomechanics Group, Heidelberg University, Germany

<sup>2</sup>Systems Design Engineering, University of Waterloo, Canada

Email: [matthew.millard@uni-heidelberg.de](mailto:matthew.millard@uni-heidelberg.de)

### Summary

Mathematical balance models have the potential to identify people at risk of falling before an injury occurs. Many models of balance depend on an accurate geometric model of the base of support (BOS). The functional BOS (FBOS) of the human foot is smaller than its full outline because not all parts of the foot can support large loads. In this work, we measure the FBOS using center-of-pressure (COP) movements in barefoot and shod conditions.

### Introduction

Several of the most general mathematical models of balance map [1] the state of the body to a balance point (BP) on the floor: if the BP can be enclosed by the BOS, the person will be able to transition to a statically stable standing pose. The dynamic balance margin (DBM) is the distance between a BP and the person's BOS. The DBM is useful for assessing balance performance, but its accuracy is affected by the BOS model's accuracy. Recently, we found that having a FBOS model, based on COP movements, allowed us to see systematic differences in balance control between older and younger adults previously obscured when using the full outline of the foot [2]. Here we define the FBOS as the convex region on the foot that can support at least half of the body's weight, a requirement of stable two-footed standing. Here we extend our pilot FBOS model [2] by evaluating the average FBOS of 11 adults when barefoot and shod.

### Methods

We recorded the foot movements and ground forces of 11 typical adults while they stood on a force plate and slowly moved their COP through the largest loop possible while keeping the foot on the ground (Fig. 1). The resulting COP trajectories were resolved in a foot-fixed frame, the convex hull of the COP extracted, and normalized by bare foot

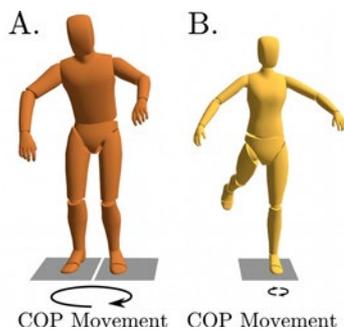

Figure 1: Double (A) and single-stance (B) FBOS tasks

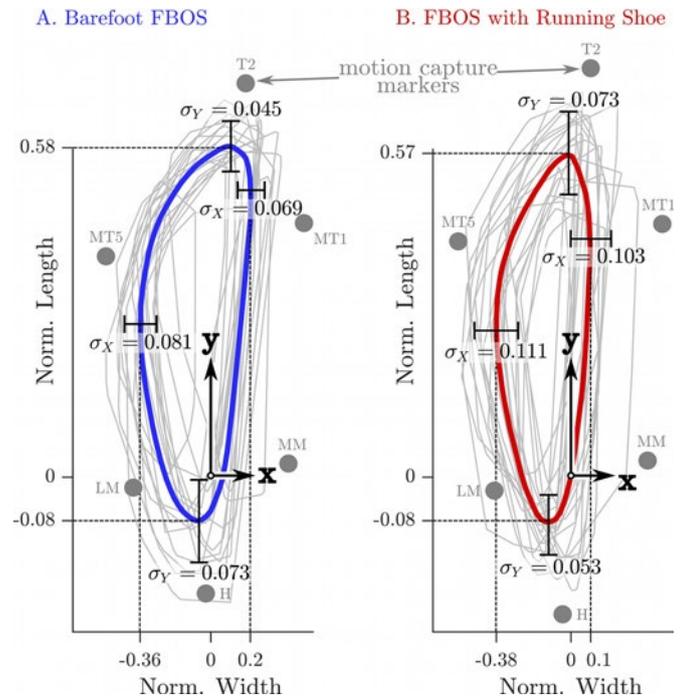

Figure 2: Barefoot (A) and shod (B) FBOS of the 11 participants length and width. The mean FBOS is evaluated by averaging across the convex-hulls of the two tasks (Fig. 1), and across the data from the left and right feet.

### Results and Discussion

The average FBOS is smaller than the foot's outline and similar in size across both conditions (Fig. 2). The FBOS model would improve the accuracy of the DBM by 17% of foot length at the heel and toe, and 24% of foot width at the sides. In physical terms, the FBOS model would improve DBM accuracy by 5.1 cm at heel and toe, and 2.4 cm at the sides, for a 30cm by 10cm foot. Though this may seem small, centimeter differences in DBM can mean the difference between standing stably and having to take a step.

## Differences in single leg postural control when assessed over time in professional rugby union players

Molly McCarthy-Ryan<sup>1,2</sup>, Stephen Mellalieu<sup>1,2</sup>, Chris Towers<sup>2</sup>, Adam Bruton<sup>3</sup>, Isabel Moore<sup>1</sup>

<sup>1</sup>Cardiff School of Sport & Health Sciences, Cardiff Metropolitan University, Cardiff, UK

Email: momccarthy-ryan@cardiffmet.ac.uk

### Summary

Postural control has been defined as ‘the act of maintaining, achieving or restoring a state of balance during any posture or activity’ [1]. Traditionally, postural control is assessed through single leg stance, with the trial being analysed as a whole. Jonsson [2] proposed the need to analyse postural control in 5 second phases due to larger force variability within the first 5 seconds of the trial. The main finding of this study is that healthy elite rugby union players demonstrate differences in postural control between-phases for both eyes open (EO) and eyes closed (EC) trials. Although for EO trials the initial seconds (dynamic phase) showed larger variability across postural control variables, in line with Jonsson [2], whereas the dynamic phase in the EC task had the smallest variability.

### Introduction

Jonsson [2] suggested postural control can be divided into two phases, dynamic and static, due to vertical force changing over time. No study has identified if this is the case for all postural control variables when assessing healthy elite male athletes. The aim of this study was to assess the changes in postural control over time in healthy elite rugby union players in single leg stance trials

### Methods

Twenty-one injury free elite male rugby union players (weight 94.86±10.40kg; height 182.35±6.52cm; age 25±4 years), completed a single leg stance in two conditions: EO and EC. A total of 3 x 20 seconds trials were collected for each. Using the filtered data, the following variables were calculated: center of pressure (COP) Sway path (m), COP velocity (m.s<sup>-1</sup>), and 95% ellipse area (m<sup>2</sup>). All variables were analysed in 5 second intervals; the first interval was 0 to < 5 seconds. The second interval was 5 to < 10 seconds; third interval 10 to <15 seconds and fourth interval 15 seconds to end of the trial.

### Results and Discussion

When looking at the effect of EO and EC on change in postural control over time the pattern observed by Jonsson [2] as only witnessed in the EO trials, whereas the opposite was observed for EC trials, although changes over time were evident in both conditions. For EO trials sway path and mean COP velocity identified differences between interval one and two, one and three and one and four, whereas 95% ellipse area had differences between intervals one and two, one and three, two and four and three and four. However, for EC trials sway path identified differences between interval one and two, one and three, compared to COP velocity who identified differences between interval one and two, one and three and one and four and finally 95% ellipse area only had differences in intervals two and four. The results indicate acute postural control changes that occur for all variables over time in both EO and EC assessments of postural control.

### Conclusions

In both EO and EC trials, changes in postural control occurred over time for all variables. Furthermore, the changes in postural control occur in different directions for EO and EC trials indicating that the different visual conditions interact with the sensorimotor system in unique ways. Postural control should be assessed in phases, with both EO and EC, where postural disturbances occur within the trial.

## Foot and ankle joint coupling in balance and gait

Rosemary Dubbeldam<sup>1</sup>, Lena I.G. Fennen<sup>1</sup>, Heiko Wagner<sup>1</sup>

<sup>1</sup>Department of Movement Science, Institute of Sport and Exercise Sciences, University of Münster, Germany  
Email: r.dubbeldam@uni-muenster.de

### Summary

Foot and ankle joint coupling has been related to task and pathology. However, little is known about their coupling in balance. This study aims to assess coupling of foot and ankle joint movements in balance and gait. Therefore, gait and 1-limb stance of 17 healthy participants was recorded and the motion of the hallux, medial forefoot, midfoot, hindfoot and leg was calculated. The relationship between (non-)adjacent segments was assessed by fitting a linear regression model. Group average coefficients of determination and regression angles were derived. In balance, a strong relationship was found between hindfoot and medial forefoot eversion. In gait and balance, hindfoot exorotation and eversion were consistently related to medial forefoot dorsiflexion, and hindfoot eversion to hallux dorsiflexion. However, in balance, hindfoot inversion was related to hallux plantarflexion as compared to dorsiflexion in gait. Furthermore, more variance was demonstrated in balance, suggesting more variation in control compared to gait.

### Introduction

Passive and active structures influence the movements of our body segments. Multiple studies have related pathology to changes in segment movement coupling, yielding insight in diagnosis and treatment options [1,2]. However, little is known about foot and ankle joint coordination during balance. The aim of this study is to analyse 3-dimensional coupling motion of (non-)adjacent foot and ankle joints in balance and compare them to those in gait.

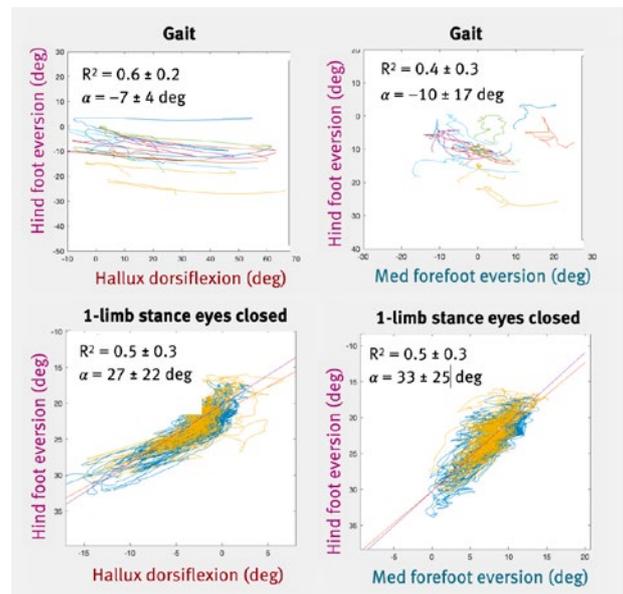

### Methods

A 3-dimensional movement analysis system was used to record gait and 2 trials of 1-limb stance with eyes closed of 17 participants (average 24 years, range 20-34 years). The motion of the hallux, medial forefoot, midfoot, hindfoot and leg was assessed [3]. Six coupled motions between segments were analysed by fitting a robust linear regression model [4]. The coefficient of determination ( $R^2$ ) and regression angle ( $\alpha$ ) were derived for each stance phase in gait (at least 10 steps) and the 60 second balance trials. Average group values and corresponding standard deviations were assessed for gait and balance. In segment coupling plots, consistency was assumed, when both segments move together along the regression line and demonstrate synchronous turning points (Figure 1) [4].

### Results and Discussion

In gait, hindfoot exorotation and eversion were consistently related to medial forefoot dorsiflexion ( $R^2$   $0.3 \pm 0.3$ ,  $\alpha = 6^\circ \pm 7^\circ$  and  $R^2$   $0.5 \pm 0.3$ ,  $\alpha = 11^\circ \pm 12^\circ$ , respectively), and hindfoot eversion to hallux dorsiflexion ( $R^2$   $0.6 \pm 0.2$ ,  $\alpha = -7^\circ \pm 4^\circ$ ). In balance, the same consistent relationships were found for

hindfoot exorotation and eversion to medial forefoot dorsiflexion (both  $R^2$   $0.3 \pm 0.3$ ), and hindfoot eversion to hallux dorsiflexion ( $R^2$   $0.5 \pm 0.3$ ). However, the regression angles increased up to  $10^\circ \pm 26^\circ$ ,  $33^\circ \pm 25^\circ$ , and  $27^\circ \pm 22^\circ$ , respectively (Figure 1). Consequently, in balance, hind foot inversion was related to hallux plantarflexion, compared to hallux dorsiflexion in gait, where the Windlass mechanism plays a role. Additionally, a consistent relationship between hindfoot and medial forefoot eversion was observed in balance ( $R^2$   $0.5 \pm 0.3$ ,  $\alpha = 33^\circ \pm 25^\circ$ ).

**Figure 1:** Foot segment coupling plots for gait (stance-phase of all participants) and 1-limb balance (2 trials of 1 participant). With average group  $R^2$  and  $\alpha$ .

### Conclusions

The results suggest, that different active and passive structures influence balance compared to gait. Furthermore, between-subject variation was larger in balance than in gait. Individual balance control mechanisms and performance, may play a role. In future, assessment of relations between task performance, muscle activation and foot and ankle segment coupling may provide additional insight.

## Intra and Intersession Reliability of Centre of Pressure Measures in Older Adults during Bipedal Static Postural Tests

Diana Soares, Iain Fletcher, Andrew Mitchell and Laura Charalambous  
 Institute of Sport and Physical Activity Research, University of Bedfordshire, Bedford, UK  
 Email: diana.soares@study.beds.ac.uk

### Summary

Research investigating test-retest reliability of centre of pressure (CoP) measures during bipedal static postural tests in older adults is sparse. The aim of this study was to assess the intra (same day) and intersession (between days) reliability of nine CoP measures in older adults aged 65 to 79 years, to identify how many trials are needed to obtain a low coefficient of variance (CoV%) during bipedal static postural tests. Using a force plate, CoP sway path and mean speed were found to be the most reliable measures, but only in the eyes open (EO) condition. ML mean velocity was reliable in both EO and eyes closed (EC) conditions. Two trials of 30 seconds were sufficient to obtain an acceptable intra and intersession reliability in these CoP measures.

### Introduction

The intrinsic variability of CoP measures, sampling duration and number of trials may affect the reliability and validity of postural stability outcomes [4,6]. Previous studies [1,3,4,5] have indicated how many trials and trial time are needed to obtain good reliability in several CoP measures in older adults. Sampling durations ranged from 30 to 120 seconds and number of trials from three to nine [1,3,5], or were not indicated [4]. Comparisons are hence difficult due to major variations across protocols. It is important that any differences observed in CoP measures are due to changes in the participants' postural control as opposed to random or systematic errors in the measurement procedure [2]. The aim of this study was to investigate the intra and intersession reliability of nine CoP measures to identify how many trials are needed to obtain acceptable reliability during a bipedal static postural test in older adults.

### Methods

Eleven healthy older adults (70.2±2.7 yrs | 165±7.6 cm | 71.5±12.9 kg) volunteered to perform a bipedal static postural test with eyes open (EO) and eyes closed (EC) (blindfolded). Participants stood barefoot on a force plate (100Hz | Kistler) as still as possible, with feet hip width apart and arms hanging by their sides in both conditions. While looking at a 10x10 cm diameter black mark on a white board placed 2 m away from the participant, ten 30 seconds trials were randomly (EO or EC) conducted with seated rest periods of 1 min between each trial. Consistent foot placement was ensured between trials and sessions by placing an outline of the feet on top of the force plate. After 1 hour of seated rest, the test session was repeated to evaluate intrasession reliability and one week later to test intersession reliability. Using Microsoft Excel, CoP measures in both anterior-posterior (AP) and medial-lateral

(ML) directions were calculated for sway path (mm), mean speed (mm), maximum speed (mm·s<sup>-1</sup>), peak velocity (mm·s<sup>-1</sup>), mean velocity (mm·s<sup>-1</sup>) and peak displacement (mm). Intra and intersession reliability for all CoP measures in each condition was estimated using the CoV% (SD/mean x 100) [2] and reliability scores were obtained (test-retest).

### Results and Discussion

Results indicated that, in both EO and EC conditions, it was found an acceptable intersession reliability (CoV% < 20%) but not intrasession (CoV% < 20%) in all CoP measures. This might be due to the participants not being familiar to stand barefoot for 30 seconds without moving. Only CoP ML mean velocity presented an acceptable intra and intersession CoV% reliability scores in both EO (0.4% < 3.7%) and EC (3.1% < 1%) conditions, when two trials of 30 seconds were averaged. This is similar to previous studies [3,5], however they used two trials of 120 seconds with EO [3] and three trials of 75 seconds with EC [5], to obtain good reliability in this CoP measure. In the present study, intra and intersession variability did not reduced as more trials were averaged in either condition. CoV% plateaued for all variables by trial 3. When two trials were averaged, sway path and mean speed presented an acceptable intra (0.4%) and intersession reliability (2.7%) but only in the EO. This suggests that visual input may have an effect when estimating reliability in CoP measures in older adults during postural analysis in quiet stance.

### Conclusions

CoP sway path and mean speed were the most reliable measures of static postural stability, but only in the EO condition when assessing older adults aged 65 to 79 years. In the EC condition, ML mean velocity is recommended. Two trials of 30 seconds were sufficient to obtain good intra and intersession reliability when using these CoP measures. Number of trials and visual conditions must be taken into account when investigating postural stability in this population as it may impact the efficacy of the results. Further investigation is needed to explain the superiority of some CoP measures in terms of reliability.

## The effect of feet position on standing balance in pediatric patients with flat feet

A.M. Khodorovskaya<sup>1</sup>, M.V. Savvina<sup>1</sup>

Physiology and Biomechanics Research Laboratory. H. Turner National Medical Research Center for Children's Orthopedics and Trauma Surgery, Saint Petersburg, Russia;  
Email: shulamif@mail.ru

### Summary

This study aims to examine the effect of feet positions on standing balance in children with flat feet and its clinical applications.

### Introduction

Pediatric flat feet are a very common concern for parents and one of the most frequent presenting complaints to a pediatric practice. The flat foot diagnosis can't be limited to a morphological examination [1]. It should be based on an accurate clinical and radiographic examination, as well as on functional and instrumental analysis such as stabilometry. An influence variation in foot position on standing balance in pediatric patients with flat feet has not been fully investigated..

### Methods

Forty nine children with fixed flat feet aged between 9 and 12 years participated in this study. (23 girls and 26 boys). Weight:  $46 \pm 6,3$  Kg; Height:  $149,5 \pm 5,7$  cm; foot length:  $24 \pm 2,7$  cm;) All subjects did not have any musculoskeletal or neurological disorders, as well as no history of surgeries and trauma of musculoskeletal structures on the lower limbs. The study conforms to the Declaration of Helsinki. Written informed consent was obtained from parents of all participants prior to the biomechanical examinations.

For the bipodal test, children were instructed to stand on the platform with arms hanging beside their body in two positions: 1) feet forming an angle of 30° degrees and heels apart-3 cm (group A); 2) feet parallel to each other and distance between the 2 ankle joint centers equal to the distance between the right and left anterior superior iliac spines (group B). For the monopodal test, patients stood on each of their lower limbs at the center of the platform.

The test was performed using Stabilan-02-stabilometric platform (ZAO OKB Ritm - Russia).Acquisition time was set at 20 seconds. The Closed Eyes test was performed before the Open Eyes one to the purpose of limiting the oculomotor control memory on balance keeping in Closed Eyes condition. The displacement of the Center of Foot Pressure (COP) was analyzed by assessing the standard indicators for the bipodal test as well as for the left leg and right-leg monopodal tests.

Statistical analysis. For comparison stabilometric variables between groups (group A and group B), the Student's t-test for independent samples was used. Normality of data was assessed through a Kolmogorov-Smirnov test. A significance level of  $p \leq 0.05$  was set for all statistical procedures, and the SPSS v. 19 software was used.

### Results and Discussion

Bipodal stabilometry showed that in group B scored significantly higher with respect to COP X mean ( $p=0.0427$ ) during the eyes-closed condition than in group A in same condition. Monopodal stabilometry tests showed that leg corresponding to the side of the larger COP X mean displacement had scored significantly higher in COP Length( $p=0.008$ ) and COP Speed ( $p=0.003$ ) during the eyes-closed and the eyes-open condition.

Feet positions have an important role in controlling posture in a standing position. We hypothesized that patients in group B would have poorer standing postural control than patients in group A, because greatly reduces stability within the foot joints. The decreased stability may be due to reduced joint congruity and consequently an increased reliance on soft tissue structures This may explain why the patient in group B position had a significantly displacement position of the COP in the medio-lateral plane than the patients in group A and not in the antero-posterior plane. Assessment of the clinical parameters of the feet does not provide complete information about the degree of flat feet [2]. Stabilometry could can be used as an additional tool for assessing the severity of flat feet and also employed for monitoring for nonsurgical patients with flat feet.

### Conclusion

The position of the feet affects the standing balance in patients with flat feet. Taking these results into account we recommend using a bipodal standing, with feet parallel to each and the distance between the 2 ankle joint centers equal to the distance between the right and left anterior superior iliac spines when performing stabilometry in pediatric patient with flat feet.

## Limits of stability in cognitively healthy individuals and mild cognitive impairment (MCI)

Andresa M. C. Germano<sup>1</sup>, Daniel Schmidt<sup>1</sup>, Niclas Masuch<sup>1</sup>, Thomas L. Milani<sup>1</sup>

<sup>1</sup>Department of Human Locomotion, Chemnitz University of Technology, Chemnitz, Germany

Email: andresa.germano@hsw.tu-chemnitz.de

### Summary

We investigated balance control in mild cognitive impairment (MCI) compared to cognitively healthy controls. Although only differences between the young and old groups were found, correlations between cognitive and balance parameters were evident. Hence, further studies are needed.

### Introduction

MCI causes structural and functional changes in the brain, being considered as a process between cognitive changes of normal aging and dementia diseases [1]. The increased rate of atrophy of affected brain regions negatively affects the ability to balance and leads to a higher risk of falls [2]. Still, studies regarding motor deficits in MCI show controversies. Therefore, we investigated balance control (limits of stability, LoS) in MCI patients compared to healthy controls. We hypothesized decreases in balance control in MCI and correlations between balance and cognitive parameters.

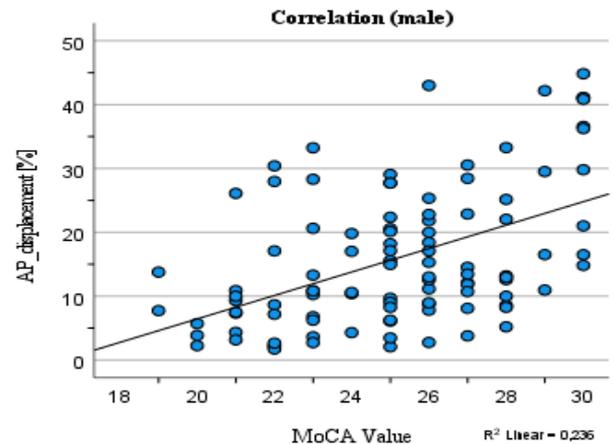

### Methods

193 participants (MCI (82.7±2.4 yrs): 55♂, 35♀; older cognitively healthy individuals (OCH) (82.3±2.7 yrs): 35♂, 40♀; and young cognitively healthy individuals (YCH) (22.8±3.1 yrs): 15♂, 13♀) took part in the LoS balance tests. The groups were determined using the Montreal Cognitive Assessment (MoCA: value < 26 corresponds to MCI). Three trials of LoS were collected using a force plate (GK-1000 Koordinator, IMM Holding GmbH, 1kHz). The protocol consists of three phases: 1) 20s of quiet stance (COP\_static); 2) the distance until the maximal forward leaning without losing balance (AP\_displacement; normalized by foot length); and 3) maintenance of maximal forward leaning position for 10s (COP\_limit). Mean±SD of the COP parameters were calculated for statistical analyses.

### Results and Discussion

Gender differences were found (Table 1). Rejecting our hypothesis, differences between the groups were found in all parameters, but only between both older groups and YCH. This reflects age-related deteriorations. Interestingly, the same behavior can be observed in foot sensitivity [3], which could explain our balance results, since skin sensitivity contributes to the control of balance. Correlations between

balance and cognitive parameters support our hypothesis, showing that motor control is affected as consequence of brain damage in cognitively impaired (Figure 1). This is in line with a previous study [4], which also reported a low cognitive performance and increased postural instability.

**Figure 1:** Exemplary: correlation between AP\_displacement and MoCA value ( $\rho = 0.470$ ,  $p < 0.001$ ).

### Conclusions

Aging effects were evident, but no additional decreased balance in MCI was present. However, correlations between balance and cognitive parameters were shown. Hence, further measurements are needed to provide insights into the brevity of motor control decline and information-processing structures in MCI.

## The vertical balance control system in children with cerebral palsy is more synchronized compared to healthy children

Igor E. Nikityuk, Galina A. Ikoeva

H. Turner National Medical Research Center for Children's Orthopedics and Trauma Surgery, Saint Petersburg, Russia

E-mail: [femtotech@mail.ru](mailto:femtotech@mail.ru)

### Summary

The analysis of stabilometric examination of patients with mild and severe cerebral palsy (CP) at the age from 6 to 12 years was carried out. For comparison, healthy children of the same age were examined, each group of children consisted of 10 people. The results of the study showed a significant decrease in the stability of the vertical balance in both groups of patients with cerebral palsy in comparison with healthy children. However, a strong correlation was found between the parameters of the statokinesiogram: area  $S$ , length  $L$ , and amplitude  $A$  of the center of pressure (COP), which significantly exceeds that in healthy children and is most pronounced in severe CP. The pathologically increased ordering of the COP trajectory of statokinesiograms in CP patients is regarded as an indicator of a deficit in postural control.

### Introduction

All forms of cerebral palsy impair the balance management system of the body. There are proposals to present postural control as a stochastic process. Such a principle of postural balance analysis may be more informative in comparison with the descriptive statistics methodology [1].

### Methods

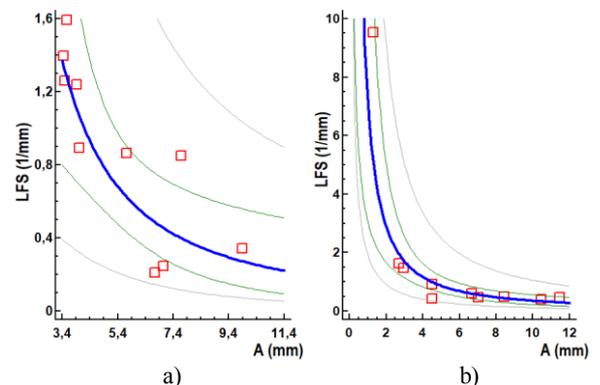

A stabilometric examination with open eyes (OE) and closed eyes (CE) of 3 groups of children, 10 people each, aged from 6 to 12 years, was carried out using the MBN Biomehanika complex. The first group - children with mild cerebral palsy, the second - children with severe cerebral palsy, the third - healthy children. The length of the trajectory passed by COP ( $L$ , mm), the area  $S$  ( $\text{mm}^2$ ) of the stabilogram, and the average amplitude of COP oscillations -  $A$  (mm) were calculated. To study the relationship of signs, correlation analysis with Spearman coefficient  $r_s$  was used. Differences were considered statistically significant at  $p < 0.05$ .

### Results and Discussion

In both groups of patients with cerebral palsy, pronounced disorders of postural balance with a significant increase of  $L$ ,  $S$  and  $A$  parameters compared with healthy children ( $p < 0,05$ ) were revealed. At the same time, the statistical differences between the stabilometric parameters of children with mild and severe cerebral palsy were not significant.

Correlation analysis showed an average inverse multiplicative relationship between parameters  $L$ ,  $S$  (LFS) and  $A$  in the group of healthy children (OE:  $r_s = -0.54$ , CE:  $r_s = -0.59$ ).

Higher modulus  $r_s$  values were found in the group of patients with mild cerebral palsy (OE:  $r_s = -0.65$ , CE:  $r_s = -0.81$ ) (Fig. 1, a). The strongest correlation in modulus between the parameters was found in the group of patients with severe cerebral palsy (OE:  $r_s = -0.92$ , CE:  $r_s = -0.93$ ) (Fig. 1, b).

**Figure 1:** Regression line (blue) for the dependence of the LFS parameter of statokinesiograms on the range of variability  $A$  in children with CP in the test with opened eyes: a) mild degree; b) severe degree.

The increased ordering of the trajectory of the center of pressure in children with cerebral palsy was described earlier [2] and can be regarded as pathological [3]. The use of the stochastic approach is highly sensitive and can provide a deeper understanding of the mechanisms used by the postural control system in patients with cerebral palsy.

### Conclusions

In patients with cerebral palsy, the vertical balance control system, despite severe disorders, is more synchronized in comparison with healthy children. Moreover, the relationship between the parameters of stabilometry in severe cerebral palsy is significantly higher than in mild.

## Energy dissipation while landing from a jump

T. Toussaint<sup>1</sup>, B. Schepens<sup>1</sup>

<sup>1</sup>Laboratory of Physiology and Biomechanics of Locomotion, Institute of Neuroscience (IoNS), Université catholique de Louvain (UCLouvain), Louvain-la-Neuve, Belgium  
Email: thibaut.toussaint@uclouvain.be

### Summary

This study highlights the mechanical behavior adjustments of the lower limbs when landing on the ground from a jump at different heights (i.e., when the amount of energy to be dissipated increases). We observe that the strategy is mainly tuned to get a safety margin in order to avoid bouncing on the ground or losing balance, and less to limit the mechanical constraints.

### Introduction

When landing from a jump, we must be able to slow down our body and dissipate the energy gained during the fall in order to reach back a stable standing position without rebounding or losing balance. The motor control must therefore be adjusted to the amount of energy to be dissipated.

The landing can be divided into two phases (Figure 1) [1,2]. During the first phase, the center of mass of the body (*CoM*) goes down and the vertical component of the ground reaction force (vGRF) increases; this behavior assimilates the lower limbs to a linear spring. During the second phase, the *CoM* goes down and up while the vGRF mainly decreases; this behavior can be described by a spring associated with a damper allowing energy dissipation. To our knowledge, the way this model is modified as function of the amount of energy is unknown. Therefore, our aim is to analyze if and how the amount of energy shapes the biomechanical properties of the lower limbs (i.e., stiffness and damping).

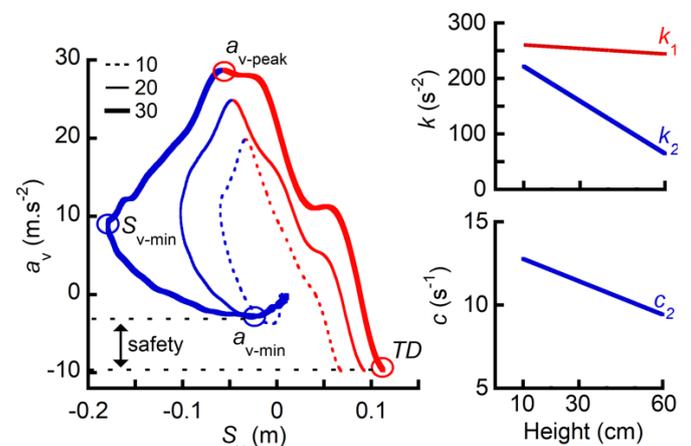

### Methods

Fifteen subjects (age: 22-31 yo) were instructed to perform a jump from a box of different heights (10, 30, 60cm) and land on both feet in a natural way. The vertical acceleration and the displacement of the *CoM* ( $a_v$  and  $S_v$ ) were computed from the vGRF, which was recorded using force-platforms.

The biomechanical behavior of the lower limbs was assessed from  $a_v - S_v$  by computing the stiffness ( $k_1$ ) from touchdown (*TD*) until the maximum value of  $a_v$  ( $a_{v-peak}$ ), and then the stiffness & damping coefficients ( $k_2$ ,  $c_2$ ) until the standing position as described by Gambelli et al. (2015). In addition to  $a_{v-peak}$ , the lowest position of the *CoM* ( $S_{v-min}$ ) and the minimum value of  $a_v$  ( $a_{v-min}$ ) were measured (Figure 1). Note that if  $a_{v-min}$  reaches the value of  $-9.81 \text{ m.s}^{-2}$ , the subject will rebound on the ground.

### Results and Discussion

The model previously described (i.e., spring–spring&damper) yields good fit with our experimental data (mean  $r^2 = 0.93$ ). When the amount of energy to be dissipated increases, the stiffness  $k_1$  remains constant while the stiffness  $k_2$  and the damping coefficient  $c_2$  decrease. Accordingly, the impact of the ground increases ( $a_{v-peak} \uparrow$ ), and the *CoM* reaches a lowest position ( $S_{v-min} \uparrow$ ) while the minimum of  $a_v$  ( $a_{v-min}$ ) remains constant. One interpretation of such behavior is that the biomechanical properties of lower limbs seem to be tuned to get a safety margin in order to avoid imbalance and rebound, rather than reducing the mechanical constraints.

**Figure 1:** Grand mean of  $a_v$  as function of  $S_v$  from *TD* until the standing position. The spring-like phase is presented in red and the spring&damping-like phase is presented in blue. Each trace represents an experimental condition (jumps from 10 to 60 cm). The stiffness & damping coefficients (line of best fit) are presented as function of height.

### Conclusions

When landing from a jump, the biomechanical properties of lower limbs are tuned according to the amount of energy to be dissipated. To deal with the increased amount energy to dissipate, the lower limbs behavior must be modified throughout landing (two distinct behaviors) and these modifications take part mainly during the second of landing.

## Anticipatory Postural Adjustments During Gait Initiation in People with Mild Chronic Low Back Pain

Rum Lorenzo<sup>1</sup>, Russo Guri<sup>1</sup>, Mannozzi Giuseppe<sup>1</sup>, Laudani Luca<sup>2</sup>, Macaluso Andrea<sup>1</sup>

<sup>1</sup>Laboratory of Bioengineering and Neuromechanics of Human Movement, University of Rome "Foro Italico", Rome, Italy

<sup>2</sup>Cardiff School of Sport and Health Sciences, Cardiff Metropolitan University, Cardiff, UK

Email: lorenzo.rum@uniroma4.it

### Summary

Anticipatory Postural Adjustments and trunk flexion are fundamental mechanisms utilized prior to walking to produce optimal biomechanical conditions. Gait initiation kinematics in people with mild Chronic Low Back Pain (mCLBP) and healthy controls was collected with force plates and motion capture. Participants with mCLBP showed altered postural preparation with respect to healthy controls, which was also associated with thorax motion during gait initiation, but tends to disappear during the first step execution.

### Introduction

Gait initiation is a transitory motor task requiring Anticipatory Postural Adjustments (APAs), which produce an initial motion of the feet Centre of Pressure (CoP) aiming at providing optimal balance and motor performance [1]. During this phase, a key functional role to generate the necessary forward momentum and initiate gait is also played by the forward leaning of the trunk [2]. However, it has been recently shown that neuro-mechanical control of the trunk is impaired in individuals with mild Chronic Low Back Pain (mCLBP) during walking and gait termination [3]. The present study aimed to investigate the effects of mCLBP on APAs and trunk kinematics during gait initiation.

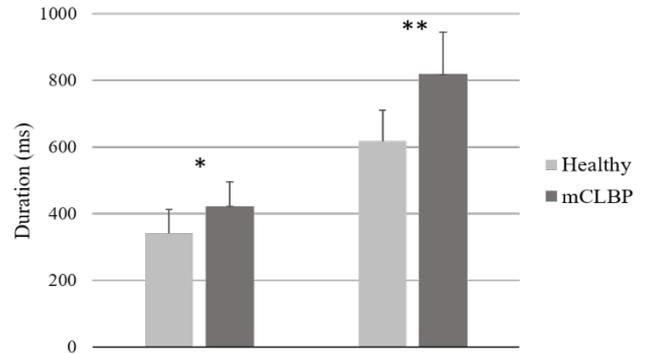

### Methods

Eleven healthy adults and 11 adults with mCLBP performed 10 gait initiation trials at their comfortable self-selected speed. Two force platforms (Fertec Corp, OH) were used to record the CoP trajectory during the preparation and execution of the first step. APAs' amplitude and duration, the initial posterior peak force and the step initiation latency with respect to the onset of ML CoP motion during step preparation were obtained. A motion capture system (Vicon, UK) was used to assess the absolute angular displacement of the thorax in the sagittal plane during step preparation and the first step length and width according to the Plug-in Gait model. Group comparison was performed by means of independent sample t-test or Mann-Whitney Test. A partial correlation analysis for repeated observation within subjects was performed to evaluate the relationship between sagittal thorax angular displacement and gait initiation parameters within each group.

### Results and Discussion

Participants with mCLBP showed longer APAs duration and step initiation latency compared to healthy participants ( $p = .012$  and  $p = .001$ , respectively) (Figure 1). No differences were observed for either APAs amplitude, first step spatio-temporal parameters or thorax kinematics ( $p > .05$ ). Greater thorax forward flexion was positively correlated with step initiation

latency in mCLBP group and the posterior peak force in healthy participants (Table 1).

**Figure 1:** APAs duration (left) and step initiation latency (right). \* $p < 0.05$ , \*\* $p < 0.001$ .

**Table 1:** Results of partial correlation analysis between sagittal thorax angular displacement ( $^{\circ}$ ) and each parameter during gait initiation.

	Healthy		CLBP	
	r	p	r	p
APA amplitude (mm)	-.12	NS	-.21	NS
APA duration (ms)	-.17	NS	.19	NS
Step latency (ms)	.15	NS	.45	<.001
Posterior peak force (N)	.45	<.001	.18	NS

### Conclusions

People with mCLBP initiate gait more cautiously than healthy controls by producing lower forces during postural preparation, as shown by the comparable APAs amplitude but the longer APAs duration. Interestingly, the longer step latency was positively associated with thorax forward flexion in participants with mCLBP, which suggests a link between APAs impairment and trunk motion, confirming the functional role played by the upper body in gait initiation. Taken together, these adaptations in postural preparation shown by people with mCLBP seem to be effective in preserving balance using a more cautious strategy, as shown by the lack of differences in the first step characteristics between this group and the healthy controls.

## Video game based kinematic assessment using a Leap Motion Controller

Dominik Buchmann<sup>1</sup>, Amartya Ganguly<sup>1</sup>, Katja Mombaur<sup>2</sup>

<sup>1</sup>Optimization, Robotics and Biomechanics, Institute of Computer Engineering, Heidelberg University

<sup>2</sup>Chair in Human-Centred Robotics & Machine Intelligence, University of Waterloo

Email: [d.buchmann@stud.uni-heidelberg.de](mailto:d.buchmann@stud.uni-heidelberg.de)

### Summary

Development of feasible assessment methods for hand kinematic analysis is of great importance in many clinical applications like physiotherapy and rehabilitation engineering. Motion analysis for kinematic assessments usually requires high end setups involving costly laboratory grade camera systems or similar detectors. Game based setups, using low cost consumer grade peripheral devices like the Xbox Kinect or the Nintendo Wii, promise repeatable and reproducible experiments for assessment. For this study a game for hand kinematic assessment was created which uses a Leap Motion Controller as the only tracking device needed. The game was then used to assess hand kinematics of the participants.

### Introduction

A game-based approach to capture and assess hand kinematics, using a Leap Motion Controller (LMC) as the main peripheral, was developed in [1]. The analysis focused on the performance of able-bodied subjects performing pick and place operations in the virtual environment using a pinch grip. Data was compared inter trial and inter participant as well as against data from available database [2]. The game was a virtual take on the standard peg-test (NHPT) [3].

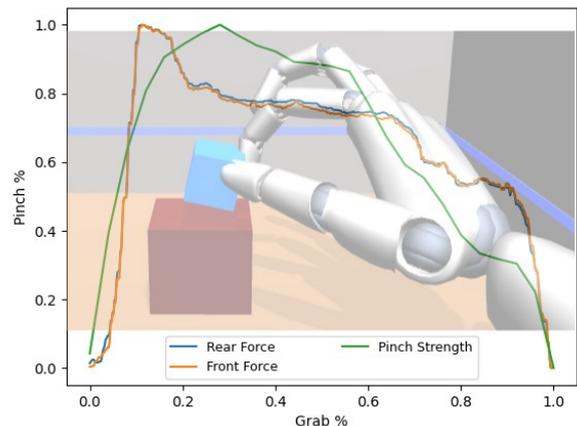

### Methods

Ten participants, age: 22,3 ( $\pm$  2), volunteered to take part in the experiment using only their stated dominant hand. Each participant was considered able-bodied in terms of being able to perform a pinch grip. Motion tracking was done using a well calibrated LMC in a portable setup with an estimated total latency of less than 100ms. Participants were shown a play through of the game but not given any rehearsal trials. Each participant then played the game three times whilst data was recorded for each trial and each participant separately. Data was timestamped, giving an overall time score, which also served as a secondary assessment of the participants motor skills.

### Results and Discussion

All participants were able to successfully complete the experiment showing the stability of this game-based setup. The pinch strength parameter, given by the LMC was found to have an inverse correlation with the distance between the index finger and thumb tips. Normalising the tracked Pinch Strength then allows it to be compared against an actual force measurement, (Figure 1). Both data indicates a rapid increasing in the beginning of the grip phase with an

overshoot. The adaption phase using the LMC is less quickly or sometimes missing most likely due to absent physical feedback. Participants in general were able to better their time scores from an average of 74.1 seconds ( $\pm$  39.69) to 38.6 seconds ( $\pm$  11.68). Which suggests an adaptation phase occurred regarding the task.

**Figure 1:** Course of the Pinch Strength compared against Force measurement on the iBox faces (Normalised) blended with a screenshot of the pick and place task in the virtual environment.

### Conclusion

Similar to assessments using the NHPT, participants on average, decreased their overall used time needed to solve the operations along the trials. Compared against data resulting from actual force sensors shows that the pinch strength is not to be taken as an actual measurement of force but rather as an indicator of the current pinch pose. Furthermore, the data suggest that visual feedback given by the game might replace the missing physical feedback to some extent.

### Acknowledgments

We thank all participants who volunteered for this experiment. We also thank our funders EIT Health 19340.

## A novel method to assess soft tissue overloading within the sole of the foot

Panagiotis Chatzistergos<sup>1</sup>, Nachiappan Chockalingam<sup>1</sup>

<sup>1</sup>Centre for Biomechanics and Rehabilitation Technologies, Staffordshire University, Stoke-on-Trent, UK

Email: [panagiotis.chatzistergos@staffs.ac.uk](mailto:panagiotis.chatzistergos@staffs.ac.uk)

### Summary

This study explores the potential use of measurements of altered tissue biomechanics for the detection of overloading within the plantar soft tissue with potential application in the management of the diabetic foot. Overloading was simulated by repeatedly loading the centre of the heel to the threshold of pain. Overloading caused measurable stiffening in the areas where pressure was most intense.

### Introduction

People with diabetes can gradually lose the protective sensation of pain in their feet leading to repeated overloading, diabetic foot ulceration (DFU) and even to amputation. In the absence of pain, soft tissue overloading is usually detected only after visible signs of DFU have developed and it is too late for effective prevention. This study aims to explore the possibility of detecting overloading based on the changes that overloading might cause in tissue stiffness.

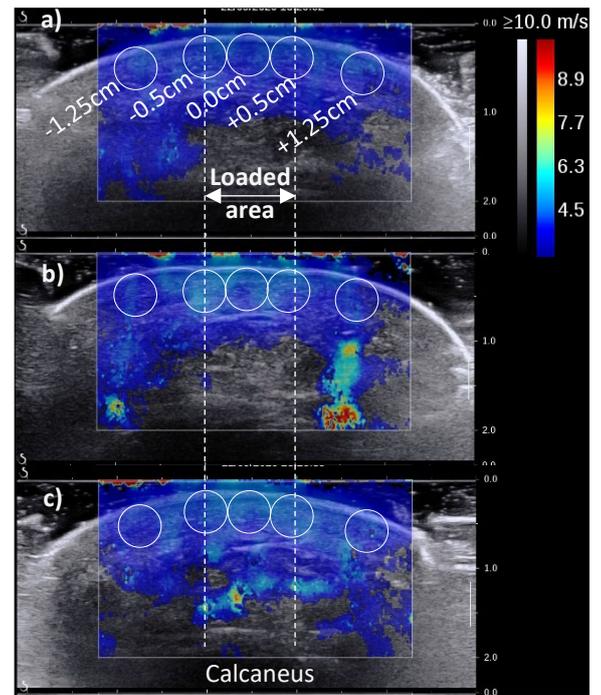

### Methods

Shear wave (SW) speed was measured (SL15-4, SuperSonic Imagine Ltd) in the axial plane at the centre the heel for 15 non-diabetic volunteers with normal sensitivity in their feet before and after overloading (age: 41y±10y, BMI: 26.8kg/m<sup>2</sup> ±5.7kg/m<sup>2</sup>). To minimise the effect of loading history the participants were asked to walk barefoot the length of the lab twice (~80 steps) before baseline imaging (Figure 1a). Overloading was imposed by pressing a small cylinder (diameter=1cm) at the centre of the heel with a hand-held dynamometer (500N Cytec) until the participant indicated pain, at which point the heel was unloaded. This loading process was repeated ten times before imaging the heel again (Figure 1b). Pressure pain threshold (PPT) was recorded for each cycle by dividing the applied force over the loaded area. To see whether any possible changes in SW speed could be eliminated by preconditioning, SW imaging was repeated after walking barefoot the same distance as before (Figure 1c). At the end, SW speed was exported for five circular areas (diameter=5mm): three in the loaded area and two outside the loaded area (±1.25cm from the centre) (Figure 1).

### Results and Discussion

Repeated measures ANOVA with Bonferroni correction for multiple comparisons revealed a statistically significant increase in SW speed in the left edge (position -0.5cm) of the loaded area which was not eliminated by walking (Table 1). Our previous work on the validation of SW elastography for the plantar soft tissue has indicated that changes in SW speed offer a reliable assessment of changes in initial stiffness[1]. Even though no other change in SW speed was statistically significant, a similar trend was also observed for the right edge

of the loaded area (position +0.5cm). Assuming a uniform distribution of loading the average (±STDEV) PPT for all participants was 0.55MPa(±0.36MPa). However, the pressure is likely to have been higher at the edges[2] which can explain the bigger changes in SW speed observed at the edges relative to the centre of the loaded area.

**Figure 1:** SW elastograms at baseline (a), after overloading (b) or after walking (c). The loaded area and circular areas for measuring SW speed at different distances from the centre are also shown.

**Table 1:** SW speed at different distances from the centre. Statistically significant changes relative to baseline are indicated with (\*).

Distance from centre (cm)	Baseline	Overloading	Overloading & walking
-1.25	5.96(±1.57)	6.19(±1.63)	5.84(±1.61)
-0.50	6.01(±1.15)	6.47(±1.24)*	6.33(±1.20)*
0.00	5.88(±1.13)	6.11(±0.98)	5.89(±1.03)
+0.50	6.18(±1.46)	6.53(±1.36)	6.28(±1.55)
+1.25	5.93(±1.72)	5.58(±1.58)	5.34(±2.15)

### Conclusions

Repetitive loading to the threshold of pain causes localised changes in tissue biomechanics which are detectable using SW elastography. Measurements of regional changes in SW speed could be used to study the effect of overloading on plantar soft tissue biomechanics.

## Friction coefficients of cancellous bone densified with autologous bone-particles in uncemented fixation

Sebastian M. Zobel, Miriam Ruhr, Michael M. Morlock

Institute of Biomechanics, Hamburg University of Technology (TUHH), Hamburg, Germany

Email: sebastian.zobel@tuhh.de

### Summary

A high bone volume to total volume ratio (BTV) is required in the close surrounding of uncemented implants as prerequisite for sufficient primary stability. This study investigated whether the friction against cancellous bone can be increased by densification with autologous bone-particles. Shear tests of native and densified samples against an implant-like surface were carried out. Densified samples showed a tendency of a higher static friction coefficient as well as a significant increase in sliding friction coefficient.

### Introduction

The successful osseointegration of uncemented implants depends on the resistance of the bone-implant-interface to micromotion [1]. Shear forces between implant and bone are of major interest and are associated with the bone quantity and quality at the interface [2]. This study investigated whether the friction coefficients of cancellous bone against an implant-like surface can be increased by densifying the intertrabecular pores with autologous bone-particles.

### Methods

Cancellous bone samples ( $n = 24$ ) were taken from 6 pairs of human femoral heads (age 65 - 77) using a hollow-core drill ( $\varnothing 25$  mm). One of each pair was densified while the other one was left native. For densification, 2 ml of trabecular bone particles - collected from the femoral heads - were quasistatically pressed into the testing surface ( $\sigma = 0.5$  MPa, Zwick/Roell, Germany). The testing surface was created by cutting the bone samples in half, creating two cylindrical, corresponding samples. Both corresponding samples were then densified or left native. The microstructure of the samples was analyzed using a  $\mu$ CT (Scanco Medical, Switzerland) to evaluate the amount and depth of the permeated particles. In the test setup, the corresponding samples were pressed symmetrically against an implant-like surface ( $\sigma = 0.5$  MPa; Figure 1).

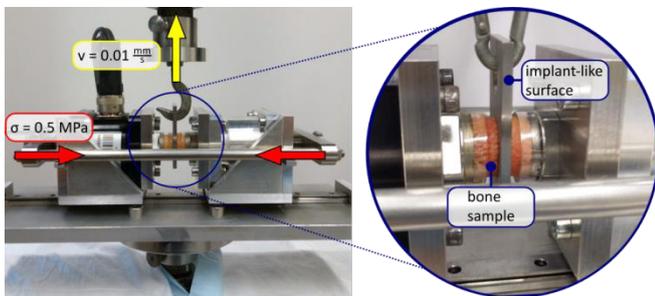

Figure 1: Experimental setup for shear testing of cancellous bone.

### Results and Discussion

The densification with bone-particles increased the BTV significantly ( $p = 0.002$ ). Increased BTV was associated with an increase in static ( $p = 0.002$ ,  $R = 0.814$ ) and sliding friction coefficient ( $p = 0.033$ ,  $R = 0.642$ ). The densified bone samples showed a tendency of higher static friction coefficient ( $p = 0.080$ ), but a significant increase in sliding friction coefficient ( $p = 0.043$ ; Figure 2) in comparison to the native samples.

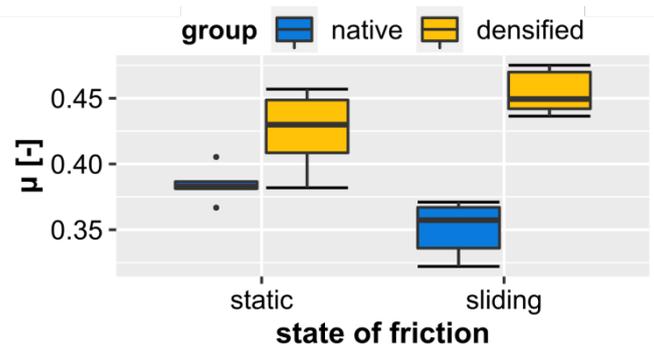

Figure 2: Boxplot of the static and sliding friction coefficients ( $\mu$ ) for the native and densified samples.

The densification depth was independent of the native BTV ( $p = 0.618$ ). The amount of densification decreased with increasing BTV ( $p = 0.041$ ). This resulted in higher densification for low dense bones. Though not significant, a negative correlation between the amount of densification and the increase in friction coefficients was found.

This might be due to the greater intertrabecular pores, in which bone particles clamp less under shear stress than in smaller pores. Hence, the increase in static friction might be a trend and the method of increasing friction coefficients with particle-based densification might be limited to medium dense bones. This needs to be further investigated.

### Conclusions

Densifying medium dense, cancellous bone with autografted bone-particles might be beneficial in increasing the primary stability of uncemented implants. The results are specific to the implant-like surface studied and friction parameters are highly dependent on the investigated system. Therefore, further experiments are required to specify these.

## A Finite Element Investigation of the Tunability of Non-Pneumatic Tyres for Wheelchair Use

### Summary

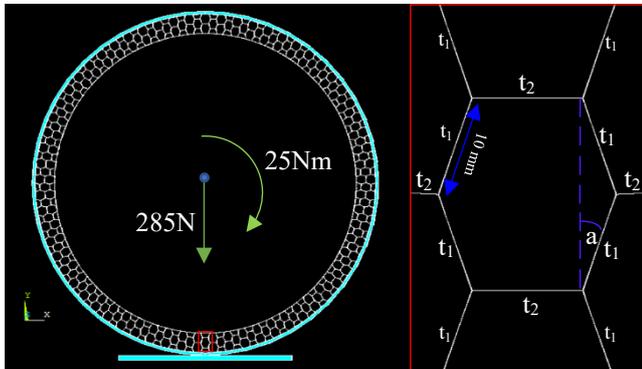

The ability to tune, to the specific needs of an individual, the vertical and shear stiffness of a wheelchair tyre can improve comfort and reduce user energy expenditure. This level of tuning is not possible with existing pneumatic tyres but could be achieved using novel Non-Pneumatic Tyres (NPT). This Finite Element (FE) analysis offers the first verification of the tunability of NPTs for use in wheelchairs.

### Introduction

A 1930s wheelchair had pneumatic tyres similar to the tyres used on wheelchairs today despite the disadvantages that have stayed the same for over almost a century [1]. These disadvantages include punctures, pressure maintenance and tuning [1]. Novel NPTs eliminate the first two disadvantages [2] and are also hypothesised to enable tuning vertical and shear stiffnesses separately (unlike pneumatic tyres) to create bespoke tyres that suit individual wheelchair user's needs.

### Methods

A parametric FE analysis was conducted using ANSYS software to test the tunability of NPTs. A wheelchair NPT was designed with similar dimensions to pneumatic tyres and a honeycomb spoke design [3](Figure 1).

**Figure 1:** The design of the wheelchair NPT model (left). The spoke design parameters used in the parametric analysis are also shown (right).

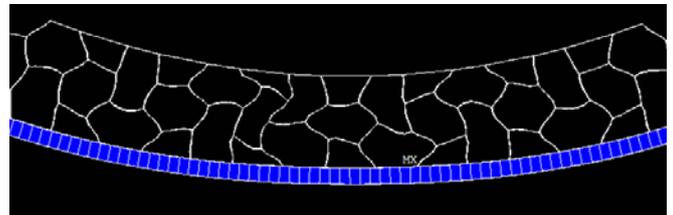

The parameters studied were internal angle ( $a^{\text{ref}}=19^\circ$ ); the thickness of parallel ( $t_1^{\text{ref}}=1\text{mm}$ ) and perpendicular ( $t_2^{\text{ref}}=1\text{mm}$ ) honeycomb plates to the radius. Parameters were adjusted to +/-10% of the reference values. A vertical force corresponding to 25% of an average person's body and wheelchair weight combined was applied to the tyre's central axis followed by a 25Nm rotational moment [4]. The vertical displacement (U) and rotation (R) of the central axis were used to assess changes in vertical and rotational stiffness respectively.

### Results and Discussion

Changes to the interior angle and uniform thickness of the honeycomb spokes altered both vertical and shear stiffnesses to almost equal measures. Changes in the different orientations of the honeycomb plates had a more noticeable impact on only one of the two stiffnesses. Changes in the thickness of the honeycomb plates almost parallel to the radius of the tyre had a large effect on vertical stiffness and an almost negligible change in shear stiffness when the thickness was altered. On the contrary changes in the thickness of the perpendicular plates had a stronger effect on shear stiffness (Table 1).

**Table 1:** Honeycomb plate thickness adjustments indicating a decoupling of the tunability of vertical and shear stiffness.

Plate Orientation	Plate Thickness (mm)	U (mm)	% Change	R (°)	% Change
Parallel ( $t_1$ )	0.9	-7.01	13%	-0.297	0%
	1.0	-6.21	-	-0.297	-
	1.1	-5.33	-14%	-0.300	1%
Perpendicular ( $t_2$ )	0.9	-6.26	1%	-0.313	5%
	1.0	-6.21	-	-0.297	-
	1.1	-6.03	-3%	-0.282	-5%

**Figure 2:** Buckling of the honeycomb spokes.

The loads applied to the tyre caused buckling of the honeycomb spokes (Figure 2). The non-linear mechanical response of the NPT means that optimal design will depend on the applied load magnitude. Further research is needed to develop a tuning method for wheelchair NPTs.

### Conclusions

The initial results have determined that vertical and shear stiffnesses of an NPT can be tuned separately through alteration of different oriented honeycomb plates, but further research should be conducted to determine if other parameters affect these stiffnesses and if they could reduce manufacturing complexity.

### Summary

The most common cause of failure of a shoulder joint prosthesis is loosening of the glenoid (scapular) component. The standardized test for evaluating glenoid loosening uses vertical displacement of the edges as a measure of loosening. However, laboratory experiments and finite element modeling studies have shown that the glenoid edge does not only move vertically, but also horizontally and with a rotational (tilt) motion. In this research an augmented ASTM test apparatus has been developed and tested that can measure all 3 types of motion of the glenoid edge, to better understand the behavior of the glenoid during loosening and hence inform future prosthesis designs.

### Introduction

Current shoulder joint prostheses most often fail due to loosening of the glenoid (scapular) component. This loosening is attributed to eccentric loading of the edges of the glenoid component [1]. The American Society for Testing and Materials (ASTM) set out a standardized test to evaluate glenoid loosening, in which the glenoid is cyclically loaded and the vertical displacement of the edges is measured.

However, laboratory experiments [2] and computational finite element modeling (FEM) studies [3] of the glenoid under load have reported that the edges not only deflect vertically, but also horizontally and with a tilting motion as the material of the component is deformed. Therefore, the ASTM standardized test does not fully quantify the glenoid reaction to loading. This could be the cause of high percentage of recurrence surgeries due to glenoid component failures. This study proposes an augmented ASTM test rig to investigate the effect of eccentric loading patterns on the glenoid component's loosening process.

### Methods

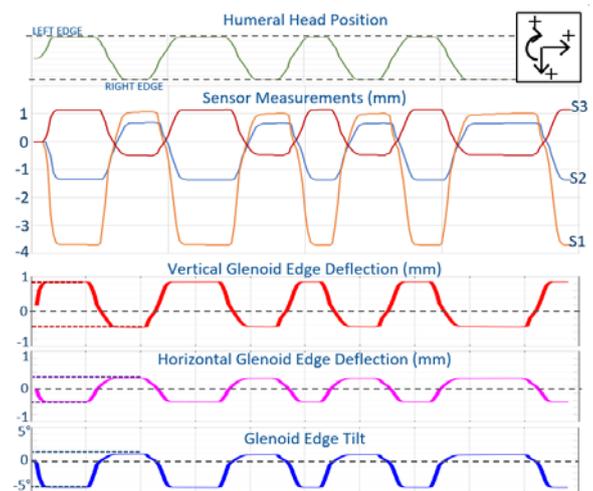

The augmented ASTM type test rig was developed with a specialized sensor assembly which can measure vertical, horizontal and tilt motions of the glenoid. The sensor assembly used two sets of 3 LDT sensors which track the motion of rigid blocks, connected to the glenoid edges by lever arms.

An analytical algorithm used the sensor readings to calculate the motion of the center of each block, which was then converted to glenoid edge motion. This algorithm was coded into MATLAB and was validated *in-silico* by means of a Solidworks motion simulation. Pilot tests were performed on a glenoid component installed in bone substitute foam. In the

pilot test horizontal motion of the humeral head component was controlled, and the associated horizontal, vertical and tilt motions of the glenoid edges were measured.

### Results and Discussion

The results show the sensor assembly system acquiring the three types of motion at the glenoid edge (Figure 1). In the figure the outputs from the three sensors on the left-hand block, connected to the left glenoid edge, are shown in relation to the position of the humeral head as it moved from the left to the right edges. These measurements were then converted to glenoid edge motion. The glenoid edge under load was compressed 0.8mm downwards (positive direction), 0.4mm horizontally to the left, and tilted outward by 5°. As the humeral head moved to the right edge, the left edge experienced tension, showing an upward motion of 0.4mm, a horizontal motion 0.4mm to the right and a tilt of 1° inward.

**Figure 1:** Sample results for four cycles of the humeral head from the left to right edge of the glenoid showing sensor measurements and corresponding glenoid edge deflection

### Conclusions

This pilot study serves as a validation of the functionality of the measurement system, which can now be used to investigate the loosening behavior of a novel glenoid design, developed at the UCT Orthopedic Biomechanics Laboratory.

## Robot-based method for analysis of knee prostheses in human cadaveric knees

Adrián Gómez, M. Nusser<sup>1</sup>, L. Kiener<sup>1</sup>, G. Tschupp<sup>2</sup>

<sup>1</sup>Biomechanical Engineering, Zurich University of Applied Sciences, Winterthur, Switzerland

Email: [adrian.gomezdiaz@zhaw.ch](mailto:adrian.gomezdiaz@zhaw.ch)

<sup>2</sup>Mathys AG, Bettlach, Switzerland

### Summary

A new robot-based method was developed and evaluated to investigate the functionality of different knee prostheses in vitro tests. A common method is the determination of the passive path, which describes a force- and torque-free knee flexion. This path provides the starting points for the stability tests. Using the robot as a reliable test device, the following requirements should be fulfilled: Automated determination of the force-free and torque-free state at 0° flexion and a high level of reproducibility and sensitivity. This study shows a new method to reliably find the starting point. To assess the measurement accuracy, 18 repetitions of a passive path were performed. To test the sensitivity, the passive path of a specimen was compared in the native state and with a medial side prostheses replacement. The new method meets all requirements for a reliable measurement and provides reproducible results.

### Introduction

Despite research efforts to improve the functionality of knee prostheses, epidemiological studies show that postoperative pain, instability or loosening of the prosthesis are common [1]. Therefore, it is imperative to test prostheses not only mechanically but also functionally. Based on another study [2] a new robot-based method was developed and evaluated to investigate the functionality of different knee prostheses in human cadaveric knees. By using the robot as a reliable test device, the following points should be fulfilled: Automated determination of the force- and torque-free point at 0° flexion, high reproducibility, and sensitivity.

### Methods

**Preparation for in vitro testing in CAD** 3D models are built based on CT scans of test specimen. Coordinate systems of tibia and femur according to Eckhoff et al. [3] and that of the robot clamp are defined and positioning adapters for the leg in the suspension cylinders are constructed.

### Preparation for in vitro experiments in the laboratory:

At a distance of 28cm and 12cm above and below the joint line the bone is cut, and soft tissue is removed, respectively. The 3D-printed adapter is fixed to the bone stumps for exact

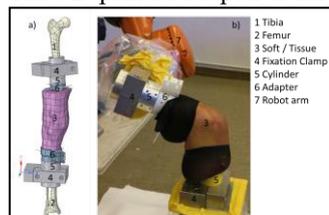

Figure 2: a) CAD-model, b) Robot set-up

positioning in the aluminum cylinder, which is filled with bone cement. The densities of the tibial tissue and the tibia are then determined experimentally.

**Finding the force-free state at 0° flexion:** The leg is clamped at 0° flexion. The load hanging on the robot arm can be calculated and is defined as a tare value in the robot program. The remaining forces at 0° degrees are the forces caused by the ligaments which the robot tries to cancel in order to obtain a force- and torque-free condition.

**Reproducibility test:** 18 passive paths of a medially and laterally supplied cadaveric knee were run through from 0° to 90° flexion while applying an axial load of 100N. The tolerances of the forces were 2.5N and of the moments 0.5Nm. **Sensitivity test:** A comparison of the passive path from 0° to 90° flexion of a specimen in the native state and with a medial knee prosthesis was performed.

### Results and Discussion

**Finding the force-free state at 0° flexion:** Due to the exact determination of the mass and density distribution, the starting point can be found reproducibly and leads to a higher quality of the results. **Reproducibility test:** The largest standard deviation of the 18 trials with respect to anterior and posterior tibial translation occurred at 28° and is 0.5mm. The standard deviation calculated for internal and external rotation amounts to 0.3° at 38°. To date, no other robot-based studies have published their reproducibility, so a comparison was not possible. **Sensitivity test:** The difference between the passive path of the two conditions was greater than the standard deviation of the repeatability measurement. This indicates that the robot measures sensitively enough to reliably test prostheses.

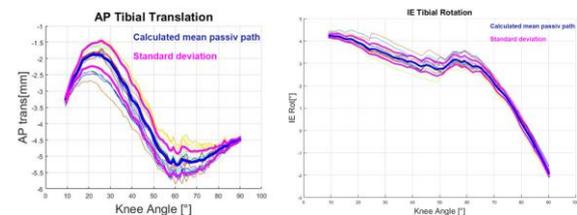

Figure 1: Left: Reproducibility of the anterior/posterior translation. Right: internal/external rotation during the passive path measurements displayed in knee coordinate system.

### Conclusions

The results show that the described new test method, is very accurate. The robot can be used to perform functionality tests and helps to increase the physiological quality of prostheses.

## Increased muscle activity in acoustic startle response among children with recurrent pain in the head/neck and abdomen due to chronic stress

Andersson <sup>1,2</sup>, Alfvén G<sup>3</sup>

<sup>1</sup>Laboratory of Biomechanics and Motor Control, Swedish School of Sport and Health Sciences, Stockholm, Sweden

<sup>2</sup>Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden

<sup>3</sup>Clintec, Karolinska Institutet, Stockholm, Sweden

Email: eva.andersson@gih.se

### Summary

With recorded EMG amplitude and time parameters, increased resting activity and potentiated acoustic startle responses were observed in the muscles involved in stress tender patterns among children with recurrent psychosomatic pain.

### Introduction

Children with recurrent pain of negative chronic stress origin from different locations have a characteristic pattern of tender points in the temporal, trapezoid, great pectoral and abdominal muscles. The aim was to study if acoustic startle reactions are higher, measured with increased EMG-responses, in muscles sites related to tender point pattern and the recurrent pain among those children as compared to healthy controls.

### Methods

Forty-two children of both sexes (10-17 years) participated, whereof 19 in a pain (PAIN) group and 23 in a control (CON) group (mean age 12,7 and 13,0 years, respectively). Acoustic Startle Responses (ASR) were elicited with a 50-ms-duration stimulus of unexpected short white noise (USWN) at 105 dB with an instantaneous rise time in both ears via headphones. The subject was laying supine on a bench in a calm milieu. The stimulus was controlled with a digital audio-stimulator. Eight ASR were given with varying time intervals, usually between 1.5 and 2.0 min, similarly for all subjects<sup>1</sup>. Surface EMG was recorded and analyzed (via Mega Electronic Ltd-system, Finland) for the six muscles OR-orbicularis oculi, TE-temporalis, TR-trapezius, PE-pectoralis major, RA-rectus abdominis and ES-erector spinae (L3-L4 level, 2-3 cm lateral to the spinal processes). The recording sites were similar to general tender point positions. The PAIN group had pain of "non-organic origin" recurring at least once a week for more than 3 months and affecting activity of daily life. Eighteen had abdominal pain in a mean of 37,2 (8-140) months all fulfilling diagnosis criteria of functional abdominal pain. All reported frequent headache, five backache and three shoulder pain. All described stress and anxiety problems and fulfilled six of

seven criteria for the diagnosis of psychosomatic pain<sup>2</sup>. Eighteen children had nine of nine stress tender points and one had seven<sup>3</sup>. One child had school-stress-induced depression. All the children met the same paediatrician specialist at several sessions until diagnosis. The matched controls were without recurrent pain problems and in general good health. Fifteen were enrolled from four school classes, and eight from personal contacts. Socio-economic status was comparable in the two groups.

### Results

The PAIN group showed significantly higher resting activity and higher acoustic startle response values ( $p < 0,05$ ), than the CON group, for all six muscles together regarding the mean amplitude in the initial 100 ms (Tab. 1), the initial 200 ms, and during the burst of activity (start  $\geq 10 \mu V$ , end  $\leq 10 \mu V$ ), as well as longer burst duration and shorter burst latency (ms). These results are based on average for all eight startle sound events (ASR) together. For PAIN compared to CON, all separate muscles showed generally higher values of EMG amplitudes and burst durations as well as shorter latencies for the burst onset in all measures with statistically significant differences or strong trends for several parameters and muscles.

### Conclusions

The results show in children and adolescents how recurrent pain of negative stress, origin from the head, abdomen, back and chest, is associated with increased acoustic startle reaction and increased muscle tension in these regions, shown with EMG amplitude and EMG timing parameters for six muscles in the body. This study, showing increased muscle excitability in children with stress-induced pain in the head, neck and abdomen, may contribute to the understanding of the mechanisms underlying the broad problem of recurrent psychosomatic pain.

### Summary

Wheeled walkers, or simply called rollators, are used to support and stabilize movements in less mobile older persons. However, it is still unclear, how the interaction between older adults and the rollator influences movement control and stability. Especially as recent findings show that rollators can also increase the risk of falling. Therefore, comprehensive biomechanical analyses in healthy young and older participants are required for a better understanding of human-rollator-interaction. Therefore, the purpose of this study protocol is to close this gap due to its novel design.

### Introduction

Falls are the primary cause of injury during daily life ambulation in older adults, with over 50% of people older than 80 years falling at least once a year [1]. Moreover, falls reduce the ability of independent living [1]. To enhance daily ambulation, rollators are prescribed to support and stabilize older persons [2]. Rollators are presumed to improve movement stability by increasing the base of support and to provide weight support by allowing the upper body to carry part of the body weight to compensate for lower limb weakness [2,3]. While these assumptions have yet to be experimentally validated [4], recent findings also show that rollators can actually increase fall risk [3]. The lack of biomechanical evaluation, including body movement and load transfer, is limiting our ability to understand this. As fall risk and human-rollator-interaction are task-dependent, it has been emphasized that analyses of various other movements (e.g., sit-to-stand) under normal and challenging floor conditions are required [3,4]. Therefore, height-adjustable force-sensing rollator handles, and a complicated set-up that allows for controlled measurement during different movement tasks and manipulations of the provided support, are necessitated for thorough biomechanical evaluation of rollator support.

Thus, the purpose of this study protocol is the comprehensive biomechanical analysis of human-rollator interaction with a novel instrumented robot rollator simulator device (Figure 1) in a young ( $n = 35$  years) and older group ( $n = 65$  years). The rollator simulator device allows for instrumented measurements of human-rollator interaction during different tasks, surface conditions, and different levels of support.

### Study Protocol

To evaluate the role of rollator support during various activities of daily living, the following tasks are included: stance, sit-to-stand, stand-to-sit, gait initiation, and straight walking. To disentangle the supportive role of touch (proprioception) versus weight assistance, the tasks are performed unassisted, with light touch of the handles, and

with full leaning on the robot-rollator-handles. To understand the stabilizing effects of rollators under greater perturbations, the young participants will also perform the tasks under more challenging surface conditions, using a balance-board during stance and a dual-task (counting backwards) during the other tasks.

Human-rollator interaction analysis will be based on:

- center of mass (CoM) displacements and reaction forces at the handles to analyze control mechanisms
- stability measures (e.g., stability margin) to evaluate influences of the rollator on user's stability;
- joint kinetics to analyze potential load reductions to the legs and load increase to the trunk and arms.

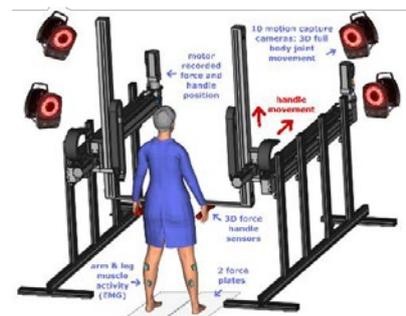

Figure 1: Robot rollator simulator device.

### Results and Discussion

Data collection of the younger ( $n = 15$ ) and older ( $n = 10$ ) study group will be conducted up to May 2021. The generated data set will allow us to understand the stabilizing effect of full rollator support versus light touch support during various movement tasks under normal and challenging floor conditions. These findings will help to increase the user guidance for conventional rollators currently used by older adults. Furthermore, the results will also contribute to the development of assistive devices for a broader scope of movements in our continuously ageing population.

## Summary

Flexion active range of motion (AROM) of thumb joints and the functional one (FROM) of 35 osteoarthritis (HOA) patients were compared with those of healthy subjects, to determine the impact of range of motion changes on hand function. AROM and FROM were measured with a Cyberglove, and FROM were computed for the angles used while performing the Sollerman Hand Function Test (SHFT). 37% of HOA patients presented an AROM reduction of CMC flexion larger than 30%. For them, an impact larger than 30% was estimated in 6 ADL, with longer execution times but only slightly lower SHFT scores. The sum of flexion AROM values of the thumb joints was also analyzed to consider inter-joint compensation. Although partial compensation was detected, it was not enough to overcome functional problems.

## Introduction

It has been proposed [1] inferring the functional impact of mobility reduction in joints caused by hand diseases through the analysis of the joint angles of healthy subjects while developing activities of daily living (ADL). However, due to the complexity of hand kinematics, motion of other joints might compensate the loss of mobility. In this work, we compare the flexion ranges of motion of thumb joints of hand HOA patients to those of healthy subjects and analyze the impact of range of motion changes on hand function.

## Methods

AROM and FROM of the right-hand thumb were measured to 35 HOA patients using a Cyberglove (carpometacarpal - CMC-, metacarpophalangeal -MCP- and interphalangeal -IP-joints). FROM was computed as percentiles 5% and 95% of the angles used while performing the SHFT tasks. ROM, FROM and sum of flexion AROM of the three joints (sROM) were compared to those of healthy subjects [1, 2]. The functional impact in ADL was estimated according to [1] and compared to real functionality measured through the SHFT scores and times to develop each task.

## Results and Discussion

37% of HOA patients (subsample A) presented an AROM reduction in CMC flexion larger than 30%. Table 1 shows AROM and FROM of healthy subjects ( $37.83 \pm 8.07$  years) and subsample A ( $69.9 \pm 11.2$  years). These patients with reduced AROM in CMC flexion present a reduction in IP flexion, as well as in FROM values in these joints (CMC and IP), but larger FROM in MCP flexion, to compensate for the constraints in the adjacent joints. This compensation may be

the origin of structural changes at MCP joint, which becomes into larger flexion AROM. However, this larger flexion does not compensate for the total sROM (Table 2) and is not enough to overcome functional problems, as patients needed longer times (Table 2) to execute those tasks where a functional impact was expected according to [1]: zipping and unzipping (T1), turning the handle (T2), fastening and unfastening buttons (T3), cutting with knife (T4), writing (T5), and pouring water (T6). Patients' age may have also contributed to these longer times [3]. However, SHFT scores are similar (Table 2).

**Table 1:** Statistics across subjects of AROM&FROM of patients of subsample A and healthy subjects, in degrees. Extension (E), Flexion (F), and abduction (A).

			CMC			MCP		IP	
			E	F	A	E	F	E	F
A R O M	Patients Subsample A	Mean	30	8	23	28	30	31	47
		Sd	8	6	3	8	14	19	14
	Healthy subjects [1]	Mean	26	42	20	21	26	37	75
		Sd	17	10	4	12	9	15	20
F R O M	Patients Subsample A	Mean	32	31	23	16	23	44	31
		Sd	2	8	0.5	4	3	4	2
	Healthy subjects [2]	Mean	21	38	23	20	16	37	42
		Sd	8	2	1	3	4	4	2

**Table 2:** Statistics across subjects of patients of subsample A and healthy subjects: execution time of tasks, sROM and SHFT scores.

		Execution time (s)						sROM (deg)	SHFT score
		T1	T2	T3	T4	T5	T6		
Patients Subsample A	mean	13	4	26	21	17	25	86	69.15
	sd	4	1	10	11	13	5	19	10.17
Healthy subjects	mean	8	3	22	11	6	21	170	72.15
	sd	2	1	6	3	1	3	23	2.20

## Conclusions

Estimating the impact of AROM reduction from data of healthy subjects successfully identified which ADL were affected, as clearly longer execution times were found in all those tasks. Conversely, the SHFT scores hardly identified the functional problems, as they were only slightly diminished.

### Summary

Patients with total knee arthroplasty (TKA) and therapists fear overloading of the operated limb due to higher loads in sports. We showed that 5-14 month after surgery in field knee kinematics during downhill hiking and knee surrounding muscle strength in TKA patients were different from healthy controls (CON). Further muscle strengthening is recommended prior to return to hiking.

### Introduction

Persons with TKA show kinematic differences during level walking and muscular impairments of the quadriceps and hamstrings muscles after surgery, as reported in laboratory studies [1,2]. Although an active lifestyle is recommended after TKA [3], potential kinematic deficits have not yet been investigated in field. Hiking is one of the most popular activities in the elderly. However, especially downhill walking is a challenging task for the knee joint and the surrounding musculature. We investigated the in field downhill walking kinematics during a hike in persons with TKA 5-14 months post-op and an age-matched CON in relationship to the muscle strength of the knee flexors and extensors.

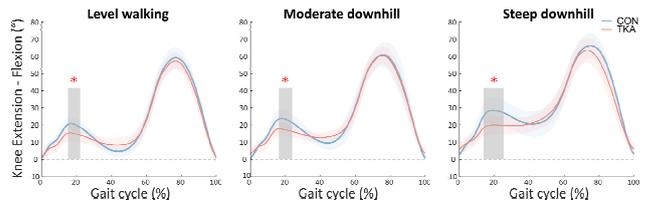

### Methods

Participants walked on a predetermined walking trail at self-selected pace wearing an inertial sensor system (XSens, Awinda, Enschede, Netherlands) for recording the 3d kinematics of the whole body. We evaluated sagittal plane hip, knee and ankle joint angles over the gait cycle at level walking and two different slopes. In addition, we measured the concentric and eccentric lower extremity isokinetic muscle strength of the knee flexors and extensors (Isomed2000, D. & R. Ferstl GmbH, Hemau, Germany) at two angular velocities (50°/sec, 120°/sec).

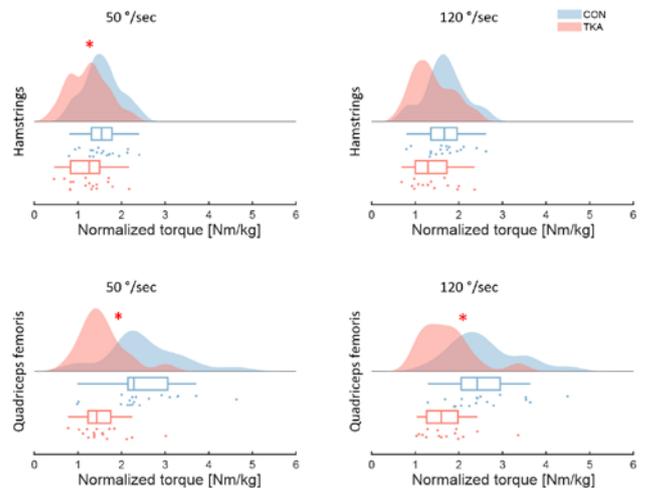

### Results and Discussion

TKA patients (n = 19) had more extended knees during stance in the operated limb than CON (n = 19) under all walking conditions (p < 0,02). Differences rose with steeper slopes (Figure 1). Hip and ankle joint angles did not differ between the groups. Muscle strength was lower in TKA for both muscle groups and all measured conditions (Figure 2). The hamstrings to quadriceps ratio (H/Q) was higher in TKA than in CON for the operated resp. weak limb (50°/sec: TKA 86,82 ± 21,84; CON 66,98 ± 18,45; p = 0,01; 120°/sec: TKA 93,57 ± 22,94, CON 77,96 ± 24,00; p = 0,05). H/Q at 120°/sec correlated with maximum knee flexion angle during stance while walking downhill at moderate slope in the TKA

group (p < 0,02), showing lower maximal flexion with higher ratio.

**Figure 1:** Sagittal knee joint angles over gait cycle during level, moderate, and steep sloped walking in TKA (red) and CON (blue). Gray areas display phases of significant differences (\*p < 0,02).

**Figure 2:** Raindrop plots, boxplots and distribution of single datapoints of normalized eccentric maximum torque (Nm/kg) of Hamstrings and Quadriceps at 50°/sec and 120°/sec in the operated limb of TKA (red) and weak limb of CON (blue) (\*p < 0,05).

### Conclusions

Even if rehabilitation was completed successfully, 5-14 month after TKA surgery muscle strength was still not sufficient to display normal gait pattern during downhill hiking. Further muscle strengthening after rehabilitation is recommended prior to return to hiking to prevent overloading.

Email: karinestoelben@gmail.com

### Summary

Here we investigate the potential of clinical tests to predict knee valgus kinematics during unilateral landing tasks in recreational male athletes. Lateral step down test, star excursion balance test, single and crossover hop test explain up to 26% of knee valgus in the preferred leg. Triple hop test explains up to 15% of knee valgus in the non-preferred leg. Clinical tests have the potential to be used as a screening tool for knee valgus kinematics.

### Introduction

The risk of athletic knee injury is typically assessed in biomechanical laboratories, which can be time-consuming and expensive. Clinical tests can assess performance, quality of movement, and dynamic balance to guide clinical decisions [1]. However, the relationship between performance in clinical tests and knee valgus during unilateral drop landing, often a source of knee injury, is currently unclear. In this study, we determine whether performance in clinical tests can predict knee valgus during a unilateral landing task.

### Methods

Forty-seven recreational athletes (24±3 years old, 80±13 kg of body mass, 177±6 cm of height) completed a battery of clinical tests and had 3D kinematics and kinetics measured during a drop jump task. Clinical tests were the Lunge, lateral step down (LSD), single, triple, and crossover hop tests, star excursion balance test (SEBT), knee flexor and extensor strength, and hip abductor and adductor strength (hand-held dynamometer). During unilateral drop jumps (preferred and non-preferred legs) 3D kinetics and kinematics were sampled at 2000 Hz and 200 Hz, respectively. Knee valgus angle was determined at initial contact (threshold of 20 N), at peak knee flexion, as well as for peak and range of motion values. The local institutional ethics committee approved this study (protocol number: 96793518.3.0000.5323). Pearson's or Spearman's tests were performed to examine the correlation between the dependent and independent variables. When  $p \leq 0.20$  was present, stepwise multiple regression analyses were performed for each dependent variable. The global effect sizes ( $f^2$ ) were also computed and interpreted as small  $\geq 0.02$ , medium  $\geq 0.15$ , and large  $\geq 0.35$ .

### Results and Discussion

The clinical tests explained up to 26% of knee valgus angle variance (Figure 1). A larger prediction was found for the preferred leg mainly at initial contact (Figure 1A) and for peak values (Figure 1E).

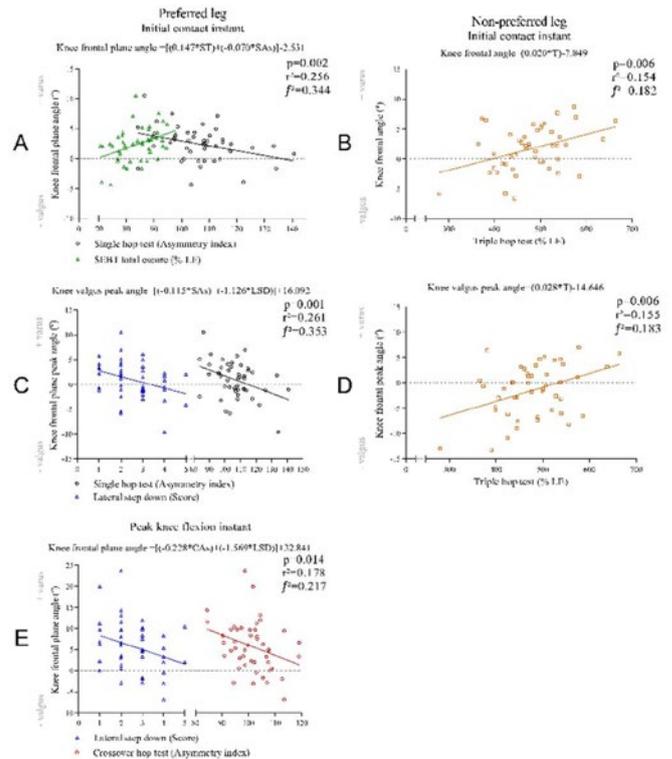

Figure 1: Knee valgus predicted by clinical outcomes.

The clinical test might be chosen according to leg preference. Preferred leg predictions combined one test of performance with one of quality of movement or dynamic balance, while non-preferred was predicted only by the performance test. The preferred leg may generally be recruited for actions requiring force and mobility, while the non-preferred leg may be more recruited for stabilization tasks [2].

### Conclusions

Different combinations of clinical tests can predict up to 26% of knee valgus angle variability for preferred and non-preferred legs during unilateral landing tasks.

### Acknowledgments

The authors acknowledge the funding from Conselho Nacional de Desenvolvimento Científico e Tecnológico.

# INFLUENCE OF MANDIBULAR RECONSTRUCTION EMPLOYING ILIAC CREST FLAP AND FIBULA FLAP ON THE LONG-TERM GAIT OF PATIENTS

Susanne Skiba<sup>1</sup>, Sybele E. Williams<sup>1</sup>, Florian Peters<sup>2</sup>, Frank Hölzle<sup>2</sup>, Catherine Disselhorst-Klug<sup>1</sup>, Ali Modabber<sup>2</sup>

Email: skiba@ame.rwth-aachen.de

## Summary

In maxillofacial surgery, facial bone defects are often reconstructed using autologous implants from the lower extremity. 43 patients, who underwent mandibular resection (22 iliac crest flap, 21 fibula flap) were assessed using clinical gait analysis on three different dates (preoperative, 3 - 14 months postoperative and 6 - 33 months postoperative). The results showed that changes in range of motion (ROM) of the patients in the iliac crest flap cohort persisted after an average of 16 months in all the joints considered, while patients in the fibula flap cohort primarily retained an increased ROM in the pelvis over a comparable period.

## Introduction

Reconstruction of bony and soft tissue defects in the facial region after tumor disease or accidents is vital for patient functionality and welfare. In mandibular resection, facial bone defects are often reconstructed using autologous implants from donor sites in the lower extremity.

Previous studies have analyzed the influence of the donor site on gait in terms of pain, clinical scores, and parameters e.g. gait speed, cadence, step length, and range of motion (ROM) [1, 2]. However, a comparison with healthy gait patterns was missing. By assessing patients and their age-matched cohort this study aims to determine the influence of the selected donor site during mandibular resection on patients' postoperative kinematics and the long-term changes in the gait pattern.

## Methods

Forty-three patients were divided into 2 cohorts based on the donor sites selected during mandibular resection. The iliac crest flap cohort consisted of 22 patients (16 male, 6 female, avg. age  $56 \pm 14$  years), and the fibula flap cohort consisted of 21 patients (12 male, 9 female, avg. age  $51 \pm 16$  years). The clinical gait of both cohorts was analyzed at one preoperative and two postoperative (median 3 - 7 months, median 13 - 14 months) appointments in a motion analysis laboratory. Using the Plug-in-Gait model (Vicon Nexus) the ROM for the pelvis, hip, knee and foot was calculated and normalized to a baseline composed of 203 steps from an age-matched healthy collective (121 male, 82 female) under identical conditions. Initial changes in gait were determined based on the difference between the first post- and preoperative appointments. Long-term effects were determined from the difference between the second post- and preoperative appointments.

## Results and Discussion

The results of the ROM for each joint in the sagittal plane are summarized in Figure 1.

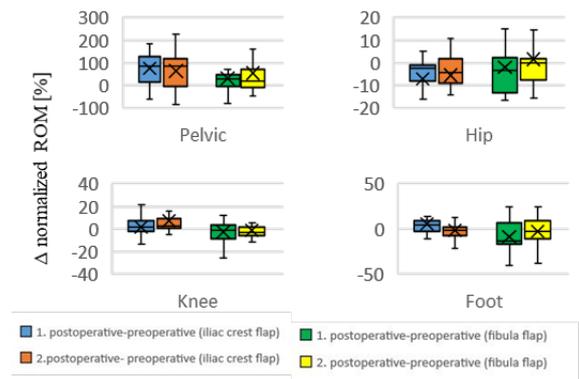

Figure 1: Differences in normalized range of motion (ROM) for 4 lower extremity joints (sagittal plane).

In the case of resection using iliac crest flap, patients showed a significant reduction in ROM postoperatively in the hip joint. Due to movement deficit, the ROM in the pelvis and knee joint significantly increased. In the long-term comparison, the ROM in the hip joint continued to reduce and the ROM of the pelvis and knee joint continued to increase. Patients in the fibula flap cohort showed a reduced ROM in dorsal plantar flexion due to the removal of muscular tissue. Movement compensation in the fibula flap cohort occurred primarily through increased pelvic tilt. With increasing time, the reduced ROM for dorsal plantar flexion regressed, but an increased pelvic tilt remained.

## Conclusions

Mandibular resection with iliac crest flap led to a long-term change in the gait pattern for the pelvis, hip and knee joints. Resection with a fibula flap resulted in a sustained pelvic tilt in the sagittal plane.

### Summary

Hand function is impaired in patients with rheumatoid arthritis (RA) [1]. In addition to traditional methods for assessing hand function, optical measurements [2] can be used to observe changes occurring at the musculoskeletal level. We leverage marker-based measurement techniques to measure hand function [3] in healthy control participants and RA patients in a pilot study to determine relevant hand movements, which allow to differentiate between RA patients and healthy controls based on hand motion characteristics.

### Introduction

Conventional assessment of lower musculoskeletal function in patients suffering from RA is performed by either questionnaires or basic functional test such as isometric grip strength or the Moberg-Picking-Up Test (MPUT) [3]. These can be aided with state-of-the-art technologies such as optoelectronic measurement systems (OMS) to quantify hand motion by tracking optical passive markers while performing the functional tests and activities of daily living. The aim of this study was to design an experimental setup that allows identifying differences in hand motion between healthy individuals and RA patients.

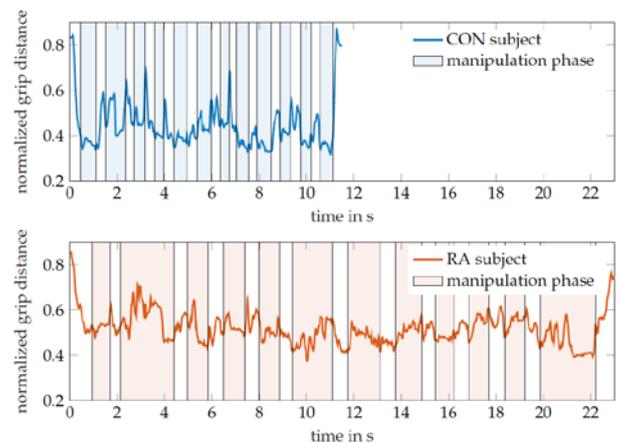

### Methods

Patients diagnosed with rheumatoid arthritis and healthy control subject without known musculoskeletal disease participated in this study. Hand segments movement was recorded using a 29-marker set up, inspired by [2], with changes to tracking of thumb metacarpal. The subjects were instructed to perform a set of motions. Here, we focus on the performance of grip strength and MPUT, performed in the clinical setup (without markers) and with the OMS setup. Additionally, two simple motions of index and little finger tapping by metacarpal joint hyper-extension with a high frequency are performed and tracked by the use of a single marker on either fingertip. Differences in hand function between the two groups were modelled using a mixed-effects regression model with the person as a random effect. P-values < 0.05 indicate a significant difference in the respective outcomes between RA and Control participants.

### Results and Discussion

Results are presented from measurements of 64 hands (35 healthy control hands and 29 RA patient hands) of 47 individuals. RA patients needed longer (mean  $\pm$  standard deviations) to complete the MPUT compared to controls in both the clinical (RA:  $17.5 \pm 4.7$  s, Control:  $14.1 \pm 4.1$  s,  $p = 0.004$ ) and the OMS setup (RA:  $20.3 \pm 7.1$  s, Control:  $16.0 \pm$

$4.5$  s,  $p = 0.007$ ). This increase in MPUT times when hand are equipped with markers is similar for control subjects and RA patients. Additionally, we show the normalized grip distance (distance between index and thumb tips, divided by the respective finger lengths) for a healthy control and an RA patient, as shown in Figure 1. The values for the distance between index and thumb fingers are  $0.45 \pm 0.11$  and  $0.52 \pm 0.07$  for the control individual and an RA patient, respectively. This suggests that the control individual was able to maintain the two fingers closer (lower mean), and was able to perform prehension with a higher degree of mobility (higher standard deviation), when compared with the RA patient.

**Figure 1:** Normalized grip distance for a healthy control and an RA patient.

### Conclusions

The use of OMS to assist in the characterization of hand movement opens new avenues in the characterization of hand motion in RA. The differences observed in the time to completion for the functional tests when using optical markers suggests the need of marker-less technologies.

**Summary**

Fragile Syndrome (FXS) is a genetic condition, mainly characterized by intellectual disability, behavioral problems and musculoskeletal alterations. Somatic mosaicism for pre and full mutation, can be a strong phenotype modulator of the FXS clinical manifestations [1]. This project aims to investigate association between abnormal motor control in FXS subjects with classical full mutation of the FMR1 gene (FX-FM) and the ones who carried a full mutation with mosaicism (FX-M). For this purpose kinematics and surface electromyography (sEMG) were acquired within standard clinical ambulatory conditions. Results showed reduced range of all lower limb joints in both groups and multiple activations of GL during gait in FX-FM subjects.

**Introduction**

FXS is the leading form of inherited intellectual disability and autism spectrum disorder, caused by a tri-nucleotide CGG repeat expansion in the promoter region of the FMR1 gene [1]. In FXS children characteristic musculoskeletal manifestations, which include hypotonia, joint laxity and flexible flat feet [6], may lead to non-physiological gait patterns [2], that justifies a referral for gait analysis. The aim of the present study was to identify the relationship between observed musculoskeletal manifestations and altered motor control in FXS children. Furthermore the presence of differences in motor control between FX-FM and FX-M was investigated. For this purpose kinematics and sEMG were acquired within standard clinical ambulatory conditions and sagittal plane kinematics and both duration, onset and offset of muscle activity during gait cycle were estimated.

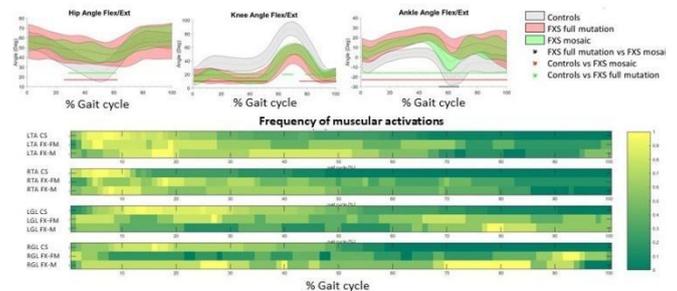

**Methods**

After appropriate informed consent by the parents, 12 FXS children, of whom 7 FX-FM (mean±SD age and BMI respectively of 9,57±2,51 years and 18,97±5,54 Kg/m<sup>2</sup>) and 5 FX-M (mean±SD age of 9,00±3,74 years and 18,70 ±2,61 BMI of Kg/m<sup>2</sup>) and 19 controls ((CS) mean±SD age of 9,68±2,90 years and 21,52±4,61 BMI of Kg/m<sup>2</sup>), were evaluated at the at the BiomovLab and at the Women and Children Health Department (University of Padua). Kinematics and sEMG data were simultaneously acquired through 4 synchronized cameras (GoPro Hero3, 30fps) and an sEMG system (8 channels FreeEmg, BTS, 1000Hz) that collected the activity of Tibialis Anterior (TA), Gastrocnemius Lateralis (GL), Rectus Femoris (RF) and Biceps Femoris (BF). Each subject performed several gait trials and at least three trials per subject were processed.

Sagittal plane kinematics was obtained as in [3] and hip, knee and ankle flexion/extension joints rotations were computed together with spatio-temporal parameters; in terms of sEMG analysis duration of contraction and onset and offset activation timing was obtained [4].

**Results and Discussion**

Results consistently showed the presence of an altered muscle activity (Fig. 1): joint kinematics highlighted a reduced range of motion of all the lower limb joints in both FX-FM and FX-M, while onset and offset activation timing revealed that FX-FM subjects continuously activated and deactivates GL throughout the gait cycle, FX-M subjects displayed a muscle activity closer to controls.

**Figure 1:** Top: Ankle, knee, hip sagittal plane angles in CS, FX-FM and FX-M groups. Bottom: Frequency of TA and GL activation in CS, FX-FM and FX-M subjects horizontal bars are color coded as in [5], according to the number of subjects in which muscle activity at each % of gait cycle is observed yellow: muscle activity is detected in all subjects, dark green: muscle is not active.

**Conclusions**

Results suggest that FX-FM subjects adopt a muscle compensatory mechanism to cope with the reduced range of motion in the lower limbs. The muscle alterations found in FX-M are milder than in FX-FM. Application of gait analysis in FXS subjects can be a useful tool to plan rehabilitation therapies.

<sup>1</sup>The University of North Carolina at Charlotte, NC, <sup>2</sup>OrthoCarolina, NC, USA

Email: nzheng@uncc.edu

### Summary

Posterior Stabilized TKA Implants are designed to be more kinematics consistent in the sagittal plane, but may also have impacts on biomechanics in the frontal plane. This study is to investigate the knee joint biomechanics of two popular PS implants (Journey II, Persona) in frontal plane for level walking and stair ascending. No significant differences were found between two implants and it is concluded that different PS implants have similar effect on frontal biomechanics.

### Introduction

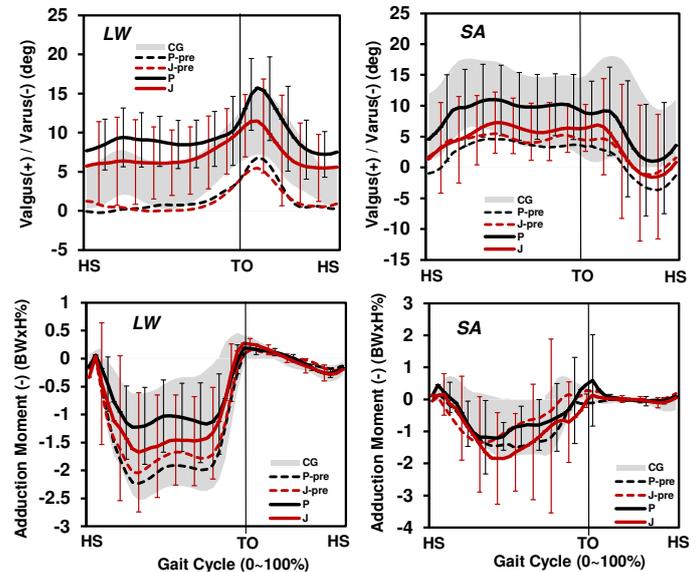

Abnormal valgus or varus positioning of the tibial component of a total knee arthroplasty (TKA) implant may cause increased possibility for loosening or implant wear and eventually lead to a revision surgery [1]. Adducting moments applied to the knee caused lift-off of the lateral femoral condyle from the bearing and increased the tendency toward dislocation [2]. The aim of this study was to compare the varus/valgus angle and loading of operated knee in level walking (LW) and stair ascending (SA) between two posteriors stabilized (PS) TKA implants - Persona (P) and Journey II (J), with the healthy control (CG). We hypothesized that there were no significant differences in varus/valgus angle and adduction/abduction moment of the knees with these implant at 6-month post-op during daily activities.

### Methods

20 patients with Journey II implant and 20 patients with Persona implant were recruited and tested pre-op and some of them also tested at 6 months post-op. Due to the pandemic, only 10 patients with implant J and 8 patients with implant P and 11 healthy subjects (CG) were included in this study. All the knees in group P were done by the one surgeon and the group J was performed by the other surgeon. A 10-camera motion capture system (FX 40, VICON) was used to record motion data at 120 Hz. Two force plates (AMTI) were used to record ground reaction force at 1200 Hz. Subjects were instructed to perform each activity five times at a self-selected pace. A custom-developed and validated MATLAB program was used to perform the kinematic analysis. One-way ANOVA was performed (SPSS 21).

**Table 1:** Maximum knee valgus angle (deg) and adduction torque (BWxHt%) at 6-month post-op during level walking and stair ascending. \*: significant difference between two implants.

	Level Walking			Stair Ascending		
	P	J	CG	P	J	CG
Valgus	16±4	13±3	15±2	13±4	11±5	14±4
Torque	1.5±0.7	1.9±0.7	2.0±0.8	1.7±0.8	2.3±0.8	1.7±0.3

**Figure 1:** Knee varus/valgus (deg) and adduction/abduction moment (BWxHt%) during LW and SA.

### Results and Discussion

No significant differences were found between two implant groups. Both groups exhibited similar valgus trend at 6-month post-op in LW, the maximum valgus angle of group P had greater changes than group J when the pre-post differences (P: 12±4, J:9±4, p=.11) were compared (Fig.1). The adducting moment of group P and group J were within the CG's range in LW. Neither group P or group J had the significant improvement during stair ascending. Considering stair ascending is the more demanding activity, muscles strength may not robust enough to perform it well at 6 months post-op. Further investigation on longer follow-ups of TKA patients may explain better in frontal plane knee biomechanics during daily activities. The findings suggested our hypothesis was approved, as there was no significant difference between the implant groups.

### Conclusions

The PS TKA designs had similar influence on knee biomechanics in the frontal plane. The functional improvement at post-op would depend on demanding levels of daily activities.

# The effect of diabetic peripheral neuropathy on lower limb biomechanics: a systematic review and meta-analysis

Erica Bartolo MSc<sup>1</sup>, Claudia Giacomozzi PhD<sup>2</sup>, David Coppini MD<sup>3</sup>, Alfred Gatt PhD<sup>1</sup>

<sup>1</sup>Faculty of Health Sciences, University of Malta, Msida, MSD 2080, Malta

<sup>2</sup>Department of Cardiovascular Diseases, Dysmetabolic Diseases & Ageing, Italian National Institute of Health, Rome, Italy

<sup>3</sup>Diabetes & Endocrinology, Mater Dei Hospital, Msida, MSD 2080, Malta

E-mail: erica.bartolo.08@um.edu.mt

## Summary

A systematic review and meta-analysis was performed to evaluate the effect of diabetic neuropathy on lower limb joint kinematics, kinetics, muscle activity and spatiotemporal parameters and their relationship to plantar pressure distribution. Sixteen studies fit the inclusion/exclusion criteria for qualitative synthesis and twelve studies were eligible for meta-analysis. Results show that, as a result of neuropathy, there may be decreased range of motion in the knee and ankle joints, resulting in limited dorsiflexion of the foot during heel strike and a resultant increase in peak plantar pressures during gait. However, overall, the current level of evidence is not sufficiently robust to determine whether altered gait patterns in individuals living with DPN are altering plantar pressures during gait and increasing the risk of ulceration. Further investigations are required to decrease heterogeneity in research.

## Introduction

In the presence of diabetic peripheral neuropathy, plantar ulceration occurs on high plantar pressure areas due to the repetitive, excessive mechanical loadings which causes tissue breakdown. Through this systematic review and meta-analysis, it is hoped that the underlying mechanism of what causes tissue breakdown is understood by looking into the effect of neuropathy on lower limb joint kinetics and kinematics, muscle activity and plantar pressures.

## Methods

A systematic literature search was done for studies published between January 2000 and June 2019, evaluating the effect of diabetic peripheral neuropathy on hip, knee, ankle and foot joint kinematics and kinetics, spatiotemporal parameters, electromyography and plantar pressures during gait.

Following a quality assessment of the sixteen studies included in this review, qualitative analysis and meta-analysis was performed on these outcome measures.

## Results and Discussion

The qualitative and meta-analysis results in this review suggested that participants living with diabetic peripheral neuropathy exhibited reduced knee, ankle and rearfoot (Sha-Cal) kinematics, higher midfoot and rearfoot peak plantar pressures and higher PTI in the medial forefoot, lateral forefoot and midfoot regions. However, conflicting results were present between studies with regards to the spatiotemporal parameters and lower limb muscle activity. Further research is required, including larger sample sizes, to decrease heterogeneity of the meta-analysis results since there is paucity of information on the effect of diabetic peripheral neuropathy on the outcome measures assessed. Literature states that diabetic peripheral neuropathy may cause a decreased range of motion in the knee and ankle joints. This may produce inadequate dorsiflexion of the foot during initial stance phase of gait, thus redistributing plantar pressures to the midfoot and forefoot regions for longer periods during gait, resulting in tissue breakdown. Further research, examining the outcome measures assessed in this review in the presence of active ulceration, might offer a better understanding as to the underlying pathomechanics of tissue breakdown.

## Conclusions

A clear understanding of the underlying biomechanical mechanism of the altered mechanical loadings might provide more accurate, patient-specific treatment options of ulceration and reduce the risk of reulceration and amputation rates in individuals living with diabetic peripheral neuropathy.

### Summary

There is a need for clinical systems that objectively assess the mobility of the upper extremities. Therefore, the aim of this study was to study the test-retest reliability of a portable motion analysis system in a small group of people with obstetrical brachial plexus palsy (OBPP).

### Introduction

To decide if an intervention has improved the arm function for a person with OBPP, it is important that there the instrument is sensitive enough to measure changes in upper limb mobility.

In clinical practice, assessment of upper limb mobility is usually based on visual estimation and use of goniometers. The visual estimations result in scores on different scales, such as the modified Mallet scale (MMS) [1] and the Active Movement Scale [2], but these visual methods to measure elbow and shoulder angles do not correlate well to objective methods such as 2D movement analysis [3].

A technique to measure mobility of the shoulder that has been developed in the last decade is motion analysis with inertial measurement units (IMUs) containing accelerometers, gyroscopes and magnetometers [4]. This is a portable system that is non-invasive and requires no equipment other than the sensors and a computer. The aim of this study was to study the test-retest reliability of a portable motion analysis system based on IMUs in a small group of people with OBPP.

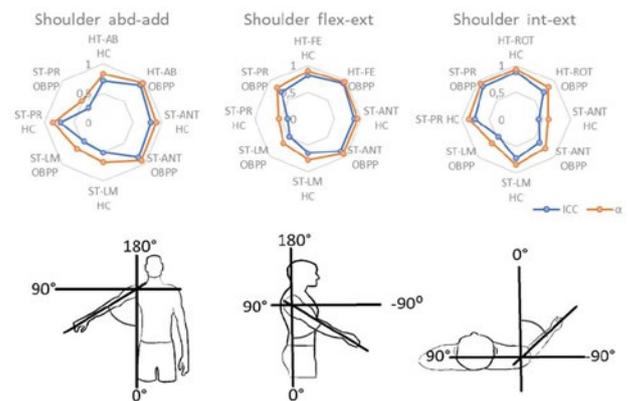

### Methods

Six persons with OBPP, aged between 7-22 years and nine matched healthy controls (HC), aged 8-25 years took part in this study. A portable motion analysis system (MoLab™, AnyMo AB, Umeå, Sweden) with 7 IMU sensors were used for collecting joint angles from the upper extremities (i.e., scapula, upper arm, and forearm). All participants were examined on two different occasions to determine the test-retest reliability. Time between examinations was on average 5.8 days for the participants with OBPP and 4.1 days for the HCs. All participants were instructed to avoid any heavy physical activity of the upper extremities for two days before each examination. On both occasions the examination was carried out by the same test leader. The performed tasks in the examination were partially based on the MMS [1]. The joint angles examined were the humerothoracic joint (HT) and the scapulothoracic joint (ST). Like Cutti et al, [5] HT was described by three

independent angles: flexion-extension (HT-FE), abduction-adduction (HT-AB) and internal-external rotation (HT-ROT). ST kinematics was described by three independent angles: anterior-posterior tilt (ST-ANT), lateral-medial rotation (ST-LM) and protraction-retraction (ST-PR). For each task, range of motion (RoM) was calculated. Intraclass Correlation Coefficient (ICC) and Cronbach's alpha ( $\alpha$ ) were then calculated as a measure of test-retest reliability for the two test occasions for each group. Values  $>0.75$  represent good reliability.

### Results and Discussion

The test-retest reliability varied between tasks and joints as illustrated in Figure 1.

**Figure 1:** Top: illustrates ICC and  $\alpha$  for range of motion in scapulothoracic (ST) and humerothoracic (HT) joints, for three shoulder tasks, in healthy controls (HC) and plexus patients (OBPP). Bottom: Analyzed movement planes (Shoulder abd-add, flex-ext and int-ext).

### Conclusions

Measuring ROM of joint angles in different anatomical planes can give a good test-retest reliability for certain anatomical planes and anatomical joint. Before this technology can be implemented in clinical practice, larger studies are needed to determine the system's validity.

## Quadriceps Muscle and Pain During Daily Activities for Total Knee Arthroplasty Patients

Fangjian Chen<sup>1</sup>, Chang Shu<sup>1</sup>, Ronald Singer<sup>2</sup>, Michael Bates<sup>2</sup>, Nigel Zheng<sup>1</sup>

<sup>1</sup>University of North Carolina at Charlotte, NC, USA

<sup>2</sup>OrthoCarolina at Charlotte, NC, USA

Email: [nzheng@uncc.edu](mailto:nzheng@uncc.edu)

### Summary

The objective of this study was to find the relationship between muscle activity of quadriceps and pain level. 25 total knee arthroplasty (TKA) patients were enrolled before and 6-months after surgery in this study. The electromyography (EMG) data from vastus lateralis and vastus medialis was processed to find the peak muscle activity and the duration of muscle activity. Pain levels were collected using Knee Society Score (KSS). Based on the correlation analysis performed for five daily activities, the relationships were found between pain and muscle activity.

### Introduction

The total knee arthroplasty (TKA) was the most common to treat the end stage of knee osteoarthritis. Although many investigations have reported that TKA improved functional performance [1], many patients still have pain and dissatisfaction to performing household duties and leisure recreational activities. It is reported that the muscle activities of vastus lateralis (VL) and vastus medialis (VM) highly affected the performance of knee during daily activities [2]. The purpose of this study was to determine the relationship between muscle activity of both VL and VM with pain for TKA patients. We hypothesized that EMG of knee extensors were not affected by the pain level.

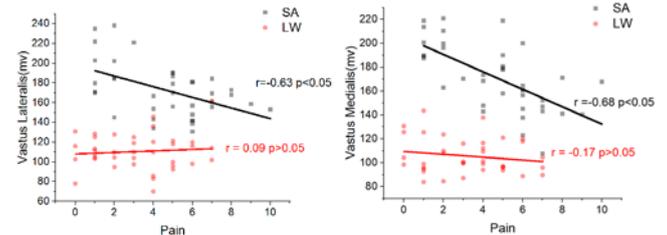

### Methods

25 subjects with posterior stabilized TKA (M/F: 18/7, age: 61±6 years, BMI: 30±5 kg/m<sup>2</sup>) were recruited and tested preoperatively and 6-month postoperatively. The study protocol was approved by an institutional research board, and all participants gave written informed consent. Muscle activity of involved (VL) and (VM) were recorded using surface EMG (Noraxon) during level walking (LW), stair ascending (SA), stair descending (SD), ramp up (RU) and ramp down (RD). A custom MATLAB code was developed to perform EMG processing (remove bias, low pass filter (10Hz), rectification, and window averaging) [3]. Peak muscle activity (PMA) was found based on the muscle activated pattern. the duration of muscle activity (DMA) was determined as previously described [4]. The pain levels were collected using the KSS for LW and SA respectively. The correlation analysis was performed using SPSS with alpha set to 0.05.

### Results and Discussion

No correlations had been found in PMA and MDA with pain during LW, RU, and RD for both muscles (Table 1, Fig. 1). Significant correlations were found between PMA and pain

level during SA and SD for both muscles. There was a significant correlation between DMA and pain level during SA for both muscles. The results showed that there were significant correlations between EMG and pain level for more demanding activities (stair ascending and descending).

**Figure 1:** Correlations between PMA of both muscles and pain levels during level walking (LW) and stairs ascending (SA).

**Table 1:** The correlation analysis of PMA and DMA with pain level during daily activities for both muscles. (\* p<0.05)

Activity	Parameters	VL	r	VM	r
Level	PMA (mv)	109±18	0.09	113±15	-0.17
Walking	DMA(%gait)	45±7	-0.15	42±9	-0.08
Stair	PMA (mv)	182±21	-0.63*	188±25	-0.68*
Ascending	DMA(%gait)	54±11	-0.45*	57±9	-0.42*
Stair	PMA (mv)	170±23	-0.56*	201±14	-0.58*
Descending	DMA(%gait)	53±20	0.08	60±24	-0.12
Ramp	PMA (mv)	96±18	-0.23	103±18	-0.18
Up	DMA(%gait)	48±10	0.12	45±6	0.13
Ramp	PMA (mv)	113±20	0.06	131±18	0.09
Down	DMA(%gait)	45±7	0.08	49±6	0.06

### Conclusions

The pain level of the knee had an impact on the activities of knee extensors only during stair ascending and stair descending.

## Comparison between two mobile applications measuring shoulder elevation angle – A Validity Study

Fredrik Ohberg, Martin Gunn, Karolina Jonzén, Urban Edström and Nina Sundström  
 Dept. Biomedical Engineering, University Hospital of Umeå, Umeå, Sweden  
 Email: [Fredrik.Ohberg@regionvasterbotten.se](mailto:Fredrik.Ohberg@regionvasterbotten.se)

### Summary

This study shows a comparison between two mobile applications (ErgoExposure and ErgoArmMeter) that can be used by ergonomists for measuring work-related shoulder exposure to poor working postures. ErgoExposure had better accuracy, but both applications seem viable to be used by ergonomists.

### Introduction

Pain in shoulder and neck affects between 7-25% of the working population and one risk-factor is continuous manual work with elevated arms [1]. To quantify and compare these factors, ergonomists use tools that broadly divide into; 1) self-reported data, e.g. worker diaries; 2) observational methods that include both simpler techniques for systematic evaluation of risk factors and advanced software analysis that computes the specific variables from video recordings; and 3) direct measurements using equipment attached to the body for measuring e.g. movement [2]. To facilitate the evaluation of interventions, better objective tools are needed for measuring exposure to poor working postures. A mobile application for iPhone (ErgoExposure) has been developed that uses the internal accelerometers and gyroscope to measure the shoulder's elevation angle when attached to the upper arm.

The aim of this study was to test the validity of ErgoExposure by comparing it to an existing mobile application (ErgoArmMeter) developed by Wang et.al. [3]

### Methods

Mobile phones were fastened to the upper arm of 11 test persons (6M/5F) who in turn performed 3 different tests: 1) static shoulder elevation (flexion and abduction) 2) dynamic arm swing at three different speeds and 3) two simulated work tasks (postal sorting and teaching, see Fig 1.). During the tests, the two mobile applications and the optical tracking system collected the change in shoulder elevation angle at each point in time. The results from both mobile applications were then compared to the results of the optical tracking system that was used as a gold standard.

Figure 1: Simulated work task. A) Postal sorting and B) Teacher.

### Results and Discussion

For ErgoExposure the static test had an overall bias (flexion and abduction) of  $-0.97^\circ$  with limits of agreement (LOA)  $-6.1^\circ$  to  $4.2^\circ$  (see Fig. 2.) as compared with ErgoArmMeter that had an overall bias of  $-1.3^\circ$  and LOA  $-7.6^\circ$  to  $5.2^\circ$ . ErgoExposure resulted in an average root mean square difference (RMDS) of  $3.06^\circ$  with an increasing error at higher speeds, from  $2.62^\circ$  at slow-paced to  $3.97^\circ$  at fast-paced arm swings. ErgoArmMeter had a higher average RMDS of  $7.44^\circ$  and showed an increasing error at higher speed. The simulated work tasks showed similar results, ErgoExposure had an average RMDS of  $1.79^\circ$  with no clear difference between the tasks. ErgoArmMeter had a higher average RMDS of  $3.21^\circ$ , but showed differences between the tasks, average for postal sorting was  $4.41^\circ$  and for teacher  $2.01^\circ$ .

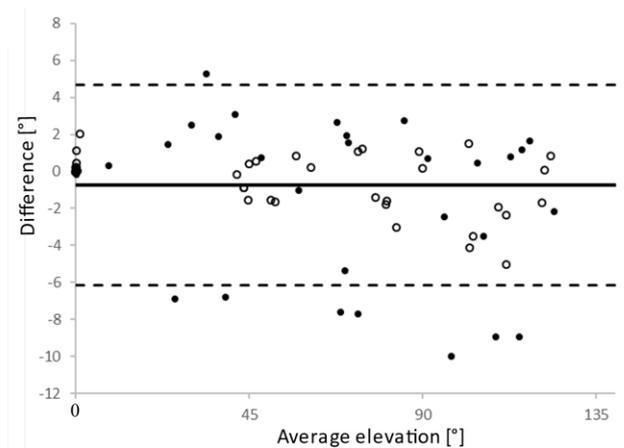

Figure 2: Bland Altman Plot of the static test.

### Conclusions

Both apps showed results within reasonable margin from the optical tracking system, where the main error came from a time lag in the dynamic tests and the simulated work tasks. Compared to other methods, both apps give accurate results for measuring shoulder elevation. ErgoExposure seems to be appropriately viable to be used by ergonomists in practice.

# INTEGRATED CONTACT ANALYSIS OF SHOE-PLATFORM MECHANICAL INTERACTIONS IN SPORTS FACILITIES

Lasse Jakobsen<sup>1</sup>, Filip G. Lysdal<sup>2</sup>, Rasmus K. Jensen<sup>2</sup>, Uwe G. Kersting<sup>2,3</sup> and Ion M. Sivebæk<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Technical University of Denmark, Denmark

<sup>2</sup>Department of Health Science and Technology, Aalborg University, Denmark

<sup>3</sup>Department of Biomechanics and Orthopaedics, German Sport University Cologne, Germany

lasjak@mek.dtu.dk

## INTRODUCTION

The contact mechanism between shoe and surface is crucial in order to avoid slipping and falling [1], enhance sporting performance or minimize the risk of sport injuries [2]. However, studying this contact mechanism, between footwear and surface, is challenging and violates the traditional Amontons–Coulomb’s law of friction, due to the viscoelastic outsole materials [3]. Hence, replicating the biomechanical test conditions are of great importance, when determining the friction properties of footwear [1]. The aim of this study is to present a test-setup able to replicate biomechanical relevant test conditions.

## METHODS

The test-setup consisted of a steel frame designed to maintain the position of a shoe, mounted above a force plate (AMTI-OPT464508HF-1000, Advanced Mechanical Technology, Inc. Watertown MA, USA). The force plate is attached on top of a hydraulic platform (Serman-Tipsmark, Randerslev, Denmark), which makes it possible to move vertical and horizontal.

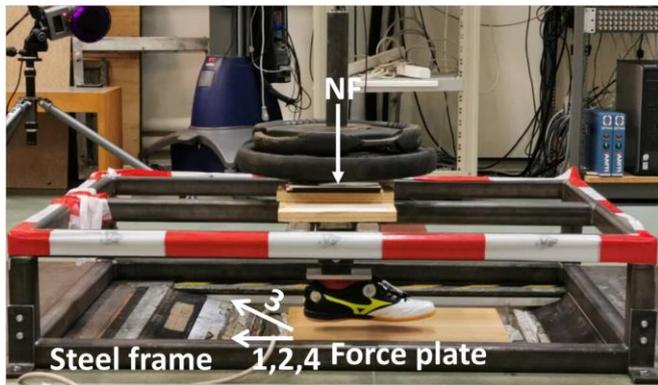

Fig 1 Illustration of the test-setup. Drag-test (1,2,4) impacting (3) illustrates platform movement directions.

An indoor Puma One size 43 (EU), (Puma, Herzogenaurach, Germany) and a square sample of a vinyl indoor sports floor (7.5 mm Taraflex - Evolution, Gerflor, Lyon, France) was used in the test-setup. Four different test conditions were performed: 1) Drag-test according to ISO 13287 (normal load (NL) 500 N, sliding velocity (S) 0.3 m/s) 2) Drag-test (NL 750 N, S 0.3 m/s) 3) Impacting, with the platform moving both horizontal and vertical (NL 750 N, S 1.0 m/s), and 4) Drag-test (NL 750 N, S 1.0 m/s). We recorded five trials of each condition.

Force data were filtered using a 2<sup>nd</sup> order Butterworth filter with a cut-off frequency of 30 Hz and 10 Hz, respectively. Zero-phase filtering was performed using MATLAB function Filtfilt, filtering both forward and reverse. All measurements

were synchronized using the kinematics of a retro-reflective marker by calculating cross-covariance and aligning data by circular shift. Ten empty force plate movements were recorded for each condition and used to subtract the inertial contribution from the hydraulics accelerating the force plate.

Coefficient of friction ( $\mu$ ) was calculated by  $\mu = \frac{F_f}{F_n}$  from the computed normal force ( $F_n$ ) and horizontal forces (friction force,  $F_f$ ) [2].

## RESULTS AND DISCUSSION

The  $\mu$  was influenced by the test conditions, where higher normal loads and sliding velocities resulted in lower  $\mu$ , which is in agreement with rubber friction theory [3]. The initial part of condition 3 mimics somewhat the initial contact, as in real-world walking or running, and shows a highly fluctuating  $\mu$ , most likely caused by the minimal damping in the present setup. However, we still consider condition 3 to be more biomechanically relevant, compared to traditional one-direction sliding tests as per ISO 13287.

Adding impacts, and potentially also damping characteristics, in the mechanical tests of footwear could possibly contribute to a deeper understanding of the shoe-surface sliding and/or sticking phenomena.

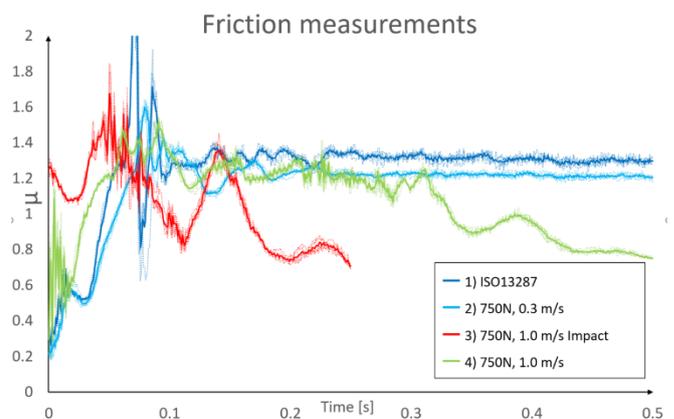

Fig 2  $\mu$  as function of time for the four different test conditions.

## CONCLUSIONS

This study presents a new test setup that can characterize the tribological behavior of shoe and surface in a traditional way, by following the traditional ISO 13287 standards, but more importantly also being able to add a novel impacting approach to the test of footwear, which is arguably more biomechanically relevant.

## Functional Assessment for Passive and Active Back Supporting Exoskeletons

Jasper Johns, Ulrich Glitsch, Kai Heinrich

<sup>1</sup>Institute for occupational safety and health (IFA), Sankt Augustin, Germany

Email: jasper.johns@dguv.de

### Summary

In this study the supportive functions of one active and two passive industrial exoskeletons were quantified and compared to the acting hip moments of 12 subjects during a symmetrical lifting task. Determining the functional support of exoskeletons is a crucial step in analyzing their ability to effectively aid the user during strenuous working tasks. The demonstrated approach aimed to establish a protocol to assess the supportive function and the potential assistance provided by the used exoskeletons. The results demonstrate that for the active system, the achieved support level depends on the selected system settings, and that different support strategies could be adopted for the passive systems.

### Introduction

Exoskeletons are a novel approach to reduce lumbar loadings in industrial workers by supporting the trunk based on a torque exerted at about hip joint level. They aim to support the erector spinae muscles and thus lower resulting compression forces acting along the spine. While previous studies have shown that exoskeletons can effectively reduce muscular activity [1], the analysis of the mechanically provided support has only been subject to few studies [2, 3]. By including the provided supportive torque into biomechanical models, it is possible to assess the direct effects of exoskeletons on internal loading of affected structures.

The goal of this paper was to quantify the provided support of three industrial exoskeletons and propose a protocol for their functional assessment.

### Methods

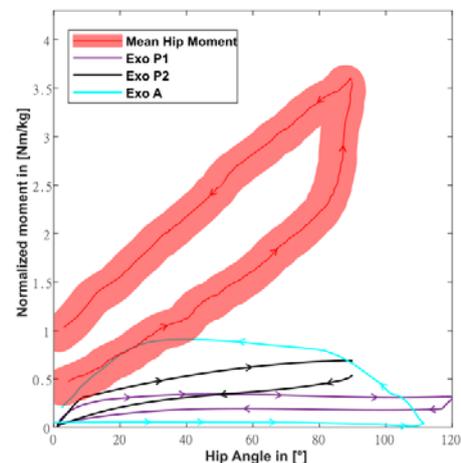

One active (A) and two passive (P1, P2) exoskeletons were tested in this study. With the passive exoskeletons, direct force measurements were conducted to determine the contact forces transmitted by the exoskeleton chest pad to the user's sternum and movements were tracked with 40 markers (with 7 to 15 additional markers to track the exoskeleton motion) and a 12 camera vision system. For the active exoskeleton, internal sensors recorded motor torques and segment positions, and data could be accessed through an online interface.

Additionally, kinematic data of 12 subjects were collected during a repeated lifting task (20 kg) and a top-down inverse dynamic model was applied to calculate the acting hip joint moments. The respective supportive torque – flexion angle relationships of the exoskeletons were created and compared to the hip joint moments during unassisted lifting.

### Results and Discussion

The tested exoskeletons provided different levels of support during certain phases of the lifting motion. While the absolute support provided by exoskeleton P1 reached an early peak of

26 Nm at around 40°, the support of P2 steadily increased until 54 Nm at 90° trunk flexion. The system settings of exoskeleton A were configured in a way that the flexion phase during lifting was completely unsupported and the electric motors delivered maximal output when the trunk extension was initiated. With the actuation only starting at the beginning of the trunk extension, the peak of 70 Nm was reached at 35° trunk flexion. Compared to the normalized hip moments during unsupported lifting, only exoskeleton A could provide substantial support during the last phase of unloaded extension. Systems P1 and P2 exhibited different support strategies, but both could only provide a fraction of the net joint moments around the hip as support during loaded trunk extension (Fig. 1).

**Figure 1:** Comparison of the hip joint moments with the exoskeletons' supportive torques. Hip joint moments were normalized for corresponding subject weight and exoskeleton support for average subject weight.

The comparison of the hip joint moments and the provided supportive torque over a lifting cycle reveals the maximal estimated assistance provided by the tested exoskeletons.

### Conclusions

For an appropriate analysis of the effect of exoskeletons on the loading of affected structures during industrial work tasks, it is important to consider the support provided by exoskeletons. Only by focusing on the multifaceted human-exoskeleton-interaction is it possible to judge their capability to effectively reduce musculoskeletal loading.

### Summary

The mechanical and structural properties of bone augmented with a calcium sulfate/hydroxyapatite (CaS/HA) biomaterial were evaluated. Plugs of human trabecular bone with and without addition of CaS/HA were imaged using synchrotron X-ray tomography. Loading was applied *in situ* during tomography. Mechanical and structural parameters were compared, and the crack propagation was followed. Adding CaS/HA increased the peak force and absorbed energy due to formation of microcracks in CaS/HA.

### Introduction

New tools for reinforcing bone or fixation of orthopaedic implants are being investigated [1]. Calcium sulfate/hydroxyapatite (CaS/HA) based biomaterials are an attractive alternative owing to their injectability, osteoconductivity and mechanical properties. Despite the wide variety of applications the biomaterial is used in, the mechanical behavior of the composite of CaS/HA and bone on a microscale is still largely unknown. Current developments in imaging techniques allow for better investigation of the mechanics of bone-biomaterial interactions at the microscale. The aim of this study was to determine if and how bone augmentation with CaS/HA alters the fracture behavior of bone.

### Methods

Eleven cylindrical plugs (Ø 6 mm, H 7.5 mm) were drilled from two human femoral heads (one male, one female). Bone marrow was removed from all plugs and CaS/HA was introduced into the 5 plugs by manual tapping. 1 plug of only CaS/HA was prepared. The plugs were imaged with synchrotron X-ray tomography (TOMCAT, PSI, Switzerland) (energy: 30 keV; scanning speed: ~2 min/scan; isotropic voxel size: 2.75 µm). Loading was performed *in situ* (displacement rate: 0.9 mm/min) and tomographs were taken at increments of 0.15 mm. Images of unloaded samples were used to obtain bone volume/total volume (BV/TV), CaS/HA volume/total volume (CV/TV), and trabecular thickness (Tb.Th). From the load curves, peak force (Fmax), stiffness (k) and work (W) were determined. One sample from each group was used for further image analysis, by selecting a region of interest where damage occurred. At each loadstep, cracks in this region were segmented. For the composite sample, a distinction was made between cracking in CaS/HA, cracking in bone and separation of the bone-CaS/HA interface.

### Results and Discussion

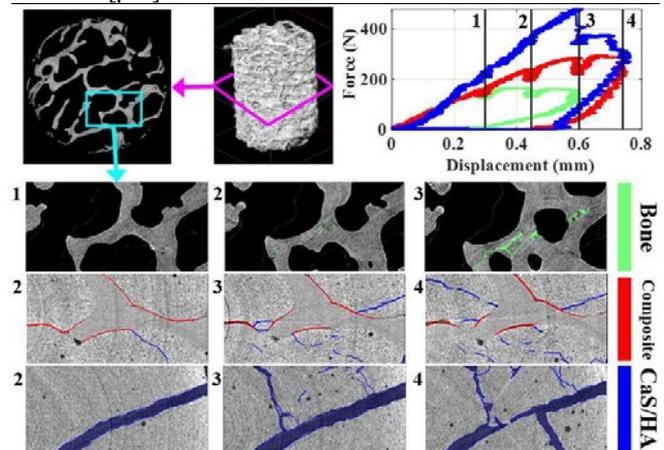

The CaS/HA-only sample had the highest peak force, stiffness and work (Table 1). The resulting fracture for this sample was

brittle (Figure 1). The composite sample showed the most plastic behavior (Figure 1). During early loading, the CaS/HA matrix developed small cracks and started to separate from the bone at the interface. However, the force kept increasing and at the last loadstep the bone was still mostly intact. The bone-only sample showed large deformations before failing at a relatively low peak force.

Reinforcing bone with CaS/HA results in an increased peak force, stiffness, and work. Most interesting is the fracture behavior leading to the increase in absorbed energy, which is caused by the large amounts of micro-cracks that are formed in the CaS/HA before global failure.

**Table 1:** Median mechanical and structural properties.

	Bone	Composite	CaS/HA
Fmax [N]	56	265	479
k [N/mm]	122	497	792
W [Nmm]	34	91	131
BV/TV	0.21	0.21	-
CV/TV	-	0.44	0.99
Tb.Th [µm]	165	175	-

**Figure 1:** Force-displacement curves of the three samples and the crack evolution over the last three load steps (numbered). Cracks' localizations are colored blue (CaS/HA), green (bone), and red (bone-CaS/HA separation).

## Microscale compressive behavior of hydrated lamellar bone at high strain rates

Cinzia Peruzzi<sup>1</sup>, Rajaprakash Ramachandramoorthy<sup>1</sup>, Alexander Groetsch<sup>1</sup>, Daniele Casari<sup>1</sup>, Philippe Grönquist<sup>2</sup>, Markus Rüggeberg<sup>2</sup>, Johann Michler<sup>1</sup>, Jakob Schwiedrzik<sup>1</sup>

<sup>2</sup>Institute for Building Materials, ETH Zürich, Switzerland  
Email: cinzia.peruzzi@empa.ch

### Summary

Micropillar compression experiments were performed in ovine bone at two orientations, over seven orders of magnitude in strain rate and at a relative humidity of over 90%. These conditions were chosen to mimic the natural conditions of bone in a human body. The determined strain rate sensitivity is similar to the reported strain rate sensitivities of bone of other species and higher length scales. This suggests that it is an intrinsic property of the bone extracellular matrix. Furthermore, an increase in post-yield energy absorption and a thickening of the shear deformation bands were observed at high strain rates ( $10^2 \text{ s}^{-1}$ ). This study highlights the importance to examine bone at several length and time scales and under clinically relevant conditions.

### Introduction

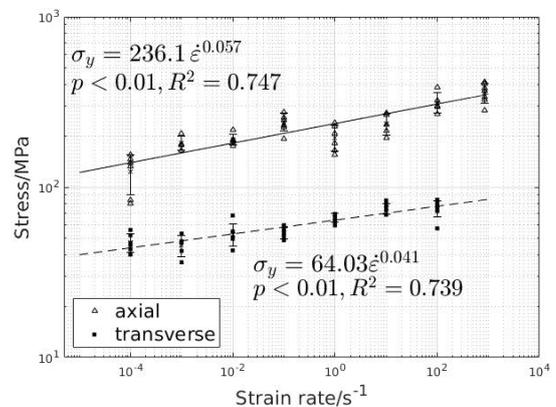

Bone is a hierarchically structured composite material. Its main components are collagen molecules, calcium phosphate minerals and water. Mineralized collagen fibrils are embedded into an extrafibrillar matrix and form lamellae, 3 to 7  $\mu\text{m}$  thick layers that are wrapped around blood vessels forming osteons in cortical bone. In daily life, bones are subjected to mechanical loading at different strain rates, such as during walking ( $5\text{--}80 \times 10^{-3} \text{ s}^{-1}$ ), sprinting ( $5 \times 10^{-2} \text{ s}^{-1}$ ) and accidental falls ( $25 \text{ s}^{-1}$ ) [1]. Microscale tests have typically been conducted at quasi-static strain rates (up to  $10^{-3} \text{ s}^{-1}$ ). In this study, we investigate the rate-dependent mechanical behavior of ovine bone micropillars at the lamellar length scale across seven orders of magnitude (up to  $8 \times 10^2 \text{ s}^{-1}$ ), under physiologically relevant humidity conditions.

### Methods

Micropillars were produced in cortical bone with a focused-ion beam (FIB) [2] using two samples from one ovine tibia. The samples are oriented in (axial) and perpendicular (transverse) to the main osteon direction. 93 micropillars (46 axial and 47 transverse) were fabricated with a diameter of  $5.52 \pm 0.14 \mu\text{m}$  and a height of  $10.35 \pm 0.68 \mu\text{m}$ . Compression experiments were performed under ambient pressure and with a relative humidity greater than 90% using a custom-built nanoindenter. Quasi-static up to impact strain rates were used ( $10^{-4} - 8 \times 10^2 \text{ s}^{-1}$ ). High resolution scanning electron microscope (HRSEM) imaging was conducted on all micropillars. To get a better insight into the deformation mechanisms six micropillars were selected for FIB cross sectioning and a further three micropillars that were compressed at high strain rates ( $10^2 - 8 \times 10^2 \text{ s}^{-1}$ ) for scanning transmission electron microscopy (STEM) imaging.

### Results and Discussion

Microscale lamellar bone exhibits a clear strain rate sensitivity being slightly more pronounced in axial ( $m = 0.057$ ) than in transverse ( $m = 0.041$ ) micropillars (Figure 1). The strain rate sensitivity is similar to reported values for bovine and human bone ( $m = 0.06$ ) [1] suggesting it is an intrinsic property of the bone extracellular matrix.

**Figure 1:** Expected yield stress extracted from axial and transverse micropillar compression tests at different strain rates.

In addition, an increase in the post-yield energy absorption and the thickening of shear bands as well as nucleation of multiple shear bands was observed for high strain rates ( $10^2 \text{ s}^{-1}$ ). This suggests that at high strain rates thin kink bands do not have sufficient time to propagate causing a change in deformation mechanism towards shear band nucleation and thickening.

### Conclusions

The findings of this study illustrate the importance to investigate bone at several length and time scales and clinically relevant conditions.

## Introduction

Finite element modelling of the brain has been used with increasing frequency to investigate brain biomechanics and pathology of injury [1]. Some models have considered the mechanical effects of vasculature on the response of the brain matter however there are only a small number of studies which investigate vasculature injury, and of these, the focus is bridging vein rupture, meaning diseases such as microbleeding and are unable to be investigated. Here we present a method for inclusion of the complete venous system in the brain from a T1 image and high resolution QSM image for finite element analysis.

## Method

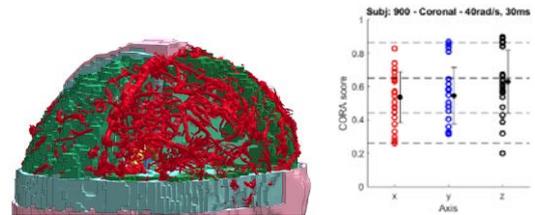

A high resolution QSM modality image of the vasculature was segmented using a combination of manual and semi-automatic tools in Mimics (Materialise Mimics Research 20.0). Thresholding was used to identify macroscale veins, a dynamic growth algorithm was used to manually segment remaining veins, and finally, a smart expansion algorithm was applied to add missing edges and discontinuities. The vasculature image was registered to the head segmentation and the centerlines/radii data was transformed to the head coordinate system.

Three steps were taken to build the Finite element (FE) model of the brain from the subjects T1 image. The subcortical structures were segmented using freesurfer, the cerebrospinal fluid (CSF) was segmented using fsl and the skull was created by thresholding the T1 image then removing the brain and CSF segmentation mask. Smoothing was applied at material interfaces.

Four head impact reconstructions were simulated in LS-DYNA for verification purposes [2]. CORA scores, a method for comparison of biomechanical reconstructions, were calculated for each receiver to verify the fidelity of the brain model. Simulations of injury events in sport, road traffic collision, and fall were ran on the model to investigate vasculature strains.

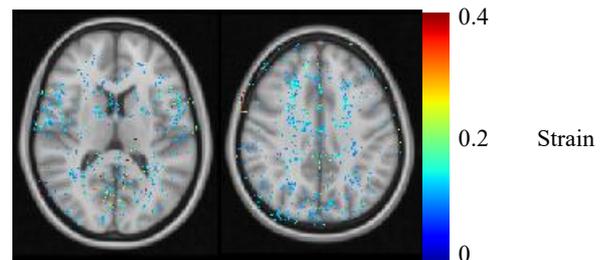

## Results

A detailed FE model of the brain was created which included 46 parts, made up of the skull, meninges, CSF, cortical, and subcortical structures (figure 1 left). The biomechanics of the model was verified using head impact data with average CORA scores giving a good/fair biofidelity rating as specified in ISO/TR-9770 (figure 1 right).

**Figure 1** (L) FE brain model with complete venous system, (R) CORA scores for each receiver per axis for reconstruction of UVA900COR4 [2]

The venous system was successfully segmented and imported onto the brain model. Good alignment of anatomical features was seen and veins < 0.4mm diameter were successfully identified. Strains were seen to peak in patterns in the brain which could indicate pathology.

**Figure 2** Axial slices of fall reconstruction showing distribution of strains < 0.15

## Conclusions

Here we present the first FE brain model to use high resolution imaging for identification and inclusion of vasculature in the brain. The brain biomechanics were verified from head impact tests showing fair/good fidelity. Injury recreations show patterns of strain in perivasculature region where vasculature injury is seen.

# The Axial Impact Response and Plantar Load Distribution of the Hybrid III and MIL-Lx under Altered Ankle Postures

## Summary

Lower extremities injuries are frequent and debilitating in frontal automotive collisions. Two commonly used ATDs (the Hybrid III and MIL-Lx) were axially impacted at conditions representative of automotive collisions, at seven different ankle postures. Results suggest that initial ankle posture must be considered when conducting safety evaluations as the distribution of load and peak recorded tibia forces changed with differing ankle postures. Furthermore, the two surrogates and their respective injury criteria are not equivalent, and thus caution with their application must be used.

## Introduction

In frontal automotive collisions, lower extremities are the most frequent site for “non-minor” injuries [1]. Anthropomorphic Test Devices (ATDs) are commonly used to assess injury risk in automotive applications, where the lower leg is typically instrumented with upper and lower tibia load cells. Injury risk is typically evaluated using these load cells based on peak axial force ( $F_z$ ) or the Tibia Index ( $TI$ , a calculated metric of forces and moments), and sometimes foot acceleration. There are many limitations to the current methods of assessing injury risk to the lower extremities; injury tolerance testing conducted on cadavers position the lower leg in a 90° tibia/foot (neutral) posture, while vehicular occupants assume a range of postures while driving [2]. The purpose of this study was to assess the impact response of two common ATD lower legs: the Hybrid III (H3) and Military Lower Extremity (MIL-Lx) under altered ankle postures, to investigate whether this influences safety evaluations.

## Methods

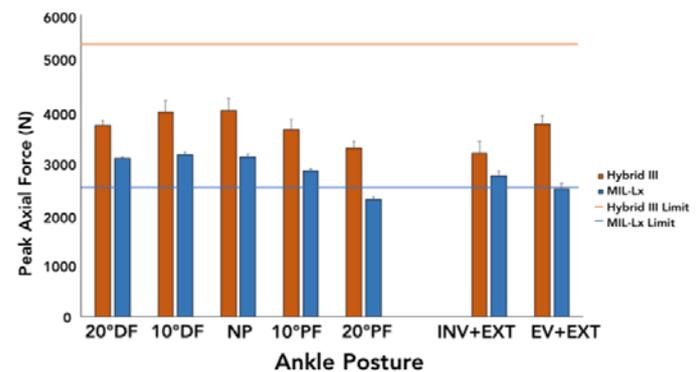

The ATDs were suspended at the knee clevis in a pneumatic impacting apparatus. The positioning of the ATDs was controlled *via* an ankle positioner and a force-sensing boot was fitted to each ATD, with sensors grouped by anatomical region and divided into the fore-, mid-, and hindfoot.

Axial impacts were delivered at a target velocity of 6 m/s and duration of 20 ms, intended to be in the range of realistic frontal collision conditions. Each ATD was impacted in seven ankle postures: neutral, 10°- and 20°-plantarflexion, 10°- and 20°-dorsiflexion, 15°-eversion with 10°-external rotation, and 15°-inversion with 10°-external rotation. Five repeated impacts were conducted at each posture. All data, including the two 5-axis tibia load cells and eight boot insole sensors, were recorded at 50 kHz.

## Results and Discussion

The average impact velocity of the 70 impacts was  $5.89 \pm 0.16$  m/s. For the impacts in which the ankle was positioned in

varying degrees of flexion, the footplate acceleration was  $125 \pm 10$  G for the H3 and  $127 \pm 8$  G for the MIL-Lx, showing no significant difference between ATD models ( $p=0.43$ ). The impact duration was significantly higher ( $p<0.05$ ) in the MIL-Lx ( $23.0 \pm 2.0$  ms) than the H3 ( $17.2 \pm 1.0$  ms). The H3 recorded significantly higher forces than the MIL-Lx in each posture (Figure 1).

**Figure 1:** Peak axial force measurements in the tibia. The limits of each ATD are associated with a 10% risk of injury, indicating a passing or failing test.

The peak axial force showed a decreasing trend as the ankle was moved from dorsiflexion through neutral and into plantarflexion. Interestingly, the H3 would have ‘passed’ all tests, while the MIL-Lx would have ‘failed’ all tests, suggesting the two surrogates and their respective injury criteria are not equivalent. The MIL-Lx generally had a decreasing  $TI$  as the foot moved from a dorsiflexed ankle posture through to plantarflexion.

When examining the distribution of the load across the plantar surface of the foot, the hindfoot carried most of the load (average 72%). As the ankle rotated from neutral into plantarflexion, a portion of the hindfoot load was transferred to the other regions, primarily the forefoot.

## Conclusions

This study emphasized the importance of selecting an appropriate surrogate as well as considering initial ankle posture when conducting safety testing for the lower extremity. This study also highlighted the importance of developing regional injury criteria for the foot and moving beyond the gross measures indicating global mechanics.

Email: birte.coppers@googlemail.com

### Summary

In this study patients 2 years after primary anterior cruciate ligament (ACL) repair with ligament augmentation showed no relevant deficits in knee biomechanics of their affected leg during landing from a single leg hop (SLH) compared to their contralateral leg and healthy controls.

### Introduction

Good clinical outcomes and patient reported data after ACL repair with ligament augmentation have been reported [1,2]. However, the functional outcome of primary ACL repair with ligament augmentation is unknown. The aim of this study was to compare kinematics and kinetics during landing from a SLH between the affected and contralateral knee in patients after primary ACL repair with InternalBrace™ (Arthrex GmbH, USA) and with the non-dominant knee in healthy controls.

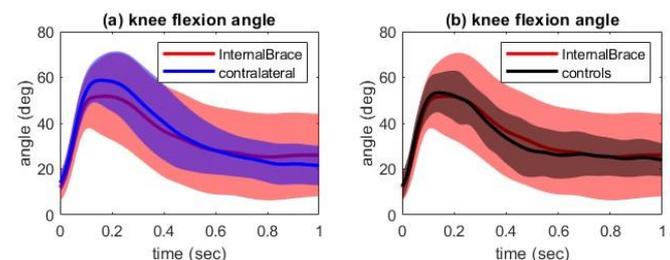

### Methods

Ten patients 2 years after surgery (5f/5m; age: 32.2±8.7 years; BMI: 22.8±2.9 kg/m<sup>2</sup>; Tegner-Activity-Score: 4.6±1.1; IKDC: 89±9) and 10 age and sex matched controls (5f/5m; age: 31.8±9.0 years; BMI: 24.4±5.0 kg/m<sup>2</sup>; Tegner-Activity-Score: 4.4±2.0; IKDC: 98±3) performed SLHs for distance. Participants were instructed to jump for maximal distance and maintain balance for 2 seconds after landing. Knee kinematics and kinetics (sagittal plane) were recorded for five trials with a motion capture system (VICON, UK) using the plug-in-gait model and two force plates (Kistler AG, Switzerland). Data of the trial with the greatest distance was used for further analysis. Joint angles, power and ground reaction force parameters were compared within patients and between the affected leg of patients and the non-dominant leg of healthy controls using t tests (P<0.05).

### Results and Discussion

We found no significant differences in the knee parameters between the affected and contralateral leg in patients (P>0.183) (Figure 1 a). Kinematic and kinetic parameters of the affected knee in patients did not differ significantly from those of the non-dominant knee in healthy controls (patients vs. controls; jump distance: 1.21±0.32 m vs. 1.21±0.34 m, P=0.778; flexion angle at initial contact: 12.8±6.4° vs. 13.4±6.0°, P=0.830; peak flexion angle: 54.9±15.6° vs.

56.4±6.6°, P=0.788; range of motion: 42.2±10.3° vs. 43.0±7.8°, P=0.836 (Figure 1 b); peak knee power: 6.6±4.9 W vs. 8.6±5.3 W, P=0.391; peak vertical ground reaction force: 377±96% body weight vs. 380±110% body weight, P=0.948). The variability especially in peak knee flexion angle was much greater among the affected legs of patients than among their contralateral leg and among controls.

**Figure 1:** Knee flexion angle during first second after initial contact (0 sec) for the affected leg compared to patients' contralateral leg (a) and to non-dominant leg of controls (b).

Overall, the movement strategy and functional condition of the knee during landing appeared to be comparable to healthy knees, which is in contrast to previous results for patients after ACL reconstruction [3,4]. The biomechanical analysis further reflects comparable result of the jump distance between patients and controls.

### Conclusions

This result is promising and supports the choice of surgical treatment of proximal ACL rupture with primary repair and InternalBrace™. Further studies are required to strengthen these results, to further explore the variability within the groups and to understand the role of proprioception, muscle strength and muscle coordination in the landing biomechanics from jumps in patients after ACL repair.

### Summary

Injury prevention is important in sport, unfortunately it is often forgotten in the daily routine. This quality control study of the new home exercise program of the Swiss national box lacrosse team was done as a physiotherapy bachelor thesis.

For this, the dynamic balance and strength of the shoulder external rotators of the throwing arm was measured at three points in time. Additionally, the influence of co-variables on the measurement results was analyzed.

### Introduction

The Swiss Box Lacrosse National Team introduced a new home exercise program for injury prevention in view of the upcoming World Championship 2019 and due to many "non-contact" injuries during the last season. The prevention program addresses the most common injuries to the foot, knee and shoulder [1,2].

### Methods

At three points in time, dynamic balance was measured with the Y-Balance Test. Additionally isometric strength of the shoulder external rotators of the throwing arm was measured with a handheld dynamometer.

The first phase served as a control phase and included the usual training. From the measured differences of the second phase, which served as the intervention phase, the differences of the first phase were subtracted to eliminate natural changes. This resulted in the final differences, which were tested for significance.

Various co-variables from the training diary, a health questionnaire and the implementation frequency of the new home exercise program were recorded and tested for a relationship with the changes in the measurement results.

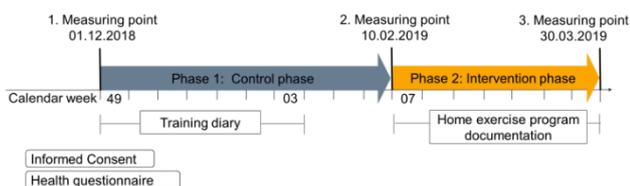

Figure 1: Quality control timeline

Table 1: final difference [ $\Delta$  Phase 2 (3. measuring point – 2. measuring point) –  $\Delta$  Phase 1 (2. measuring point – 3. Me measuring point)]

Total of participants (n=18)	Final difference Y-Balance left (%)	Final difference Y-Balance right (%)	Final difference Force measurement (Newton)
Mean (SD)	1.79 (6.08)	0.654 (5.86)	3.83 (62.9)
Median [Min, Max]	0.165 [-6.07, 16.0]	1.25 [-9.19, 12.4]	14.0 [-146, 107]
p-value	0.34	0.28	0.71

### Results and Discussion

In 18 included subjects, the one-sample Wilcoxon test did not detect a significant change for either the Y-balance test or the isometric strength measurement of the external shoulder rotators at a significance level of 0.05. The p-values are 0.34 for the Y-balance test on the left, 0.28 for the Y-balance test on the right and 0.71 for the force measurement.

Only by means of Stepwise Model Selection a correlation of single co-variables with the final differences could be shown.

### Conclusions

After the seven-week implementation of the home exercise program, no significant change in dynamic balance and isometric strength measurement of the external shoulder rotators was achieved. Lack of compliance, a small sample size and the quality criteria of the strength measurement doubt concerning the validity of the results [3,4]. The influence the co-variables have on the results cannot be determined in this study. Finally, we recommend paying more attention to the topic of injury prevention including the reliable implementation.

Email: info@isb2021.com

## Summary

The presented study described in this abstract deals with human head interaction during a vehicular frontal crash with the unsecured deformable object (impactor) placed in the vehicle. The primary study focuses on head injury determination through Head Injury Criterion (HIC) calculation and comparison of the HIC calculation with the well-known value of HIC equal to 1000. The value of HIC equal to 1000 represents a potential injury risk with a dangerous effect on the human health condition [1], [2].

## Introduction

The study presented in this abstract deals with a familiar situation, when people are going on a trip via vehicle and place their luggage or objects of daily use in the car. When a vehicle accident happens, these objects are acting as projectiles with high kinetic energy. If these objects interact with vehicle occupant bodies, they may cause a severe injury.

The frontal vehicular crash situation is described with a focus on unsecured object vs. human head direct interaction. [1] The unsecured object assumed for the study is a plastic bottle, which is fully filled out with water without internal pressure. The bottle has a deformable body – elastoplastic effect. The model of the vehicle occupant is the Hybrid III 50<sup>th</sup> percentile male dummy for the frontal crash.

## Methods

An experimental approach was used [1]. The experimental setup had these parts: Airgun (with pressure vessel and optical measuring barriers) Nylon body projectiles with different mass (0.5 [kg], 1 [kg], 1.5 [kg]) and plastic bottle deformable impact part Hybrid III 50<sup>th</sup> percentile male dummy with instrumentation vehicle seat with restraint system DA system DEWE A4.

HIC values (15 [ms]) were calculated through software NI DIADEM, including Crash Analysis Toolkit (specific math modules). HIC is calculated through formulas (1) and (2) [2].

$$HIC = \max_{t_1, t_2} \left\{ \left( \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} a \, dt \right)^{2.5} (t_2 - t_1) \right\} \quad (1)$$

$$a = \sqrt{a_x^2 + a_y^2 + a_z^2} \quad (2)$$

The symbol  $a$  in Eq. (1) represents resultant head acceleration, and it is calculated from Eq. (2), where  $a_x$ ,  $a_y$ , and  $a_z$  are components of "resultant" acceleration. Symbols  $t_1$  and  $t_2$  are a time interval for the HIC calculation process (15 [ms]).

## Results and Discussion

Obtained experimental results show that the critical value of HIC is in impactor velocity interval from 40 [km/h]/1.5 [kg] to 50 [km/h]/ 1.0 [kg]. For an impactor with a weight of 0.5 [kg], the critical HIC value of 1000 was not obtained due to the airgun capabilities relying on the airgun pressure system construction. Figure 1 shows obtained experimental results in a graphical form with approximation curves from which higher HIC values and relating impactor velocities can be calculated – for impactors with a mass around 0.5 [kg].

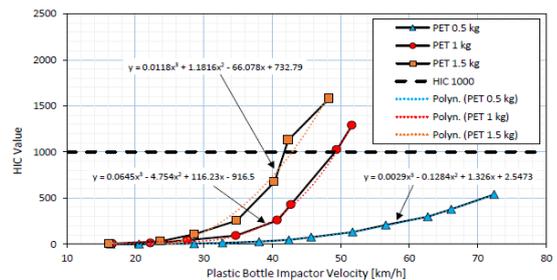

Figure 1: HIC (15 ms) values Obtained from Experimental Analysis and their Comparison with Critical HIC value 1000

The presented experimental study focuses only on the human head interaction with loosen object/impactor and is not taking into account interactions with airbags and other parts of the vehicle body. Also, the water behavior in the bottle is neglected when the bottle is filled out with water randomly – a verification study will be performed.

## Conclusions

The study describes the head injury potential of a special type of impactor acting on a human head. Obtained results show the importance of the solved problem, but other experiments should be performed to understand and cover it.

### Summary

The aim of this study was to assess the impact of a three-month non-invasive weekly Mixed Reality (MR) activity on the gait of people with mental disabilities. Gait and cognition were analyzed before (T0) and after (T3) training. At T3, the subjects' walking speed, Walk Ratio, Functional Ambulation Performance Score and stride length had significantly increased, showing an improvement in gait mobility and stability. Cognition score has been maintained.

### Introduction

Although not included in the diagnosis, people with mental or cognitive disabilities are subject to motor impairments. Cognitive and motor systems are interlinked. For instance, training working memory can increase the walking speed of ageing people [1]. From these cognitive-motor interactions, combined with recent technological developments, new therapeutic approaches are emerging. This includes Mixed Reality, whereby a headset can be used to superimpose virtual holographic elements with which it is possible to interact, on the real environment.

A MR activity can improve balance in healthy subjects [2], but its influence on the motor skills of mental disabled people has not been proved yet. The hypothesis is that cognitive-motor training using Mixed Reality will improve the subjects' motor skills objectified by gait parameters.

### Methods

Eight residents from a home for disabled adults (mean±SD: age = 51.5±15.7 years old, height = 1.6±0.1 m, mass = 55.8±8.0 kg) participated to the study. Gait spatiotemporal parameters (STP) were assessed with a Zeno™ walkway gait analysis system and cognition was evaluated using MoCA (Montreal Cognitive Assessment) before (T0) and after (T3) training. The three-month weekly intervention consisted in using the application PopBallons™ (Actimage, France) on a Microsoft HoloLens 2® MR device for 15 to 25 minutes. Its purpose is to find, walk to and pierce virtual balloons with the finger. Both cognitive and motor functions are thus stimulated.

T3-T0 differences distribution normality was tested with a Shapiro-Wilk test. The significance of the changes in gait STP was therefore tested with a Student's t-test and a Wilcoxon test was used for the MoCA score difference.

### Results and Discussion

Gait speed, Walk Ratio, Functional Ambulation Performance Score (FAPS) and stride length have significantly increased

after the three-month Mixed Reality intervention (Table 1). Mobility, balance, and gait stability seem to be enhanced, which is in line with previous studies results [1,2].

**Table 1:** Gait STP and MoCA before and after MR training

	T0		T3		p-value (*p < 0.05)
	Mean	SD	Mean	SD	
Speed (m/s)	0.63	0.21	0.75*	0.29	<b>0.049</b>
Stride Length (cm)	74.18	18.67	85.33*	22.27	<b>0.018</b>
Walk Ratio (cm/(step/min))	0.38	0.10	0.42*	0.07	<b>0.012</b>
FAPS	73.63	18.75	78.75*	18.66	<b>0.029</b>
MoCA	6.25	4.46	6.50	5.66	0.957

The current study's gait speed mean change (+19%) is similar to Azadian et al. (+22%) in which the activity carried out was only cognitive, but the training load was much higher (3\*45min/week). Thus, a cognitive-motor Mixed Reality training appears more efficient than an only cognitive one to improve motor skills. Although riskier than computerized cognitive exercises, this MR task shows less risk and physical demands than traditional physical activity for frail people.

This greater effect might be due to the dual task character of the MR activity. Indeed, it has been shown that dual task training can improve both cognitive and motor functions [3]. Contrary to de Andrade et al. results, the current study does not reveal any MoCA improvement. Their intervention lasted nevertheless longer. The MoCA score might thus increase later in the case of a longer MR intervention. In any case, cognition did not significantly decrease.

### Conclusions

To conclude, a three-month weekly Mixed Reality cognitive-motor training improves gait parameters in people with mental disabilities in spite of a low training load. Further research should focus on how MR could also improve cognition, with higher training loads or different MR activities.

## Gait asymmetry results in symmetric relative efforts between affected and unaffected side musculature in children with hemiplegic cerebral palsy

### Summary

Tendency to minimize the energy cost of walking is thought to be a central factor in determining the way individuals walk. However, the recent study on post stroke individuals suggest that factors other than energy cost minimization may gain importance in determining gait pattern among clinical populations [1]. The present study in children with hemiplegic cerebral palsy suggest that the preference of asymmetric gait pattern may arise from tendency to equalize relative efforts between affected and unaffected side musculature.

### Introduction

Self-optimization hypothesis predicts that the central nervous system innately coordinates limb movements so that the resulting gait patterns coincide with the minimal energy expenditure. Evidence for this comes primarily from studies on unimpaired locomotion, which have shown that humans (and animals) self-select many gait parameters to minimize their energy expenditure, and even a small perturbation to preferred gait pattern, such as asymmetry, altered step length or width, increase the energy cost of walking. [2]

However, the recent findings of Nguyen et al. (2020) on post stroke individuals suggest that factors other than energy cost minimization may gain importance in determining preferred asymmetric gait pattern among clinical populations. The authors noted that persons with chronic stroke self-select an asymmetric gait despite being capable of walking more symmetrically; however, the energy cost of walking does not seem to be a central driver in gait asymmetry, because it did not differ between the self-selected asymmetric versus more symmetric gait, which was achieved using biofeedback. [1]

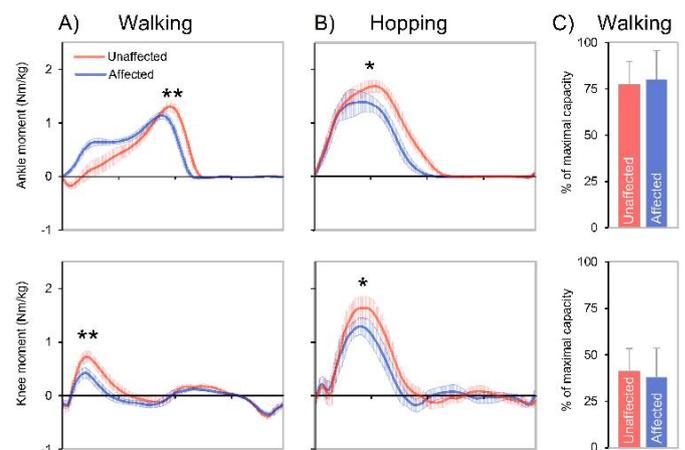

We hypothesized that a tendency to equalize relative efforts between affected and unaffected side musculature may be an important factor to explain the preference of asymmetric gait. We used children with hemiplegic cerebral palsy (CP) as a model to study this idea, because they walk asymmetrically due to compromised neuromuscular function of the affected side lower limb [3].

### Methods

We examined gait pattern asymmetries and relative muscle efforts of the ankle and knee extensors between unaffected versus affected lower limbs in children with hemiplegic CP. Ten children with hemiplegic CP (13 yrs.) and 10 healthy peers (13 yrs.) performed gait and maximal two-leg hopping in motion analysis laboratory. To quantify relative efforts, muscle moments generated by knee and ankle extensors were quantified during gait and then related to maximum moments generated by the same muscle groups during the hopping test.

### Results and Discussion

During walking at self-selected speed ( $1.22 \pm 0.08$  m/s) hemiplegic CP children demonstrated 0.04 s shorter contact time ( $p=0.004$ ) and tendency towards smaller step length (2.1 cm,  $p=0.1$ ) on the affected side compared to unaffected side. In the affected side, the walking-related ankle and knee extensor moments were 14% ( $p=0.002$ ) and 41% ( $p=0.007$ ) lower, respectively, compared to unaffected side (Fig. 1A). During all-out hopping test, the maximal moments developed in the affected side were 17% ( $p=0.033$ ) and 27% ( $p=0.021$ ) lower, respectively, in the ankle and knee extensors (Fig. 1B). However, no differences were found in the relative ankle ( $p=0.103$ ) and knee ( $p=0.292$ ) extensor muscle efforts in the affected versus unaffected lower limbs (Fig. 1C). This suggest that by shifting muscular contributions from the affected side to the unaffected side, children with hemiplegic CP can equalize the relative muscular efforts between limbs in walking.

**Figure 1.** Muscle moments and relative efforts of the ankle and knee extensors.

### Conclusions

Asymmetric gait in children with hemiplegic CP results in symmetric relative muscle effort in affected versus unaffected side ankle and knee extensors, which is likely an important strategy to prevent locomotor-induced muscle fatigue. These observations may also explain why gait asymmetry tend to be a very persistent in children with hemiplegic CP and why they often fail to adopt better, more symmetric gait patterns.

## Summary

Maximum short and long term finite time Lyapunov exponents were estimated to determine stability of lower limb kinematics and muscle activations in lower limb amputees (AMP) and compared to able-bodied (AB) participants. Shank loss increases bilateral muscle activation variability and prosthetic limb ankle and bilateral hip angle instability.

## Introduction

Typically, pathological gait is identified by comparing averaged gait cycles to a norm with variability defined as the standard deviation (SD) between cycles. These analyses assume cycle independence and that variation is random, contradicting the inherent dynamic nature of gait. Local stability quantifies the systems corrective response to perturbations. Knowledge of lower limb AMP gait dynamics may help prevention of falls. This study aimed to compare the stability and variability of AMP kinematics and muscle activations during walking to AB individuals.

## Methods

Marker motion (250 Hz) and electromyography (EMG; 2000 Hz) data for twelve AB (male) and three unilateral transtibial AMP (2 male) participants, who had provided informed consent, were recorded during at least 15 mins of treadmill walking (AB: four, 4 minute, AMP: three, 5 minute trials) at overground preferred walking speed (AB:  $1.46 \pm 0.2 \text{ m}\cdot\text{s}^{-1}$ , AMP:  $1.46 \pm 0.1 \text{ m}\cdot\text{s}^{-1}$ ). EMG was recorded from bilateral ankle (tibialis anterior, soleus, gastrocnemius lateralis and medialis), knee (rectus femoris, vastus lateralis, biceps femoris long head, semitendinosus) and hip (rectus femoris, biceps femoris long head, semitendinosus, gluteus maximus) musculature, locations determined with ultrasound.

Marker trajectories were lowpass filtered (12.2 Hz) and lower limb joint angles were calculated. Gait events were determined by kinematic algorithms [1,2]. EMG with impact spikes were replaced with a common signal matched for duration that preserved temporal features. EMG were: band pass filtered (20 – 450 Hz), demeaned, amplitude normalized, rectified, low pass filtered (6Hz), down sampled (250 Hz).

Trials were divided into two, 2 minute segments. Signals were time normalised to 101 data points. SD was calculated across the gait cycle and mean SD obtained. Maximum short ( $\lambda^*_s$ , 0 to 1 strides) and long ( $\lambda^*_L$ , 4 to 10 strides) term finite time Lyapunov exponents [3] were estimated to determine stability. Phase space was reconstructed using a time delay method. Optimal time lag and embedding dimension were determined by averaged mutual information [4] and false nearest neighbour [5]. EMG phase space was reconstructed in 8 dimensions, four joint muscle signals and time delay copies.

## Results and Discussion

AB kinematic stability and variability were bilaterally similar and agree with previous literature [6]. AMP kinematic  $\lambda^*_s$

differed from AB for the prosthetic limb ankle and bilateral hip (Table 1). Elevated prosthetic limb ankle angle  $\lambda^*_s$  implies increased instability and a slowed response to perturbations, due to the absence of a control system. Prostheses had repetitive joint movement, indicated by reduced variability (intact:  $1.4 \pm 0.3^\circ$ , prosthetic:  $0.8 \pm 0.2^\circ$ ). Increased AMP hip angle  $\lambda^*_s$  may be due to a compensatory mechanism for the instability from the prosthesis, this instability was not reflected in the variability.

AMP EMG stability variables were comparable to AB (Table 1). All intact and prosthetic limb muscles displayed increased variability compare to the mean AB limbs (mean increase 25% and 41%, respectively).

**Table 1:** Mean (top) and standard deviation (bottom) of mean amputee (AMP, I: intact, P: prosthetic limb) and able-bodied (AB, L: left, R: right limb) bilateral short ( $\lambda^*_s$ ) and long ( $\lambda^*_L$ ) term Lyapunov exponents for joint kinematics and muscle activations.

		Ankle		Knee		Hip		
		$\lambda^*_s$	$\lambda^*_L$	$\lambda^*_s$	$\lambda^*_L$	$\lambda^*_s$	$\lambda^*_L$	
Kinematics	AB	L	0.52	0.06	0.96	0.08	0.66	0.07
		R	0.09	0.01	0.07	0.01	0.08	0.01
	AMP	I	0.49	0.06	0.99	0.08	0.66	0.07
		P	0.12	0.01	0.07	0.01	0.11	0.01
	AMP	I	0.57	0.05	0.97	0.07	0.79	0.06
		P	0.08	0.01	0.06	0.01	0.14	0.01
AMP	P	0.83	0.06	0.96	0.06	0.73	0.06	
	P	0.11	0.01	0.04	0.01	0.14	0.01

### Summary

This study analyzed hip contact forces in paediatric patients with increased femoral antetorsion and healthy controls during gait by means of personalized musculoskeletal models based on individual morphological data. Hip contact forces were found to be less medially and less posteriorly oriented during early stance in patients with increased femoral antetorsion.

### Introduction

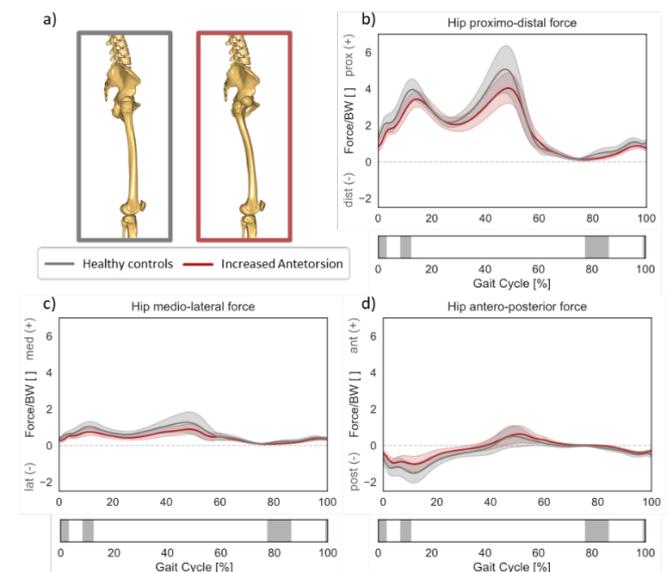

Kinematic and kinetic gait deviations due to increased femoral antetorsion have been described in the literature [1,2]. Passmore et al. compared joint loadings using a generic and subject-specific musculoskeletal model in patients with increased femoral antetorsion and increased tibial torsion [2]. However, no study to date compared joint loadings between patients and controls. Furthermore, the orientation of the intra-articular forces might be of interest with regards to acetabular cartilage damage that could arise during adulthood in concomitance with other morphological alterations, such as femoroacetabular impingement syndrome [3]. Therefore, the aim of the current study was to analyze hip contact forces (HCFs) in patients with increased femoral antetorsion and controls using personalized musculoskeletal models based on individual morphological data.

### Methods

Forty-two pediatric patients with isolated, CT-confirmed increased femoral antetorsion (26 females, mean age □ 12.8 years, mean antetorsion □ 39.4°) [1] and 9 healthy controls with MRI-confirmed normal torsion (5 females, mean age □ 12 years, mean antetorsion □ 21°) were included in this retrospective study. Patients were referred to gait analysis because of gait abnormalities going along with an increased femoral antetorsion  $\geq 30^\circ$ . Kinematic and kinetic data were recorded during 3D gait analysis using the Plug-In Gait model. The collected motion capture data was used as input for an inverse dynamics analysis (Any□ody Technology, Denmark) to evaluate HCFs, reported in a pelvis-based reference frame. Subject-specific models were created from a generic lower-limb model [4], which was scaled according to marker data from a static trial. The modelled femurs were morphed (Figure 1a) to match each subject's femoral antetorsion measurements. Differences in HCF 3-dimensional components between patients and control group were evaluated over the whole gait cycle through statistical parametric mapping (SPM) with two-tailed, two-sample t-tests ( $\alpha = 0.05/3$ ).

### Results and Discussion

Statistically significant differences in HCF components were observed between the two groups in various phases of the gait cycle (Figure 1b,c,d). The resulting HCFs were less medially and less posteriorly oriented during early stance in patients with increased femoral antetorsion, even though they also presented an overall lower HCF magnitude.

**Figure 1:** Predicted HCF 3D components in patients with increased femoral antetorsion (red) and controls (grey). Significantly different phases of the gait cycle are indicated below each force component.

### Conclusions

A better understanding of the forces that are produced within the acetabulum is necessary to improve individual diagnoses and to optimally plan targeted realignment of the lower extremities. Future work should also focus on investigating how such morphological deformities can affect the mechanics of the adjacent joints and/or potentially impair muscle functionality.

### Summary

Computer-assisted surgery (CAS) can provide real-time feedback of the knee kinematics during surgery. Understanding the link between this passive kinematics and the knee kinematics during gait could help surgeons evaluate the quality of the surgery. This study compared the adduction-abduction (AA) angle assessed by the surgeon during surgical navigation to AA during gait after total knee arthroplasty (TKA) for 8 patients. This preliminary study showed fair to moderate correlations between those angles but needs further investigations to increase the number of patients and clarify the results.

### Introduction

Computer-assisted surgery (CAS) is intended to improve the accuracy and precision of component position and leg alignment during TKA [1], especially the correction of the knee AA angle [1]. During surgery, the surgeon has a real-time feedback of multiple parameters such as the passive knee range of motion, AA angle in function of the flexion, or ligament balance. The intra-operative passive movements applied by the surgeon to assess the knee function was showed to have no significant differences with an active movement without loading in a recent study [2]. However, there is currently no evidence that knee kinematics evaluated during this passive movement is similar to the knee kinematics during weight-bearing activities such as gait. Thus, the objective of this study is to compare AA angles assessed by the surgeon during surgical navigation to AA measured during gait after TKA.

### Methods

Eight patients (median [IQR], 72 [10] years old, 159.0 [16.4] cm, 76.0 [49.7] kg, 6 females) undergoing primary TKA participated in this preliminary study. During surgery, after definitive TKA implantation, passive flexion-extension movements were measured with the Knee 3 CAS system (Brainlab, Germany) to assess passive knee kinematics. Three months after surgery, patients performed a standardized treadmill gait analysis [3] (KneeKG, Emovi, Canada) to assess active knee kinematics during walking at a comfortable self-selected speed.

The homogenization of conventions for knee kinematics computation was done based on the ISB recommendations [4]

and used the hip joint centre, medial and lateral femoral epicondyles and malleoli. Knee AA measured with navigation was expressed in function of knee flexion and fitted with a 3<sup>rd</sup> order polynomial [5]. The knee flexion measured during treadmill gait was used as input in the polynomial to estimate the AA value of navigation for a gait pattern of flexion. Finally, a Spearman correlation was performed between the AA angle curves measured during surgical navigation and treadmill gait for each patient. Correlations were classified in poor ( $r < 0.2$ ), fair ( $r: 0.21-0.40$ ), moderate ( $r: 0.41-0.60$ ), good ( $r: 0.61-0.80$ ) and very good ( $r > 0.81$ ) [6].

### Results and Discussion

Three patients had fair correlations and 5 had moderate correlations which indicates a link between passive and active weight-bearing knee kinematics (Table 1). Surprisingly, three correlations were positive and 5 were negative. This could be linked to the multiple differences between the measurements such as: passive and active conditions, intraoperative (with arthrotomy) and normal, closed condition, intra-cortical pins and external harness to fixate motion capture markers, or the pointing of the epicondyles: on the bone for navigation and on the skin for treadmill gait.

### Conclusions

The results indicate a link between passive knee kinematics and active weight-bearing knee kinematics during gait. However, this preliminary study needs further investigations to increase substantially the number of patients and understand the differences in correlations sign between patients.

### Acknowledgments

# The change of foot clearance and cognitive performance between single and dual task conditions of healthy older adults and people with Parkinson's syndrome

Ilke Warmerdam<sup>1</sup>, T. Eiken<sup>1</sup>, Clint Hansen<sup>1</sup>, Walter Maetzler<sup>1</sup>

<sup>1</sup>Department of Neurology, Kiel University, Kiel, Germany

Email: e.warmerdam@neurologie.uni-kiel.de

## Summary

People with idiopathic Parkinson disease (IPD) and healthy older adults experience a change in gait and cognitive performance with aging and while performing actions simultaneously, which is common in everyday actions. This study explored the interaction between foot clearance and cognitive performance during dual tasking. IPD patients had higher dual-tasking costs in more complex cognitive tasks than healthy older adults. Healthy older adults prioritized the cognitive task, IPD patients did not prioritize any task.

## Introduction

Aging affects gait and cognitive performance. People with idiopathic Parkinson disease (IPD) might even be more affected. Gait and cognitive performance are important factors for quality of life of the affected. One important gait parameter is foot clearance (maximum vertical height of the foot during the swing phase). A smaller foot clearance, as well as a lower cognitive performance can result in an increased risk of falling [1,2]. In everyday life, actions are often performed simultaneously which can potentially lead to an even smaller foot clearance. The aim of this study is to explore the interaction between foot clearance and cognitive performance during dual tasking.

## Methods

Ten IPD patients (65 ± 11) and 12 healthy older adults (70 ± 9) were recruited. Gait analysis was performed with a 3D optical motion capture system (Qualisys A, Göteborg, Sweden). Cognitive performance was assessed with two tests on a smartphone: a simple reaction time test and a more complex Stroop-test, where subjects choose the number with the highest value. In the neutral part the numbers are in the same font size, in the congruent part the higher is bigger and in the incongruent part the higher is smaller. Gait was analysed on a 5 m walkway on which subjects repeatedly walked up and down. First these tasks were performed separately (single task) and afterwards the cognitive tests were performed while walking (dual task).

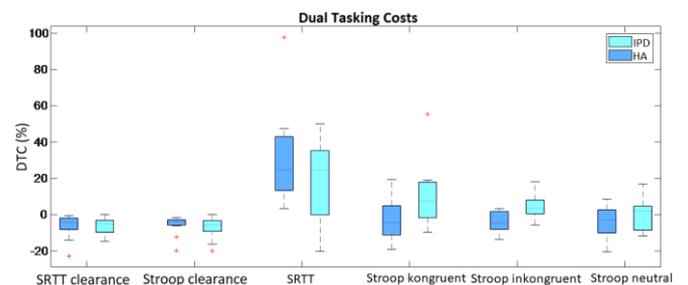

After the measurements, the difference between single-tasking and dual tasking performance was evaluated by calculating the dual tasking costs (DTC)

$$DTC(\%) = \frac{dual\ task - single\ task}{single\ task} * 100$$

Mann-Whitney-U-tests were performed for the comparison of the foot clearance, cognitive performance and the DTC.

## Results and Discussion

No significant differences were found between healthy older adults and IPD patients regarding the foot clearance and the cognitive performance. Only for the most difficult testing situation (incongruent part of the Stroop test), the DTC were higher for the IPD group compared to the healthy older adults (Figure 1). Comparing DTC of cognitive performance with DTC of foot clearance showed that IPD patients did neither prioritize foot clearance nor cognition. However, healthy older adults prioritized cognition over foot clearance.

**Figure 1:** Dual Tasking Costs. IPD = idiopathic Parkinson disease, HA = healthy older adults, clearance = foot clearance during cognitive test, SRTT = simple reaction time test.

The groups did not significantly differ in the Montreal Cognitive Assessment (IPD 26 ± 2; older adults 25 ± 4), which might explain the lack of significant differences between the two groups looking at the cognitive performance. Healthy older adults might prioritize the cognition because of the absence of gait problems, which allows them to concentrate more on the cognitive performance. Vice versa, IPD patients may need to focus more on their gait, and might therefore divide their attention evenly over the cognitive and the walking task.

## Conclusions

While there was no significant difference between IPD patients and healthy older adults regarding the foot clearance and the cognitive performance, the DTC of IPD patients were higher in more difficult cognitive tasks. IPD patients prioritize neither foot clearance nor the cognitive performance, while healthy older adults prioritize the cognitive task.

### Summary

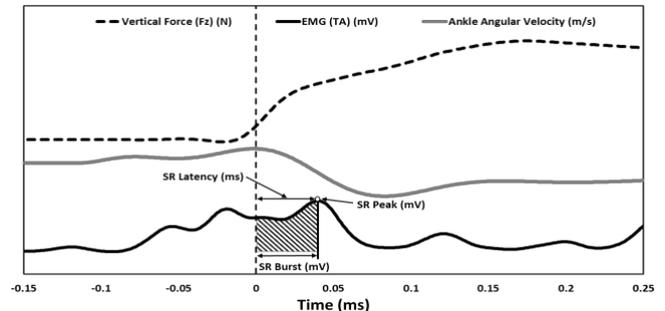

Evidence from electrically evoked cutaneous reflexes support the role of foot sole cutaneous afferents in modulating the excitability of spinal motoneurons innervating muscles of the lower extremity. The purpose of this study was to employ a non-electrical method of facilitating cutaneous afferent feedback (adding texture to the walking surface) to investigate its effects on stretch reflex (SR) latency, peak magnitude and integrated EMG of the muscle burst. There was a significant positive relationship in texture response between SR burst and SR peak in both the anterior platform tilt direction ( $r=0.495$ ,  $p=0.01$ ) and the posterior platform tilt direction ( $r=0.714$ ,  $p<0.01$ ). Results of this study highlight the individual responses of cutaneous afferent facilitation on SR excitability.

### Introduction

Evidence from electrically evoked cutaneous reflexes supports the role of foot sole cutaneous afferents in modulating the excitability of spinal motoneurons innervating muscles of the lower extremity [1]. This cutaneous reflex facilitation has been limited to electrical stimuli [2]; however, the effect of alternative cutaneous afferent facilitation methods, such as adding textured materials under the foot sole [3], on mechanically induced stretch reflex excitability remains unclear. The purpose of this study was to determine if the addition of texture, as a method of enhancing plantar-surface cutaneous mechanoreceptor feedback, will modify stretch reflex characteristics.

### Methods

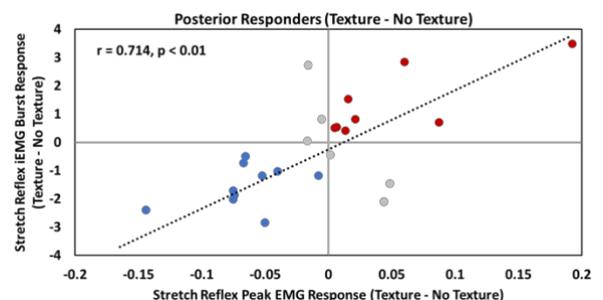

Thirty healthy young adults ( $23.2 \pm 9$  years) participated in 48 block-randomized walking trials of planned gait termination. Cutaneous afferent feedback was either 'non-facilitated' or 'facilitated' (texture added to the walking surface). The walking surface during the second last step of termination was unexpectedly manipulated to tilt in two directions: anterior or posterior. In the anteriorly tilted platform perturbations, the ankle moved into plantarflexion generating a stretch reflex (SR) response in the tibialis anterior (TA) muscle. In the posterior tilted platform directions, the ankle moved into dorsiflexion generating a stretch reflex response in the medial gastrocnemius (MG) muscle. All participants were instrumented with a standardized 12-IREM marker setup and kinematics were recorded with two Optotrak Certus cameras (SF=100Hz). Kinetic and EMG data were measured with three AMTI force plates (embedded flush to the walking platform) and a Noraxon Ultium EMG system (SF=1000Hz). The stretch reflex characteristics were comprised of 3 dependent variables: SR latency, as well as peak amplitude (SR Peak) and total amplitude of the agonist burst (SR burst) (Figure 1).

**Figure 1:** The vertical ground reaction force ( $F_z$ ), ankle angular velocity, and EMG (TA) were used to calculate the SR latency (time, ms), SR peak (maximum amplitude of muscle burst, mV) and SR burst (integrated EMG, mV).

### Results and Discussion

A significant interaction between the direction of platform tilt and cutaneous afferent facilitation on the SR peak ( $F_{1,25}=4.25$ ,  $p=0.042$ ) and SR burst magnitude ( $F_{1,25}=8.52$ ,  $p=.004$ ) was found. There was a significant positive response between SR burst and SR peak texture response in both the anterior platform tilt direction ( $r=0.495$ ,  $p=0.01$ ) and the posterior platform tilt direction ( $r=0.714$ ,  $p<0.01$ ) (Figure 2).

**Figure 2:** The relationship between responders (positive (red), negative (blue)) and non-responders (grey) in the posterior platform tilt directions between SR Peak and Burst.

### Conclusions

As expected, there was no effect of texture on SR latency. Results of this study highlight the individual dependent responses of cutaneous afferent facilitation on SR excitability. This inter-subject variability is important in future studies exploring cutaneous afferent facilitation on SR excitability.

## Application of deep learning based pose estimation methods for clinical gait outcome measures

Logan Wade<sup>1</sup>, Laurie Needham<sup>1</sup>, Murray Evans<sup>1</sup>, Steffi Colyer<sup>1</sup>, Darren Cosker<sup>1</sup>, James Wilson<sup>1</sup>, Polly McGuigan<sup>1</sup>  
<sup>1</sup>Centre for Analysis of Motion, Entertainment Research and Applications, University of Bath, Bath, United Kingdom  
 Email: [lw2175@bath.ac.uk](mailto:lw2175@bath.ac.uk)

### Summary

Clinical gait analysis measures were compared between deep learning-based pose estimation methods (OpenPose, AlphaPose and DeepLabCut) and standard marker-based motion capture.

### Introduction

Markerless motion capture employs deep learning-based pose estimation methods and has the potential to streamline data collection and processing. Such methods could improve the viability of gait analysis in a clinical environment. Numerous open-source pose estimation algorithms have been developed, but to date no comparison has been made between algorithms to examine their accuracy compared to marker-based motion capture. This study aims to compare clinical gait analysis measures (specifically those related to knee osteoarthritis), to examine if gait analysis performed by open-source markerless methods could be used for clinical applications.

### Methods

Fourteen healthy participants performed over-ground constant speed walking while motion capture was obtained from 15 Qualisys cameras and 9 machine-vision cameras at 200 Hz. Image data from each machine-vision camera were processed using OpenPose[1], AlphaPose[2] and DeepLabCut[3]. 2D image plane coordinates from each pose estimation method were back-projected into the 3D space, where the intersect of the back-projected rays were taken to represent the 3D joint centre locations. Right ankle, knee and hip joint-centre locations were used to calculate step length, step width, velocity and planar joint angles over one stride. Outcome measures were compared using Bland-Altman and correlation analysis between marker-based and markerless methods.

### Results and Discussion

AlphaPose presented the best agreement with marker derived methods across most variables, followed by OpenPose and DeepLabCut (Table 1). AlphaPose and OpenPose sagittal measures had a lower bias compared to frontal measures (Table 1) and this was especially evident in the frontal plane at the hip, which was systematically offset across the whole

stride for all methods (Figure 1). This systematic offset was likely due to erroneous manual identification of hip joint centre location within the training data of the markerless algorithms. Variability (SD of bias) was at best, 3.5 ° in the sagittal plane and 2.2 ° in the frontal plane, which may be too large to detect small meaningful changes during gait in some clinical conditions (Table 1). Therefore, these open-source methods are likely still too imprecise for many clinical applications.

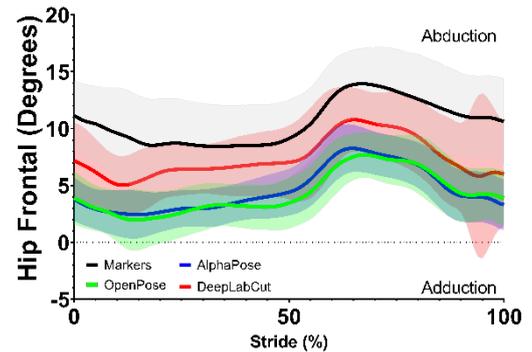

Figure 1: Mean ( $\pm$  SD) frontal plane hip joint angle.

### Conclusions

The spatial measures produced by AlphaPose and OpenPose may be sufficiently accurate to detect changes in gait, however sagittal variability, frontal accuracy and frontal variability are currently too large for most clinical applications. Researchers and clinicians need to carefully consider the desired outcome measure and accuracy required for their specific application, before implementing these markerless motion capture methods in their current form.

### Summary

Various spatiotemporal parameters alterations are observed in obese subjects. Principal component analysis (PCA) could improve subject's classification reducing optimal set of variables. Kinematics of fourteen subjects (with and without obesity) during walking was recorded. PCA showed that the two main principal components included the same variables: body mass index (BMI) and active range of motion (AROM) of ankle flexion. These variables could explain the different strategies in gait pattern of obese subjects.

### Introduction

Obesity prevalence has increased continuously over the past decade. Obese subject's walking is mainly associated with a decrease of speed and various spatiotemporal parameters alterations according to their weight and age [1].

PCA can be used to minimize the optimal variables to be explored. The aim of the study is to propose a functional set of variables classification associated with obesity based on PCA.

### Methods

Seven obese subjects (mean  $\pm$  standard deviation; age = 34.57  $\pm$  16.11 years, height = 1.73  $\pm$  8.19, BMI = 36.11  $\pm$  4.57) and seven paired normal weight subjects (BMI = 23.7  $\pm$  2.49) were selected according to their age and height. All subjects voluntarily performed six walking gaits at their preferred velocity. Subjects low body kinematics have been recorded according to an optoelectronic system (Vicon ® Nexus, 8 cameras, 100 Hz) synchronized to two force plates (AMTI ® Accugait, 1000 Hz). AROM were assessed for clinical estimation of: hip flexion and abduction, knee flexion and ankle plantar flexion. Subject speed, stride length, cadence, step length and stride time were also computed.

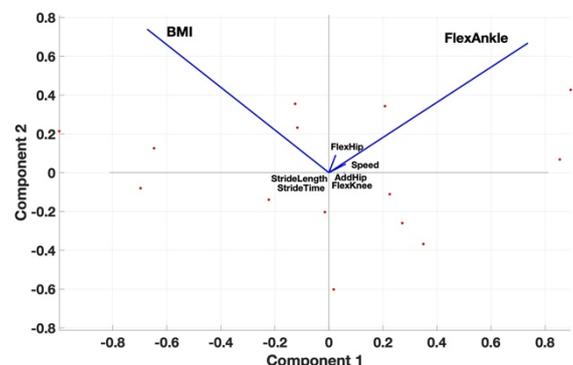

A normalized and centered PCA has been used to study the relations between the kinematics, spatiotemporal variables and BMI.

### Results and Discussion

PCA showed that the two first principal components explained respectively, 74.8% and 23.4% of the result variance. These two principal components included the same variables: BMI and AROM of ankle. For the first principal component, contributions of BMI and AROM of ankle flexion were respectively -67.1% and 73.6%. For the second principal component, contributions of BMI and AROM of ankle were respectively 73.8% and 66.7% (figure 1). Decreasing AROM

of ankle associated with the increase of BMI seem to be the main variables to classify gait pattern of obese subjects.

Alterations in spatiotemporal gait parameters at preferred walking speed in obese adults have been currently reported [1]. Few studies have defined the influence of ankle muscular activity during gait in obese adults [2]. The preliminary results of the present study are in agreement with the hypothesis that ankle plantar flexion could mainly affect gait pattern and velocity of obese subjects at preferred speed [3].

**Figure 1:** Variables contributions in the two principal components.

The first principal component could present one ankle plantar flexion self-optimization strategy in obese subjects in order to limit knee load associated with overweight [1]. The second component could present the muscular increased and prolonged ankle activities during the support phase in obese subjects [2]. In both cases, ankle play a determinant support to obese subjects in order to compensate AROM restrictions of hip and knee. The increase of subject's recruitment is needed to improve the validity of the PCA results.

### Conclusions

PCA showed that BMI and AROM of ankle plantar flexion could be the main variables explaining the different strategies in gait pattern of obese subjects.

## Perturbed Treadmill Walking Effect on Cognitive Vigilance

Alex P. Moorhead<sup>1</sup>, Giuseppe Lorenzini<sup>1</sup>, Stefano Marelli<sup>1</sup>, Enrico Marchetti<sup>1</sup>, Marco Tarabini<sup>1</sup>  
<sup>1</sup>Department of Mechanical Engineering, Politecnico di Milano, Milan, Italy

### Summary

Whole-body vibration (WBV) as experienced during work, recreation, and transportation, have potentially detrimental consequences on health [1]. The cognitive strain of WBV on subjects during dual tasks is less well known. In order to measure the effect of lateral WBV while walking on cognitive vigilance, a device was designed and manufactured by our lab for subjects to perform a Psychomotor Vigilance Test (PVT) while walking atop a laterally vibrating treadmill. Preliminary results show that PVT reactions times increase (worsen) during vibration, walking, and dual motor tasks, however, return to baseline after testing.

### Introduction

Whole-body vibration (WBV) has been established as being potentially dangerous or beneficial depending on the exposure dosage [2]. The human response to vibration has also been shown to be dependent upon both posture and activity [3]. Employees who are exposed to WBV commonly must perform tasks which involve both physical and mental (dual task) vigilance. However, little research has studied the effects of WBV on cognitive performance during dual task scenarios. Understanding this is essential to creating safety and performance guidelines for WBV-exposed employees. To do so, subjects must be safely exposed to WBV while also having their cognitive vigilance evaluated.

### Methods

Healthy male subjects 20-40 years old have been recruited to test the effect of lateral WBV on cognitive vigilance. Subjects performed five sessions of Psychomotor Vigilance Tests (PVT) in one day. One baseline PVT session is performed while standing without vibration or walking followed by three PVT sessions in randomized order to avoid a learning effect: walking without vibration, vibration without walking, and walking with vibration (dual task). Subjects then perform a final standing PVT session without walking or vibration. After each session, subjects are given a two minute rest.

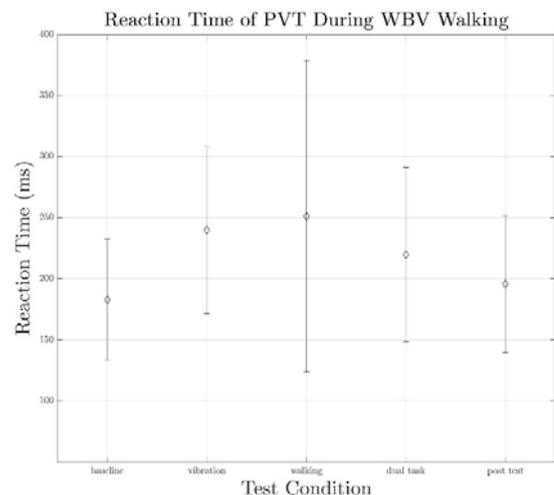

To perform the PVT sessions, a custom device was developed using a Wemos Lolin D1 mini board, based on the ESP8266-EX microcontroller, connected to a speaker and two LED panels to create audiovisual stimuli, as well as a custom handheld push button to respond. A custom firmware was developed to manage the PVT device which communicates via Wi-Fi with a custom MATLAB (version R2018b, MathWorks; Natick, Mass., USA) script.

When the test is initiated, a panel of blue LEDs are illuminated while a speaker simultaneously emits a low frequency (LF) tone. After a random period of time (2-9 s) has elapsed, a second panel of green LEDs are illuminated and the LF tone switches to a high frequency (HF) tone. At the moment the

audiovisual stimuli change, the subject must react as quickly as possible by pressing the handheld button. The reaction time is measured by the microcontroller and sent to MATLAB. The system then provides a 1.5 s reset time when the lights and speaker are turned off. The sequence is repeated ten times per minute for five minutes resulting in fifty reaction times per trial session.

### Results and Discussion

Preliminary results, as seen in Figure 1, show that both the mean and standard deviations of reaction times during a PVT test are greater when the subject is performing the test during exposure to vibration and is highest when walking.

**Figure 1:** The mean (diamond) and SD (bars) reaction time of PVT tests across the five testing conditions.

### Conclusions

While it was expected that dual task walking would result in the greatest increase in PVT reaction times, it appears that walking on its own creates the greatest strain on cognitive vigilance. It can be observed, however, that vibration has a similar (yet lesser) effect as well. Since results are currently preliminary, it will require greater subjects to statistically prove which treatment has the greatest effect on PVT times. Further investigation can help understand the limits of vibration safety as well as the cognitive performance of employees while performing dual occupational requirements.

# The effect of gait speed on plantar pressure data measured with the GAITRite instrumented walkway

Clara Leyh<sup>1,2</sup>, Véronique Feipel<sup>1,2</sup>

<sup>1</sup>Laboratory of Functional Anatomy, Université Libre de Bruxelles (ULB), Belgium

<sup>2</sup>Laboratory of Anatomy, Biomechanics and Organogenesis, Université Libre de Bruxelles (ULB), Belgium

Email: [clara.leyh@ulb.be](mailto:clara.leyh@ulb.be)

## Summary

94 healthy controls and 125 subjects suffering of low back pain walked at three different self-selected speeds on the GAITRite instrumented walkway to evaluate the effect of gait velocity on plantar pressure distribution. Except for peak time, that decreased, with increasing gait speed, no medial midfoot pressure parameter changed with velocity. Peak pressure and integrated pressure (P\*t) behaved almost likewise: they increased at the heel and decreased at the lateral forefoot when changing gait velocity from self-selected preferred gait speed. Contact area increased proportionately with gait speed at the lateral and medial heel and at the medial forefoot. We conclude that the GAITRite can highlight the effect of gait speed on plantar pressure distribution, despite its independence to anatomical landmarks.

## Introduction

The GAITRite® walkway is a portable pressure-sensor mat that detects footfalls. Each footprint is represented by the GAITRite software as a quadrangle divided in 12 trapezoids (six medial and six lateral) for which it computes resistive plantar pressure parameters [1]. Since this pressure mat is easily (no patient preparation) and broadly used in clinics [2], it appears interesting to study if plantar pressure parameters, provided for each trapezoid, agree with previously reported data in the literature; with a special focus on the impact of gait speed on plantar pressure [3-4].

The aim of this study was therefore to evaluate, using the GAITRite, a 6,1 m long electronic walkway, the effect of slow, preferred and fast self-selected gait speeds on the evolution of plantar pressure parameters at the lateral and medial heel, mid- and forefoot in healthy subjects and subjects with low back pain.

## Methods

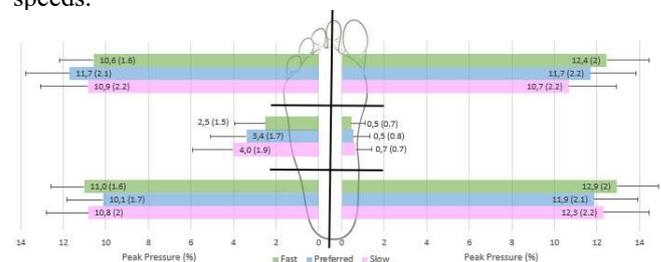

94 healthy controls and 125 subjects with low back pain (LBP) walked barefoot three times at three different self-selected speeds (slow, preferred, fast) over the GAITRite walkway (CIR Systems). The order of gait speeds was randomized. Average values over all three trials were computed.

The GAITRite Gold software (version 3.9) computed, for each of the 12 footprint trapezoids, four dependent variables: **P\*t** (integrated pressure over time in one zone, expressed as a percentage of the overall integrated pressure over time), **peak time** (first time point at which one or more sensors in a zone were at their maximum level, expressed in seconds), **area** (sum of the active sensor areas within a zone; expressed in square centimeters) and **peak pressure** (maximum pressure per zone, expressed as a percentage of the overall maximum pressure per foot). To simplify the results, the data of the 12 trapezoids were assembled in 6 sections defined as medial and lateral fore-, mid- and hind-foot.

Normality of all data distributions was explored. Repeated measures ANOVA were completed to investigate differences in pressure parameters between gait velocities. Tukey HSD test were computed to explore interactions between velocity and pressure zones. The level of significance was set at  $p < 0.05$ .

## Results

All parameters were significantly different in terms of velocity ( $p < 0,003$ ). A velocity-zone interaction was also found for all four parameters ( $p < 0,0001$ ). Figure 1 shows the average peak pressure in the different zones and for all gait speeds.

**Figure 1:** Peak pressure average and standard deviation for each foot zone and gait velocity (slow, preferred and fast).

Except for medial midfoot at preferred and fast speeds, **peak time** decreased for all pressure zones with velocity increase. No changes in **P\*t**, **area** and **peak pressure** were found in the medial midfoot. In contrast, these parameters decreased significantly at the lateral midfoot with increasing gait velocity ( $p < 0,0001$ ). **Area** increased proportionately with gait speed at the lateral and medial heel. In addition, at the medial heel, area was similar at preferred and fast speed. At the lateral hindfoot, **P\*t** increased from preferred speed to slow and from slow to fast while **peak pressure** increased from preferred speed to slow or fast walking velocity. At the medial heel, **P\*t** was equal at slow and preferred speed but increased at fast gait velocity; **peak pressure** increased from preferred speed to slow and from slow to fast. Lateral forefoot **area** was not influenced by gait velocity. **P\*t** and **peak pressure** decreased in that zone from preferred to slow and/or fast speed, respectively. Medial forefoot **area**, **P\*t** and **peak pressure** increased with increasing gait speed.

## Conclusions

The results agree with those of the literature [3-4] and are of interest given the independency to anatomical landmarks or clinical regions of interest in the processing of the footprint mask by the GAITRite software. To evaluate the impact of LBP on plantar pressure, future studies are needed with a special care in controlling for gait speed differences.

# How does modulating load impact the limits of stability during walking? Inferences from simulated body-weight support and load carriage conditions

Yong Kuk Kim, Michelle Gwerder, Deepak K Ravi, William R Taylor, Navrag B Singh  
 Laboratory for Movement Biomechanics, Institute for Biomechanics, ETH Zurich, Switzerland

## Summary

This study investigated the movement of the center of mass of the whole body (CoM) and the swing foot with respect to the boundaries formed by the base of support (BoS). The vision to get a better understanding of temporal co-ordination between CoM and feet placement. With different weight conditions, load-carriage resulted in adaptability in swing foot placement. Whereas, body-weight support resulted in instability, might allow better flexibility for upcoming stride.

## Introduction

In order to walk continuously, CoM needs to be regulated over the BoS (Physical Boundary:  $B_p$ ). While the spatial constraints imposed to achieve this task successfully are established [1], the temporal limits have not been fully understood. Time to contact (TtC) provides an estimate of the duration of contact with BoS in a continuous manner, and thus promises to fill the gap on temporal constraints. In addition, quantifying TtC on CoM vs. a particular extremity – swing foot – allows us to assess the temporal co-ordination (K, Figure 1B) needed to achieve walking stability [2].

Simulating weight bearing vs load carriage provide ideal conditions as not only are they encountered in daily life, they also perturb the swing foot dynamics. Therefore, the aim of this study was to investigate the TtC under body weight loading (via body-weight support vs. load carriage).

## Methods

Twenty healthy participants (9 females; Mean(SD): 24(2) yr; 174.4(7.5) cm; 69.3(8.2) kg) performed in a randomized order: normal walking (Normg), 20% additional (20+), and 40% additional bodyweight (40+) with a weight vest as well as 20% less (20-) and 40% less bodyweight (40-) in a clinical harness system. Participants walked on a treadmill for 6 minutes each condition. 3D kinematics were obtained via an optical motion capture system (Vicon Motion Systems, UK) by placing 38 reflective markers over both lower limbs (Fig 1A) at 500 Hz. The centroid of 7 pelvis markers was used to estimate CoM.  $B_p$  (Fig 1A) was defined as the position (anteroposterior direction, AP) of the first metatarsal of the stance foot.

## Results and Discussion

The CoM in Normg approached  $B_p$  at 72% (TtC<sub>CoM</sub> approaching 0, Fig 1B), while the swing foot crossed  $B_p$  at 49% of swing phase(sp). Supporting body weight expedited (66% sp), while load carriage delayed the approach of CoM to  $B_p$ . The swing foot approached CoM (in AP) at ~12% sp (K=1, Fig 1B), and thereafter continued to lead CoM in the movement towards  $B_p$ . Supporting body weight delayed (~14% sp), while adding weight hastened (~10% sp) the approach of

the swing foot to CoM. When swing foot leads the CoM towards  $B_p$  it allows adaptability in foot placement [2] as seen in the load carriage condition. However, it might come at a cost of inflexibility, due to the delayed CoM approach to  $B_p$  might result in insufficient time to plan for the upcoming stride. With body-weight support, CoM lags the swing foot for a longer period of time inducing a considerably larger single limb stance phase (than Normg) resulting in unstable walking. Here, as the swing foot crosses the CoM late anticipatory, during the swing, adjustments might be difficult.

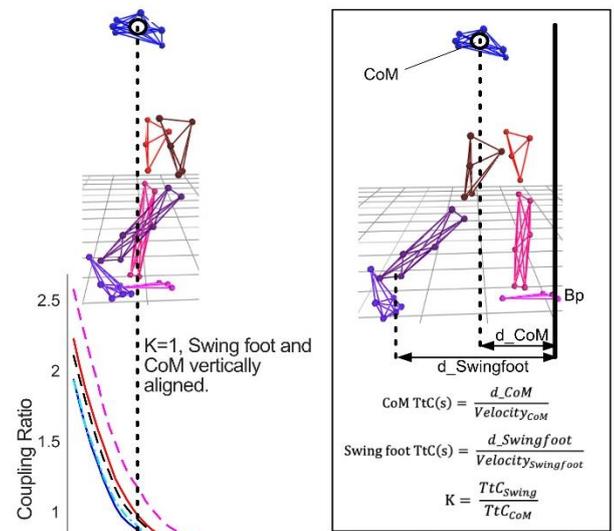

Figure 1A. Equations Ttc and K.

## Detecting Gait from a Shank-Worn Inertial Measurement Unit Using Harmonic Frequencies

Robbin Romijnders<sup>1,2</sup>, Elke Warmerdam<sup>2,1</sup>, Clint Hansen<sup>2</sup>, Gerhard Schmidt<sup>1</sup>, Walter Maetzler<sup>2</sup>

<sup>1</sup>Digital Signal Processing and System Theory, Kiel University, Kiel, Germany

<sup>2</sup>Neurogeriatrics, University Hospital Kiel, Kiel, Germany

Email: robr@tf.uni-kiel.de

### Summary

Preliminary results shows that harmonic frequency analysis of accelerations and angular velocities obtained with a shank-worn inertial measurement unit can be used to distinguish between walking and other cyclic activities.

### Introduction

In [1], the authors have shown that gait can be distinguished from other cyclic activities by using harmonic frequencies. A foot-worn inertial measurement unit (IMU) was used to record accelerations and angular velocities during in-lab gait assessments and unsupervised semi-standardized gait tests in the home environment from 121 controls and 7 participants with Parkinson's Disease (PwP), respectively. Here, we extend their work by testing if the methods also apply to a shank-worn IMU.

### Methods

A home-like assessment was performed at the University of Tübingen (details in [2]) where participants performed daily-life-relevant, non-instructed activities, including walking around in the hospital corridors, making coffee, and ironing clothing. Before each home-like assessment, the rigidity of the lower legs were checked (Item 3.3, UPDRS Part III [3]).

Participants were equipped with shank-worn IMUs attached at the frontal sides of each shank. Data were processed for the left and right shank independently. Data from the rigidity assessment and data from a manually extracted walking bout

were analyzed in the frequency domain to determine whether harmonic frequencies were present.

### Results and Discussion

Here, we have analyzed the data from one participant diagnosed with Parkinson's Disease (male, 38 years). During walking the medio-lateral angular velocity signal shows a typical harmonic pattern, where minimally two harmonics can be observed in the frequency range up to 6 Hz, as indicated by the peaks (green square) at multiples of the fundamental frequency (red triangle) (Figure 1). For the rigidity assessment, the fundamental frequency is generally higher, and less harmonics (< 2) are observed.

### Conclusions

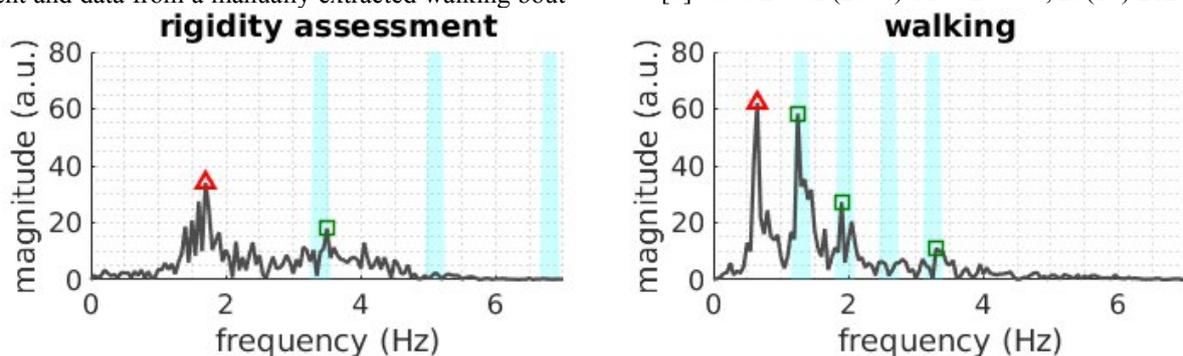

The methods of [1] can be extended to shank-worn IMUs, although this needs to be validated with more participants and various non-walking cyclic activities.

### Summary

Stereophotogrammetry could be considered as an optimal solution for quantifying spatio-temporal gait outcomes from complete turning maneuver. Nevertheless, relevant algorithms estimating foot-to-ground events have been extensively validated for straight-line walking. This study showed that these approaches can indeed be translated to curvilinear walking with a minimal loss of accuracy.

### Introduction

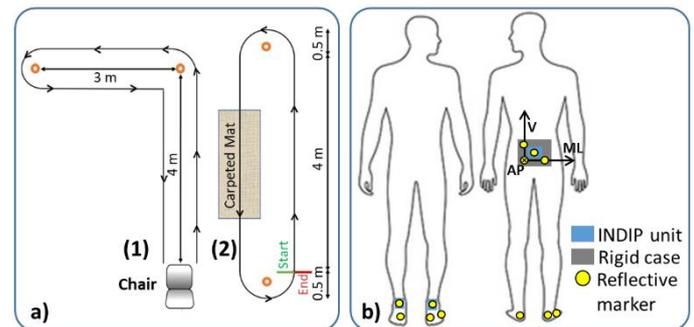

Spatio-temporal metrics are used to quantify functional gait limitations. These are traditionally extracted from straight-line walking (*s-walk*), even if their quantification while turning (*t-walk*) might be more sensitive in detecting impairments [1]. Quantification of spatio-temporal metrics relies on accurate identification of foot-to-ground gait events (GEs), for which stereophotogrammetry (SP) is a convenient solution if interested in multiple consecutive steps acquired during complex tasks. SP-GE algorithms, however, have been mostly validated on *s-walk* [2] and only on limited portions of *t-walk* [3]. This study will therefore aim to assess the GE reliability for *t-walk* of the method proposed by Zeni *et al.* [4].

### Methods

Twenty healthy subjects (13 males, age: 29.7±9.0, BMI: 23.2±2.8 kg/m<sup>2</sup>) were included in this study, after providing written informed consent. They were asked to perform two motor tasks including 90- and 180-degree turns (Figure 1). Subjects were equipped with a wearable multi-sensor system (INDIP) including sixteen force-sensing resistors embedded in each pressure insole (PI) [5], thus providing reference GEs (r-GE). Twelve marker trajectories (10-camera Vicon T160; four markers on each foot and four on a rigid case on the lower back) were used to detect marker-based GE (m-GEs) [4] and the pelvic axes. The latter were used to detect: (i) initial (IC) and final contacts (FC) as maximal and minimal displacement of heel and toe markers with respect to a marker on the rigid case along the pelvic anterior/posterior axis, respectively; (ii) turns defined from thresholds on angular velocity and rotations around the vertical pelvic axis [1]. SP and INDIP signals ( $f_s = 100\text{Hz}$ ) were synchronized as described in [5].

For each r-GE, the relevant time error ( $\Delta t$ ) was calculated matching the closest m-GE event. Based on the identified

turns,  $\Delta t$  were classified as either curvilinear ( $\Delta t_c$ ) or straight ( $\Delta t_s$ ) walking error; sampling at 100 Hz imposes a minimal  $\Delta t$  of 10 ms. Descriptive statistics of  $\Delta t$  distributions were calculated in terms of accuracy (mean) and precision (standard deviation); statistical differences were evaluated with independent Mann-Whitney U tests (IBM SPSS 26).

**Figure 1:** a) Motor tasks: L-Test (1) and surface test (2). b) Markerset, pelvic axes and INDIP units.

### Results and Discussion

Table 1 shows results for 1298 GEs (669 ICs) and relevant  $\Delta t$  from 19 participants (data from one participant was discarded due to poor PI signal quality). Negligible differences in  $\Delta t$  were observed between the two walking conditions and only FC- $\Delta t_c$  values were significantly larger than FC- $\Delta t_s$ .

### Conclusions

In conclusion, this study showed that kinematic data can be used to estimate GEs with a minimal loss of FC accuracy in curvilinear walking. The impact of such inaccuracies on other spatio-temporal metrics still needs to be assessed but is expected to be negligible.

Email: bernhard.dumphart@fhstp.ac.at

### Summary

Reliability and validity of a low-cost insole device to measure plantar pressure and force were evaluated. Reliability in terms of the intraclass correlation between a test and retest showed excellent agreement ( $\geq 0.9$ ). In terms of validity, results indicated an overall high correlation ( $R^2: 0.84$ ) between the insole and force plate data. Despite, some technical limitations, this insole device seems to be a promising alternative to measure plantar pressure and force in the field.

### Introduction

Gait analysis (GA) has become an important tool for clinical decision-making in various patient groups [1]. The gold standard, 3DGA, allows describing kinematic and kinetic aspects of human locomotion. However, 3DGA is limited to specialized facilities, is expensive, and time-consuming. Being bound to a stationary laboratory is another limitation. For this reason, different types of wearables have recently been introduced and are gaining popularity. These allow the investigation of real-world scenarios, not in a confined research environment, but where patients perform their day-to-day activities. Nevertheless, new sensors and technologies need to meet certain quality criteria before they can be used. Therefore, this study investigates the validity and reliability of temporal and kinetic variables of a low-cost (~250€) mobile pressure insole device (stappone, stAPPtronics GmbH).

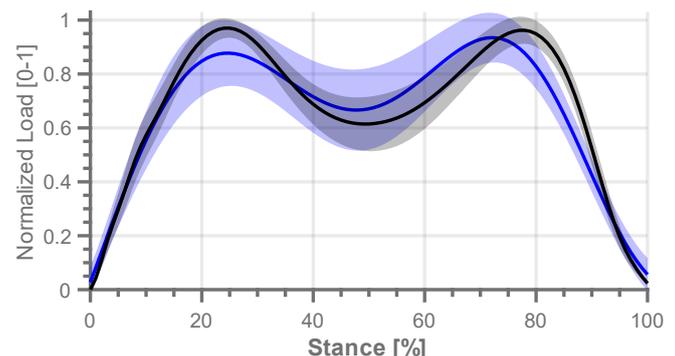

### Methods

Ground reaction forces (GRF) sampled at 1000 Hz and insole-pressure data sampled at 100 Hz of the dominant leg from 48 healthy participants were recorded simultaneously during a test and retest, approx. 15 minutes apart. Five to eight valid trials per participant and session were recorded on a 10-meter walkway at a self-selected speed. Reliability was assessed by calculating the intraclass correlation coefficient (ICC, model 2,k) of discrete variables from averaged test and retest data of the insole. Variables comprised the first (F1) and second (F2) force peaks, the mid stance valley (MSV) and their timestamps in milliseconds. Validity was assessed by calculating the linear fit method (LFM) [2] between the signals of the GRF and the insole for each trial. All signals were filtered using a 4th-order Butterworth filter with a cutoff frequency of 10 Hz. For the LFM calculations, data was normalized to a range of 0 and 1 because the insole only measures relative loads expressed as bits between 0 and 1023 (dimensionless).

### Results and Discussion

The ICC showed excellent agreements ( $\geq 0.9$ , range of 95% confidence interval (CI): 0.71 – 0.99) for all temporal and

kinetic parameters. Results are in agreement to earlier studies reporting ICCs of 0.81 to 0.97 [3, 4]. Differences in sampling rate, testing protocols, sample heterogeneity and investigated parameters must be considered when comparing various studies. In terms of validity, the LFM results indicate an average  $R^2$  value over all trials of 0.84 ( $\pm 0.08$ ) with the 95% CI ranging between 0.84 and 0.85. This shows that on average 84% of the variance in the insole data can be matched by the variance in the GRF data, implying an overall good representation. The similarity of both systems is represented in Figure 1, where the mean and standard deviation of the GRF (black) and insole (blue) trials are compared. Nonetheless, local differences in some areas like the F1, F2 and the MSV can be recognized. These differences in peak height and timing might be attributed to a varying number and size of sensors in the heel and forefoot area of the insole. The rather wide standard deviation might be explained by a pre-load of the sensors due to constant contact of the foot with the insole in the shoe, even during swing.

**Figure 1:** Mean and standard deviation of the normalized vertical GRF measured by the force plate (black) and the insole (blue).

### Conclusions

The insole shows good results for both the reliability and validity criteria in a healthy sample. Further research on pathological gait is needed, but otherwise, the insole indicates a promising alternative in rehabilitation and field scenarios.

## Effect of aging and physical activity level on recovery within the stride during walking

Leopoldine Kury<sup>1</sup>, Aitor Fernandez Menendez<sup>1</sup>, Davide Malatesta<sup>1</sup>

<sup>1</sup>Institute of Sport Sciences of the University of Lausanne, University of Lausanne, Lausanne, Switzerland

Email: leopoldine.kury@unil.ch

### Summary

This study aimed to investigate the effect of aging and physical activity level on pendular energy-saving mechanism in active and sedentary older ( $\geq 65$ yr) and young individuals. Twelve sedentary older, 11 active older and 21 young individuals walked at  $1.11 \text{ m}\cdot\text{s}^{-1}$  on an instrumented treadmill. Mechanics of walking were assessed. Compared to young individuals and independently of their physical level, older adults walked with a significant higher pendular recovery (+14;  $P < 0.001$ ) and significant lower external mechanical work (-18%;  $P < 0.001$ ). Recovery within the stride was significantly higher during the first half of the double contact phase and the second half of the single contact phase in older than in Y participants ( $P \leq 0.01$ ). Our findings showed that older participants, seem to adapt their walking pattern to improve their pendular energy recovery in order to limit the external mechanical work, especially during the step-to-step transition phase.

### Introduction

Physical activity seems to limit the physiological changes in walking performance due to aging. The aim of this study was to investigate the effect of aging and physical activity level on pendular energy-saving mechanism in active and sedentary older ( $\geq 65$ yr) and young individuals.

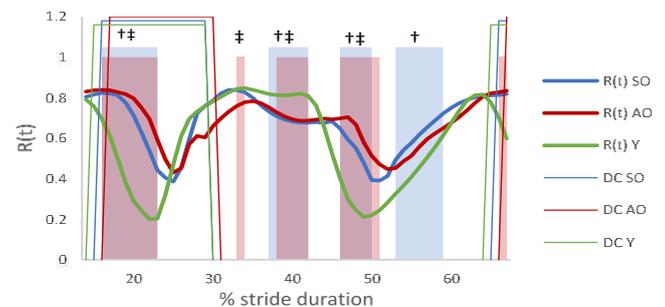

### Methods

Twelve sedentary older (SO  $71.6 \pm 4.3$ yr), 11 active older (AO  $71.5 \pm 3.7$ yr) and 21 young ( $24.3 \pm 2.0$ yr) individuals walked at  $1.11 \text{ m}\cdot\text{s}^{-1}$  on an instrumented treadmill and mechanics of walking [positive external mechanical work ( $W_{\text{ext}}$ ) and average and instantaneous pendular recovery within the stride [R(t)]] were assessed [1].

### Results and Discussion

Compared to young individuals and independently of their physical level, older adults walked with a significant higher pendular recovery ( $+14\%$ ;  $P < 0.001$ ) and significant lower  $W_{\text{ext}}$  (-18%;  $P < 0.001$ ). R(t) was significantly higher during the first half of the double contact phase and the second half of the single contact phase in OA and SO than in Y ( $P \leq 0.01$ ; Figure 1). The older individuals performed less  $W_{\text{ext}}$  during the push II phase, making kinetic ( $E_k$ ) and potential ( $E_p$ ) mechanical energies more out of phase, reducing the phase shift between the two curves in this phase. These findings corroborate previous one, showing that, compared with young individuals, older individuals performed an average of 10% less individual limb work during double contact phase [2]. As reported in obese individuals [3], older individuals seem to improve the pendulum mechanism to reduce the amount of  $W_{\text{ext}}$ .

During the single contact, the within-step analysis of pendular energy recovery showed that there were two zones in which older individuals had a skillful R(t) compared with young subjects. These zones were just before and slightly after the maximum  $E_p$  in the ascent and descent of the COM, respectively, in the middle of the single contact phase (Figure 1). In the former zone, older individuals improved the R(t) to minimize the  $W_{\text{ext}}$  necessary to increase the height of the COM. In the second zone, a smaller amount of  $E_p$  has to be absorbed by the muscles, favoring the transduction of  $E_p$  to  $E_k$ , as previously shown in African women carrying loads on their heads [1]. The only zone in which the young individuals had a higher R(t) than older subjects was in the transition between the mid- and terminal stance which may represent critical events in terms of gait dynamic stability and motor control [4] that penalize pendular energy transduction in older individuals.

**Figure 1:** Recovery within the step [R(t)] as a function of the percent of stride duration (% stride duration) for the 3 groups (SO: sedentary older; AO: active older; Y: young). DC: double contact phase. † Significant difference between the sedentary older and young individuals (SO vs Y;  $P \leq 0.05$ ); ‡ Significant difference between the active older and young individuals (AO vs Y;  $P \leq 0.05$ ).

### Conclusions

Compared with their young counterparts, older individuals, regardless of the level of activity, walk at  $1.11 \text{ m}\cdot\text{s}^{-1}$  with lower  $W_{\text{ext}}$  and higher recovery. R(t) shows that older individuals improve pendular energy recovery in the phases of the step where they have to perform  $W_{\text{ext}}$ , especially at the beginning of the double contact phase during the step-to-step transition. Ageing specifically and not physical activity level seems to modify pendular recovery during walking.

## Residual force depression is increased following greater *in vivo* muscle shortening work

Brent J. Raiteri<sup>1</sup>, Daniel Hahn<sup>1,2</sup>

<sup>1</sup>Human Movement Science, Faculty of Sport Science, Ruhr University Bochum, Bochum, Germany

<sup>2</sup>School of Human Movement and Nutrition Sciences, University of Queensland, Brisbane, Australia

Email: [brent.raiteri@rub.de](mailto:brent.raiteri@rub.de)

### Summary

This study aimed to reveal whether reducing muscle shortening work in the human tibialis anterior (TA) relative to that performed in a fixed-end contraction would reduce residual force depression (rFD). TA muscle fascicle shortening during active force production was reduced by lengthening TA's muscle-tendon unit (MTU) to effectively stiffen its MTU and steady-state torques following lengthening (Len) were compared with those attained during fixed-end reference contractions (Ref) at the same muscle activity level and MTU length. Preliminary results show that *in vivo* rFD increases with greater muscle shortening work and highlight that following Len muscle performance can be enhanced because of less preceding positive muscle work.

### Introduction

A long-lasting tension deficit exists following active muscle shortening compared with fixed-end contractions at the same muscle length and activation level, which is termed rFD [1]. Although rFD is often assumed to be absent during human voluntary fixed-end contractions, rFD can exist because of initial muscle shortening during active force development, which occurs due to MTU compliance [2]. As rFD increases with increasing muscle shortening work in electrically-stimulated muscle [3], we tested whether a reduction in TA muscle fascicle shortening amplitude before reaching a given voluntary muscle activity level and MTU length would enhance steady-state dorsiflexion torque due to reduced rFD.

### Methods

Pilot data was recorded from one healthy male participant who laid prone on a bench with their right foot secured to the footplate attachment of a dynamometer (IsoMed2000, D&R Ferstl GmbH, Germany). Voluntary fixed-end ramp-and-hold Ref contractions were performed over 12-s up to a constant muscle activity level of 30% of maximum voluntary contraction (MVC) at an ankle joint angle of 20° plantar flexion (PF). TA muscle activity was displayed as a 250-ms root-mean-square amplitude calculation and this signal was maintained within two horizontal lines spaced 6% MVC apart throughout each contraction. MTU-lengthening-hold contractions (Len) at a matched muscle activity level were also performed over the same duration, whereby TA's MTU was lengthened with a 20° PF rotation as muscle activity increased during the ramp phase of the ramp-and-hold contractions and then held constant for 10-s. The stretch velocity was 10°·s<sup>-1</sup> and therefore the ramp duration was 2-s to ensure that steady-state dorsiflexion torques and muscle fascicle lengths could be compared between Len and Ref at the same muscle activity level and MTU length.

TA muscle activity was recorded using surface EMG at 2000 Hz and bandpass analogue filtered between 10-500 Hz, prior to being sampled at 2000 Hz. TA muscle fascicles within its superficial compartment were imaged with B-mode ultrasound using a 60 mm veterinary transducer operating at ~154 Hz with an image depth of 40 mm (LV8-A2; Teleded, Vilnius, Lithuania). Fascicle lengths (FLs) were determined offline in Matlab (R2019b, MathWorks, USA) by implementing a semi-automated tracking algorithm [4]. Net ankle joint torque and crank arm angle were recorded at 2000 Hz and synchronized with ultrasound and EMG recordings using a 16-bit A/D card within a Power1401 data acquisition interface (Spike2, CED, Cambridge, UK). rFD was estimated as the time-matched steady-state mean torque difference over 6-s between Len relative to Ref and expressed in % MVC.

### Results and Discussion

Preliminary results show that steady-state TA muscle activity levels and TA FLs during Len (27.9% MVC and 58 mm) were similar to Ref (27.8% MVC and 58 mm). As expected, TA fascicles were found to shorten 4.5 mm less during the ramp phase of Len compared with Ref, where TA fascicles shortened 2.4 vs. 6.9 mm, respectively. This led to reduced rFD during Len as evidenced by an increased steady-state torque of 2.7% MVC compared with Ref, where torques were 45.3 and 42.6% MVC, respectively. This level of enhanced torque might be increased further when muscle shortening work is completely abolished [3] and this will be attempted in future experiments.

### Conclusions

Preliminary results suggest that *in vivo* rFD can increase with greater TA muscle shortening work during submaximal voluntary dorsiflexion contractions. These findings highlight that reduced rFD can enhance muscle performance following MTU lengthening. Future research will investigate the relationship between *in vivo* muscle shortening work and rFD.

## Relationship between metatarsophalangeal joint flexors and lower limb strength—a preliminary investigation

Enrico Roma<sup>1</sup>, Romain Tourillon<sup>1,2</sup>, Antoine Michel<sup>1</sup>, Pascal Edouard<sup>1</sup>, François Fourchet<sup>2</sup>, Guillaume Y Millet<sup>1</sup>, Jean-Benoit Morin<sup>1</sup>

<sup>1</sup>University Saint-Etienne, France <sup>2</sup>La Tour Hospital, Switzerland  
Email: [enrico.roma@univ-st-etienne.fr](mailto:enrico.roma@univ-st-etienne.fr)

### Summary

This study evaluated the reliability of a method to measure the metatarsophalangeal joint (MPJ) flexion strength, offering insight for foot training. The relationship between lower limb and MPJ strength was also investigated, showing that the MPJ strength is an independent construct. Finally, quadriceps strength was shown to be the major predictor of dominant leg concentric jump impulse (DLCJI) while plantar flexion and MPJ strength did not contribute significantly.

### Introduction

The foot is a complex joint system with multiple degrees of freedom and plays a role in athletic tasks. Its structure allows to transmit lower limb muscles force output to the ground and to generate forward propulsion. Consistent literature showed the relevance of foot strength in relation to performance or lower leg injury prevention [1], yet no study has investigated its relation to lower limb muscles strength. Besides, the literature lacks homogeneity in the assessment since the main action evaluated ranges from functional movement to toe flexion (TF) around the MPJ or interphalangeal joint (IJ) [2]. The present study evaluated the reliability of a MPJ flexion strength measure and its relation to lower limb muscles strength and DLCJI.

### Methods

22 healthy volunteers, 25.8(5.7) years, 1.76(0.07) m, 71.1(11.2) kg were evaluated across two testing sessions, 3 to 5 days apart. Participants performed four MPJ flexion maximal voluntary isometric contractions (MVICs) with a custom-made ergometer placing the toes on a force platform (Kistler) with ankle joint in full plantar flexion and MPJ in dorsiflexion. Maximal force was determined as the highest peak force recorded from four MVICs. Three isometric MVICs of ankle plantar flexion at 0° and knee extension at 90° on an isokinetic dynamometer (Con-Trex) were performed. Maximal DLCJI during three countermovement jumps on two Kistler force plates were kept for the analysis. The four trials of the first session were used to test intra-session reliability. Intraclass correlation coefficients (ICC) were calculated using a 2-way mixed effect model, single measurement for absolute agreement. Coefficient of variation (CV) was computed as the mean of the intra-individual CV's. Standard error of prediction (SEP) and minimal detectable differences (MDD) were always reported [3], while Limits of Agreement (LoA) only for inter-session reliability. Results were reported as mean (SD) [min-max]. To predict the DLCJI, a hierarchical multiple regression was used.

### Results and Discussion

In session one, the maximal force was 231 N (84) [67-413], versus 241 N (84) [106-416] in session two. According to the 95% CI, the ICC ranges between 'moderate' and 'good' for both intra-session and test-retest reliability. The mean force is higher to previously reported data [4], however, these studies used a TF gripping task. To our knowledge, this is the first study to evaluate maximal voluntary MPJ isometric flexion in maximal ankle plantar flexion. MPJ flexion strength did not correlate with knee extension ( $r=0.17$ ,  $t(22)=0.827$ ,  $p=0.417$ ) and plantarflexion ( $r=0.13$ ,  $t(22)=0.622$ ,  $p=0.5404$ ) peak force, neither in absolute nor in relative (lean body mass) terms. The MPJ strength appears as an untied construct compared to the overall lower limb strength, suggesting that it should be evaluated and possibly trained in a specific way. DLCJI can be explained only by knee extension of the variable considered (DLCJI,  $\beta=0.32$ ,  $t(22)=3.662$ ,  $p=0.001$ ),  $R^2=0.379$ ,  $F(1, 22)=13.41$ ,  $p=0.001$ . Our results partially contrast previous findings [5], that reported a significant but low ( $r=0.382$ ) correlation between CJI and TF strength, but without accounting for knee extension strength.

**Table 1: Reliability statistics**

	ICC	95% CI	CV (%)	SEP (N)	MDD 95% (N)	LoA-lower	LoA-upper
Intra-session	0.812	0.690-0.903	14.0	32.5	121		
Test-retest	0.880	0.738-0.947	7.8	28.7	109	-82.3	75.2

### Conclusions

This study presents a moderate to highly reliable method to evaluate MPJ flexion strength. It may be useful to assess the effect of a training protocol targeting intrinsic and extrinsic toe flexors, as our data showed the specificity of this construct. Finally, it is suggested that when research aims to investigate the link between "functional task" and MPJ strength, considering the overall strength is important.

# Comparison of leg muscle activity levels during different fitness tests in elderly individuals using surface electromyography

Jonina Oddsson <sup>1</sup>, Weinback A<sup>2</sup>, Godhe M<sup>1,3</sup>, Andersson E<sup>1,3,4</sup>.

<sup>1</sup>Laboratory of Biomechanics and Motor Control, Swedish School of Sport and Health Sciences, <sup>2</sup>Scandinavian College of Naprapathic Manual Medicine, <sup>3</sup>Department of Molecular Medicine and Surgery, Karolinska Institutet, and <sup>4</sup>Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden

Email: jonina.oddsson@gih.se

## Summary

Ten older adults participated in a study measuring activity levels in eight leg muscles during various submaximal and maximal fitness tests for field contexts<sup>1-4</sup>. Several statistically significant differences emerged in comparisons of different fitness tests and maximal exercises, respectively. For example, fast walking gave significantly higher values for all hip and leg muscles compared to normal walking speed.

## Introduction

Physical activity, including strength training, is a common form of training for seniors. A desire in certain training and test exercises for older adults is to be able to give specific advice to individuals based on how much different muscles are involved. Knowledge about activity levels for muscles in different test and training tasks can be obtained with electromyographic recordings (EMG). The aim of the study was to investigate in seniors muscle activity levels in eight different leg and hip muscles during some fitness tests and maximum voluntary contractions (MVC).

## Methods

Ten seniors (women and men, 66-89 years, who regularly participate in supervised exercise at least once a week) performed six physical field context tests (primarily for the hip and leg muscles)<sup>1-4</sup>. We also recorded 16 static maximum voluntary contractions (MVC), designed to maximally activate the gluteus maximus (GM), lateral hamstrings (BF-biceps femoris-caput longum, medial hamstrings (SEMI-semi-tendinosus/semimembranosus), rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), gastrocnemius (GASTR) and soleus (SOL) muscles. Surface EMG activity levels were analyzed regarding mean amplitude (mV) in each exercise. The EMG levels for each exercise, muscle and individual were expressed as a percentage of the highest measured value found in any of the assessed MVC exercises. Mean values ( $\pm 1$  Standard Deviation, SD) were calculated for all participants' normalized EMG values. Statistically significant differences between the recorded exercises for each muscles' activity level (expressed as a percentage of MVC level) were calculated via one-way ANOVA followed by post-hoc Fisher LSD-test ( $p < 0.05$ ).

**Table 1** Mean EMG-amplitude values ( $\pm$ SD) in percentage of MVC in two of the assessed field-context fitness tests designed for seniors.

Fitness tests	GM	M	F	SEMI	RF	VL	VM	ASR	SOL
Five-repetition sit-to-stand <sup>1</sup>	17 $\pm$ 17	18 $\pm$ 11	19 $\pm$ 14	38 $\pm$ 13	39 $\pm$ 14	39 $\pm$ 16	15 $\pm$ 7	10 $\pm$ 10	
Timed up & go <sup>2,3</sup> from a chair & back <sup>2,3</sup>	10 $\pm$ 14	5 $\pm$ 9	9 $\pm$ 11	3 $\pm$ 8	30 $\pm$ 12	3 $\pm$ 12	40 $\pm$ 20	59 $\pm$ 20	

## Results

High activity levels (% of MVC), were noted in a number of exercises. An example was a dominance in the muscles of the front thigh during the exercise "wall sit" i.e. a static sitting position without a chair, with 90° in the hip and knee joint. Here, the mean amplitude was for RF 42%, VL 50% and VM 49%, whereas the levels of the hip extensors were significantly lower, GM 9%, BF 7% and SEMI 6%, and the activity for the lower leg muscles SOL was then 24% and for GASTR 12%. In the 10-meter-walking-test<sup>4</sup>, which was performed both at a self-selected calm normal walking pace and walking as fast as possible, a significantly increased activity ( $\approx$ 15-35% higher values) was seen in all registered muscles, in the faster execution ( $p < 0,05$ ). The mean EMG-levels in the fastest versus the normal walking speed were for GM: 25% vs 11%, BF: 36% vs 21%, SEMI: 41% vs 21%, RF: 57% vs 22%, VL: 34% vs 17%, VM: 50% vs 23%, GASTR: 53% vs 31%, SOL: 66% vs 48%. All three quadriceps muscles had obvious activity in the two tests "Five-repetition sit-to-stand" and "Timed-up-and-go" (TUG), while within the calf muscles the latter test, TUG, revealed higher activity (Tab. 1). The muscles within a synergy could show their highest EMG levels in separate MVC tasks, in which factors of importance could be i.e. how and where the external resistance was given in the MVC task, and if nearby joints were flexed or extended.

## Conclusions

Several statistically significant EMG activity differences emerged for the muscles in the tests. It may be of interest to see which fitness tests result in higher respectively lower muscle activation for evaluations of leg strength and function in different health test contexts. Thus, results might be useful in various gym and clinical settings to give specific advice to older adults regarding how much different muscles are involved in certain training and test exercises.

### Summary

Over the last decade, the importance of fatigue as (modulating) risk factor for developing sports injuries has been emerging. This study investigated the utility and validity of two versions of a high-intensity intermittent exercise protocol to include in biomechanical injury preventive screening. Long-lasting fatigue-related alterations in cardiovascular and muscular characteristics were demonstrated after similar fatigue protocol versions, which either terminated after a fixed number of circuits, or terminated at a fixed subjective measure of exhaustion. Therefore, both fatigue protocols are deemed valid and can be utilized in biomechanical injury preventive screening in male jump-landing athletes.

### Introduction

Fatigue reduces the capability to react properly to biomechanical demands of a rapidly changing physical environment [1] and can be considered as a modulator for risk factors for developing lower extremity injuries. Since previous biomechanical studies used fatigue protocols without having information about the extent to which fatigue effects persist in the protocol, validated fatigue protocols with sports specific characteristics are required. This study investigated the utility and validity of the high-intensity intermittent exercise protocol (HIIP) [2] and a modified version of 5 circuits (HIIP-5) to include in biomechanical injury preventive screenings. Whilst the former has the advantage of standardized level of exhaustion, the latter has the advantage of a fixed protocol duration. The purpose of this study was to determine the cardiovascular and muscular effects and the duration of these acute fatigue effects following the cessation of both versions of the fatigue protocol.

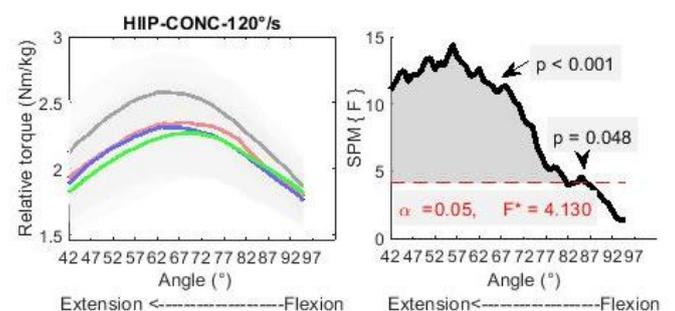

### Methods

Twenty healthy male volleyball (n=10) and basketball (n=10) players, participated in this study. Physical performance, objective and subjective cardiovascular and muscular parameters were extracted continuously before and up to 30 minutes (0, 15, 30 minutes) after cessation of the HIIP and HIIP-5. Subjective scores of fatigue were extracted by means of the rate of perceived exertion for breathlessness (RPE-B) and legs (RPE-L). Objectively, mean counter-movement jump (CMJ) height and heart rate (HR) were continuously monitored and peak blood lactate levels were compared to resting values. The impact of each fatigue protocol on maximal concentric (CONC) muscle force of the quadriceps

was determined by means of isokinetic dynamometry (Biodex System 3 Pro<sup>®</sup>). Raw isokinetic muscle force data were filtered and imported in Matlab (Matlab, version 2020b) for individual curve analysis using IKD1D ([www.ikd1d.org](http://www.ikd1d.org)). Repeated measures ANOVA with Bonferroni-correction was applied to determine fatigue-related cardiovascular and/or muscular alterations using SPSS (IBM SPSS statistics 26) for discrete outcome variables and Statistical Parametric Mapping for torque-angle profiles ([www.spm1d.org](http://www.spm1d.org)).

### Results and Discussion

Scores for the RPE-B and RPE-L increased significantly, respectively up to 20 and 30 minutes following termination of both the HIIP and HIIP-5 ( $p < 0,001$ ). Mean CMJ height decreased and HR increased significantly up to 30 minutes following cessation of the HIIP and HIIP-5 ( $p < 0,001$ ). Peak blood lactate levels increased significantly after HIIP and HIIP-5 ( $p < 0,001$ ). A significant main effect of HIIP and HIIP-5 was found for the isokinetic CONC muscle force of the quadriceps with a significant reduction at 0, 15 and 30 minutes post-fatigue compared to pre-fatigue ( $p < 0,001$ ) (Figure 1).

**Figure 1:** CONC torque-angle profiles for the quadriceps before and after HIIP. Black line pre-fatigue, red line post-fatigue 0 minutes, blue line post-fatigue 15 minutes, green line post-fatigue 30 minutes.

### Conclusions

The HIIP and HIIP-5 seem valid tools to induce long-lasting cardiovascular and muscular fatigue effects and can be utilized in biomechanical injury preventive screening in male jump-landing athletes.

## Investigating osteoarthritis in the human hip using three-dimensional finite element models

### Summary

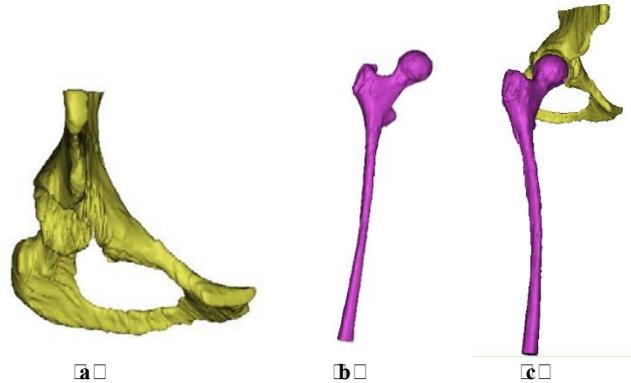

This project uses complex three-dimensional finite element models to investigate the impacts of osteoarthritic damage regarding loading patterns and stress points in the human hip. This study could show the isolation of the structure and exclusion of other factors that may influence biomechanics of the hip. This will ascertain the extent of the influence the osteoarthritic damage itself has upon locomotion and loading of the hip.

### Introduction

Osteoarthritis (OA) is a term for the degeneration of cartilage present in joints in the body, causing stiffness and pain from bone contacting bone and the myriad of issues stemming from this contact [1]. Specifically, hip osteoarthritis refers to the damage of the articular cartilage found on the head of the femur and surface of the acetabulum, and the discomfort and impaired movement associated with these two bone surfaces rubbing together. Current literature suggests that this can cause a shift in loading of the hip, theorised to be the patient altering gait mechanics, therefore loading patterns, to alleviate the symptoms of osteoarthritis [2,3]. It could be the anatomy of the damaged cartilage influences loading patterns, even when isolated from patient attempts to alter the load. Through the creation of a complex three-dimensional finite element healthy hip model, it is possible to simulate differing loads placed upon the joint and the articular cartilage, and evaluate where specifically points of stress on the structure are located in a healthy human hip. An OA version of the complex three-dimensional human hip model was also created to undergo the same experimental process, yielding comparable data on stress points in the structure. Using this model, behavioral elements have been removed from the study, allowing an evaluation of the extent the articular cartilage itself plays a role.

### Methods

MRI scans of a healthy human hip were taken from a 20-year-old female. The subject had no medical issues relating to the hip or spine [4]. This MRI data-set was then put into Mimics Research 21.0 software where the pelvis (including: partial ilium, complete ischium, partial pubis, and complete acetabulum with articular surface, acetabular fossa and acetabular labrum), femur (including: complete proximal end with femoral head articular cartilage), and ligaments (iliofemoral, the pubofemoral and ischiofemoral) were segmented and converted into a three-dimensional model (Figure 1). Subsequently, the model was copied the articular cartilage and femur head re-segmented to represent an OA hip. This involved the flattening of the superior side of the femur head and thinning of the cartilage [5]. Changes were made in line with clinical presentations of hip OA across multiple MRI scans found in the literature. These models were imported to finite element analysis software, ANSYS. They were tested with varying loading and boundary conditions to analyse sensitivities. Material properties and loading values of differing tissue was taken from the literature.

**Figure 1:** Rough draft models for cancellous femur (a), cancellous pelvis (b) and both combined (c). Set to model cortical bone, cartilage and ligaments.

### Results and Discussion

The finite elements analysis showed a shift in loading patterns, even when separated from a human subject and their gait mechanics, due to the abnormal shape of the hip joint created by OA, in turn causing the OA model to possess differing stress points to the healthy model. The data provides evidence of the significant role the articular cartilage alone plays in loading patterns, helping to further our understanding of OA and its relationship with biomechanics.

The developed finite element model could be used as an asset for further research of the human hip including: investigating biomechanics of different clinical presentations of osteoarthritis, long term effect of altered gait mechanics on the hip, investigating new methods of total hip arthroplasty.

### Conclusions

Articular cartilage and femur head structure resulting from OA changes the loading patterns of the human hip during gait, independent of loading patterns caused by patients altering gait mechanics themselves.

## Summary

Fast completion and short ground contact times (CT) during cutting and turning are essential performance parameters during sports games. Coordination is assumed to be important with high joint variability (JV) potentially compromising speed. In the present study, it was aimed to investigate the relationship between JV in the lower extremity and CT during a 135° cutting manoeuvre (CM). Overall, the correlation between CT and the adjusted coefficient of multiple determination (ACMD) showed an increase for joint angles and a decrease for moments from proximal to distal. The approach may be helpful to understand the relationship between performance and injury risk in complex tasks.

## Introduction

Fast completion and short CT during CM are essential performance parameters during team sports [1]. JV, calculated by the ACMD [2], was linked to performance as joint coordination is assumed to be important for CM. However, the relationship between CT and JV has not been studied yet. Therefore, the purpose of this study was to investigate the relationship between 3D-JV of the lower extremity joints and CT during a 135° CM.

## Methods

Twenty-three participants performed a minimum of fifteen 135° CM with maximum effort on artificial turf. Kinematic and kinetic data were acquired with a motion analysis system and a force plate. We calculated 3D lower extremity joint kinematics and kinetics of the right leg. ACMD of joint angles, joint moments, and ground reaction forces were computed. All parameters were correlated with CT by using Kendall's tau ( $\alpha=0.05$ ).

## Results and Discussion

We can see a trend to decreased angular JV from distal to proximal, while correlations are elevated in the sagittal plane. An opposite trend is seen for joint moments, while all ground reaction force components show very high ACMD values (Fig.1). JV and CT for the hip moment in the sagittal and frontal planes were strongly related, as was the knee moment in the frontal and transverse planes (Tbl.1). Likewise, the

sagittal hip angle and the transverse knee rotation plane were significantly related.

JV of ankle kinetics also relates to CT, while knee and hip kinetics and non-sagittal plane kinematics show weaker predictive value. It remains to be investigated how muscle contractions are controlled to maintain a stable force output while kinematics, in particular, vary substantially.

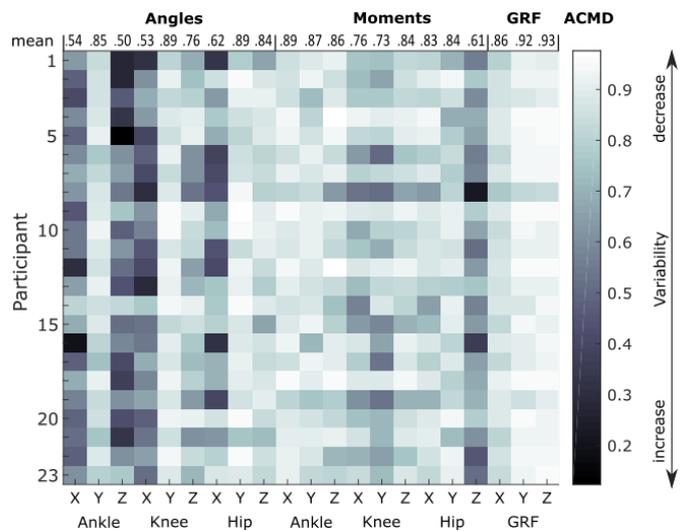

Figure 1: ACMD values of the lower extremity joint parameters and overall participants. X Y Z are frontal, sagittal and transverse plane.

## Conclusions

CT as an indirect performance parameter is related to the variability of joint kinematics and kinetics during cutting manoeuvres. This connection could be important for performance improvements, prevention, or even the characteristics of injuries. Therefore, further studies should quantify the relationship between variability in cutting trials and injury risk.

### SUMMARY

Recent studies suggest that women may be less fatigable than men, but this has been mostly studied in isometric test condition and in the acute recovery phase. This study assessed the sex influence on the delayed neuromuscular fatigue two and four days after a 20 km graded running race by using a pluri-articular horizontal force-velocity (HF- $\square$ ) test. Only men presented delayed performance decrease in power. Sex, but not recovery time, influenced the timing of the synergistic muscle activations patterns.

### INTRODUCTION

Women are usually reported as less fatigable than men after a fatiguing running exercise [1]. However, this has mainly been assessed by monoarticular isometric tests which tend to overestimate the fatigue observed in pluriarticular tests [2]. On the other hand, previous studies have rarely detected any delayed fatigue in pure-concentric tests. Yet, no studies have assessed the fatigue-induced changes of the force-velocity relationship and in the associated muscle activation patterns. Our purpose was to analyze the influence of sex on the delayed neuromuscular fatigue after a 20 km graded running race by using a concentric pluriarticular test.

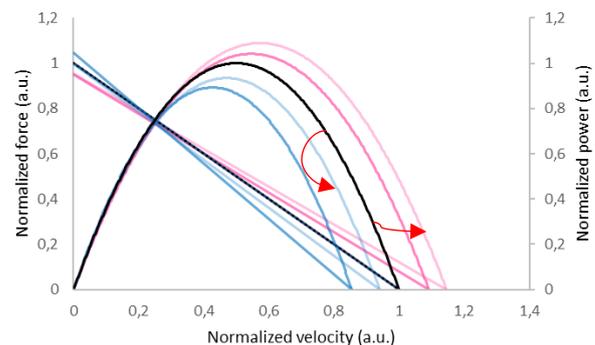

### METHODS

Seventeen recreational runners (nine women) completed the race. They underwent three recording sessions: a week before the race (PRE), two and four days (2D and 4D) after the race. Delayed onset muscle soreness (DOMS) was quantified using a visual analogue scale (0-10). For each session, the HF- $\square$  test was performed under four resistive conditions. Surface EMG activity of eight ipsilateral muscles was recorded synchronously with the bilateral force production. For each session, force-velocity (F- $\square$ ) and power-velocity (P- $\square$ ) relationships were quantified by the theoretical values of maximal force at null velocity ( $\bar{F}0$ ), maximal velocity at null force ( $\bar{V}0$ ) and the resulting  $\bar{P}max$  [3]. Muscle synergies were extracted from the EMG signals through non-negative matrix factorization [4] and divided into motor modules (i.e., relative muscle contribution) and motor primitives (i.e., temporal coefficients) for the heaviest load.

### RESULTS

Mixed ANOVAs showed DOMS in most muscles at 2D, but only for women in the hamstrings ( $p < 0.001$ ). A sex  $\times$  time interaction was found for  $\bar{V}0$  ( $p < 0.025$ ) and  $\bar{P}max$  ( $p < 0.024$ ), but not for  $\bar{F}0$  (Figure 1). Planned contrasts showed significant decreases at 2D only for men in  $\bar{V}0$  ( $p < 0.009$ ) and

in  $\bar{P}max$  ( $p < 0.004$ ). Regardless of the session and sex, three muscle synergies were extracted from EMG data. The first synergy referred to the movement initiation with a major influence of the knee extensors, especially in women ( $p < 0.001$ ). There was a session effect on the relative contribution of knee extensors, flexors and ankle flexors to this synergy ( $p < 0.033$ ) and in women the main activity of motor primitives was shifted later in time compared to men ( $p < 0.001$ ). The second synergy (mid push-off) showed a similar involvement of all muscles. In women, the motor primitives of this synergy were narrower (i.e., shorter in duration) and shifted later in time compared to men ( $p < 0.001$ ). The third synergy corresponding to the late push-off phase showed a main contribution of the ankle joint flexors and extensors, with no sex- or session-related differences in the timing of motor primitives.

**Figure 1** Normalized F- $\square$  and P- $\square$  relationships as compared to PRE (black curves) for men (blue curves) and for women (pink curves) at 2D and 4D (in bold and light, respectively)

### DISCUSSION AND CONCLUSIONS

This study reveals a sex influence on the F- $\square$  profile in a pluriarticular concentric test. Only men presented a 2D drop in performance. The relative muscle contributions to the movement initiation synergy were affected by both sex and session, suggesting that women modulate this synergy differently than men along the recovery. Sex also influenced the main activation timing of the initiation and mid push-off synergies. Taken together, our results suggest that the sex-specific organization of muscle synergies might explain the different timeline of recovery after a fatiguing run.

## Age-Related Lower Limb Muscle Co-Activation in Sit-to-Stand/Stand-to-Sit Performances

<sup>2</sup>Geriatric Medicine, Carl von Ossietzky University of Oldenburg, 26121 Oldenburg, Germany

Email: anna.brinkmann1@uni-oldenburg.de

### Summary

Dynamic muscle stability in functional tasks like Sit-to-Stand/Stand-to-Sit performances requires muscle co-activation of knee extensors and flexors. For a comparison of a geriatric patient and a healthy young subject, biomechanical and neurophysiological STS parameters were analyzed to determine muscle co-activation. Modified STS movement strategies induced higher co-activation in the geriatric patient due to sustained distribution of knee extensor and flexor muscle activity.

### Introduction

Transitional movements in every-day life require active motor control units for horizontal and vertical displacement of the whole body's center of mass (CoM). During Sit-to-Stand/Stand-to-Sit (STS), balance control and coordination of the trunk and lower limbs are maintained through muscle co-activation (CA). Age-related physiological changes may lead to muscle weakness (1) and an increasing muscle CA during postural control (2) inducing altered movement patterns in functional tasks. Little is known about performance strategies of older, physically impaired persons during concentric and eccentric STS. Thus, the aim of the present pilot study was to focus on changes in biomechanical and neurophysiological STS parameters of a geriatric patient.

### Methods

A geriatric patient (m, 68y, 1.70m, BMI: 35.90 kg/m<sup>2</sup>) and a young participant (m, 27y, 1.93m, BMI: 24.97 kg/m<sup>2</sup>) performed independently three series of a five timed STS (3). A standardized armless chair (0.45m seat height) was placed on a force plate in a laboratory setting (4). STS vertical CoMz velocity and acceleration were analyzed and phases defined according to (5). Unilateral EMG of Vastus Medialis (VM),

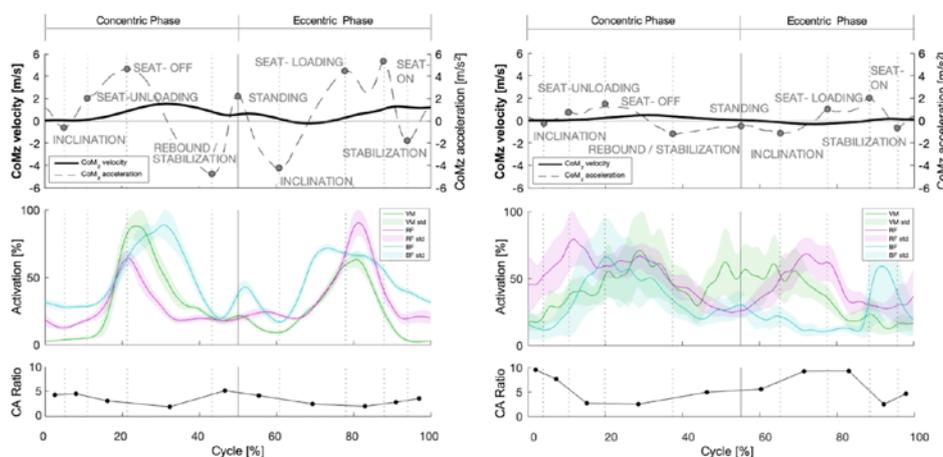

Rectus Femoris (RF) and Biceps Femoris (BF) were recorded (SENIAM guidelines), sampled (1 kHz) and amplified (2.5 kHz). EMG data was full-wave rectified, RMS filtered and normalized to STS peak value. Thus, relative muscle activation for concentric and eccentric STS was obtained and then used for the calculation of knee extensor (KE) and knee flexor (KF) CA ratios.

### Results and Discussion

Existing differences in mechanical and muscle-specific STS parameters for the geriatric patient and the young participant are presented in Figure 1 and Table 1. Calculated CA ratios quantify the distribution of KE and KF activity for each STS phase (Figure 1). Lower CA ratios of the young participant indicate phasic muscle activation in which KE activity was followed by KF activity in concentric STS and reversed activity in eccentric STS. Predominantly higher CA ratios of the geriatric patient represent a more persistent KE and KF activity in concentric and eccentric STS indicating an altered movement strategy during postural control (6). The geriatric patient needed more time to rise from a chair and to adjust balance (7) (Figure 1, Table 1). In contrast, faster descending with high CA ratios led to a rigid posture reducing the degree of freedom and forced the patient to plump down onto the chair (8). The geriatric patient showed slower peak CoMz velocity and acceleration for both STS phases (Table 1).

### Conclusions

This pilot trial was a proof-of-concept characterizing the distribution of muscle-specific parameters between concentric and eccentric STS performances for further application in studies. Results indicated changes in STS movement strategies inducing higher CA in the geriatric patient compared to a young study participant.

**Figure 1:** Mean CoMz velocity and acceleration, normalized mean EMG muscle activation plus standard deviation for three series of a five timed STS with respective KE/KF CA ratio for a young (left) and a geriatric (right) participant.

**Table 1:** Comparison of STS parameters of a young (total STS time: 2.1 s) and a geriatric participant (total STS time: 2.4 s).

Parameter	Concentric STS		Eccentric STS	
	Young	Geriatric	Young	Geriatric
Cycle	50.00 %	55.30 %	50.00 %	44.70 %
Rising/Descending	28.71 %	35.39 %	37.92 %	33.30 %
Stabilization	5.71 %	17.81 %	12.08 %	11.44 %
Peak CoMz Velocity	1.52 m/s	0.48 m/s	1.29 m/s	0.32 m/s
Peak CoMz Acceleration	4.78 m/s <sup>2</sup>	1.20 m/s <sup>2</sup>	5.34 m/s <sup>2</sup>	2.04 m/s <sup>2</sup>

Email: christoph.bauer@zhaw.ch

### Summary

A new, stimuli transmitting shoe sole technology transfers the ground composition mechanically to the sole of the foot when walking on uneven surfaces. Healthy participants evaluated the user experience of this sole technology.

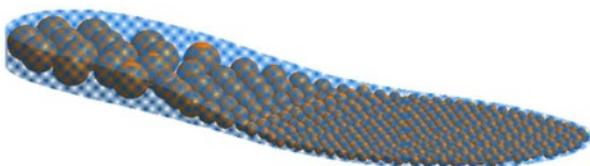

All participants felt the stimuli transmission. The strongest sensation was in the forefoot region, where also most complaints occurred. Of the tested grounds like pavement and soft grounds, slight preferences were shown for nature trails, although preferences differed widely.

### Introduction

With comfortable, shock-absorbing shoes, the mechanoreceptors of the sole of the foot are no longer stimulated. Consequently, a trend goes back to minimal shoes. However, also these have been shown to be insufficient to provide enough stimulation. This lack of stimulation leads to worse proprioception, which can lead to poor posture and to a risk of injuries. [1] Therefore, a new shoe sole technology is needed, which transfers the ground composition to the sole of the foot and may provide enough stability through an integrated foot bed.

### Methods

The stimuli transmitting shoe sole technology is performed mechanically. The shoe sole consists of hard plastic balls, which are pushed towards the sole of the foot due to uneven surfaces (Figure 1).

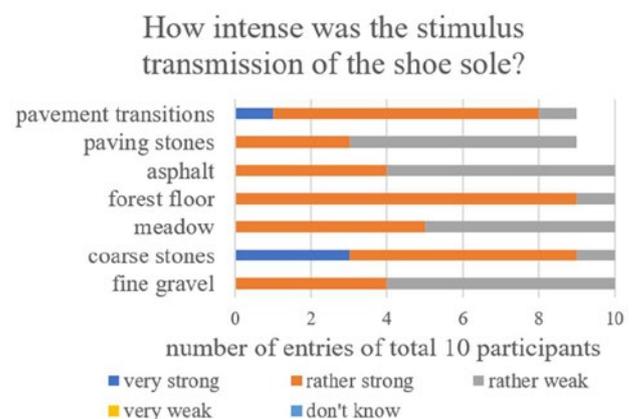

**Figure 1:** shoe sole technology with balls in orange

This shoe sole technology was evaluated by the user experience. Questionnaires covered walking sensation, comfort, complaints and intensity of sensory transmission. Answering options were on a Likert scale as well as open questions. The tests consisted of a two-week user study with the aim to evaluate the shoe sole in daily life as well as a one-hour monitored parcours evaluating the shoe sole on specific grounds (like stones, forest etc.). All participants were healthy with shoe size EU 38-43. The user study included 20 participants (Ø 64 years). Additionally, 10 persons (Ø 41 years) participated in the parcours.

### Results and Discussion

**Intensity:** Most of the participants rated the stimulus transmission as very or rather strong. Nobody rated it as very weak. In the parcours, the strongest sensation was on coarse stones and pavement transitions, followed by the forest floor (Figure 2).

**Figure 2:** intensity of stimulus transmission depending on ground

**Comfort & complaints:** The majority perceived the shoe sole as very or rather comfortable. Participants perceived the stimuli strongest in the forefoot, where also most of the complaints occurred. The complaints were reported as tired feet, pain, pressure and burning feet, and occurred roughly every third day.

**Ground composition:** Nature trails seemed more comfortable than hard grounds, even though the opinions about hard grounds diverged. The most uncomfortable walking was on unpaved, downwards grounds.

### Conclusions

All participants perceived the stimuli transmission of the shoe sole. However, the product polarizes. While some considered the stimuli as comfortable, others found them too strong. The forefoot was the part with the strongest stimuli sensation, but also with the most complaints.

## An Integrated Cloud Platform to Perform *In Silico* Standard Testing for Orthopedic Implants

Vincenzo Carbone, Alberto Palazzin, Marc-Antonio Bisotti, Roberta Bursi  
 Research and Development, InSilicoTrials Technologies S.p.A., Trieste, Italy  
 Email: [vincenzo.carbone@insilicotrials.com](mailto:vincenzo.carbone@insilicotrials.com)

### Introduction

Regulatory bodies impose stringent pre-market controls to certify the safety and compatibility of medical devices. However, internationally recognized standard tests may be expensive, time consuming and challenging for orthopedic implants because of many possible sizes and configurations. In addition, cost and time of experimental standard testing designed, developed, and used for generic devices may nullify the advantages of 3D-printed custom implants.

Modeling and simulation (M&S) can be used to virtually test medical devices before prototyping, helping manufactures and points-of-care to improve design reliability, speed up development process, and accelerate regulatory approval. We engineered an integrated cloud platform to perform *in silico* testing for orthopedic implants, assessing mechanical safety and electromagnetic compatibility in a completely virtual environment, in line with recognized standards and regulatory guidelines.

### Methods

The InSilicoTrials.com platform contains two M&S tools for orthopedic implants: CONSELF and NuMRis.

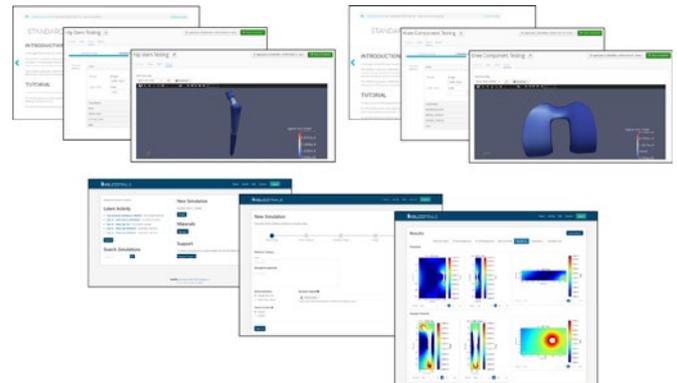

CONSELF (conself.com) uses Salome-Meca 2017 to compute static implant stresses and strains on metallic orthopedic devices, following the requirements and considerations of ASTM F2996-20 Standard Practice for non-modular hip femoral stems [1] and ASTM F3161-16 Standard Test Method for total knee femoral components [2]. Simulation results were consistent with those reported in the two standards.

NuMRis (numris.insilicomri.com) uses ANSYS HFSS and ANSYS Mechanical 2019R3 to compute radio-frequency energy absorption and induced heating during magnetic resonance imaging in 1.5T and 3T MRI coils, replicating the ASTM F2182-19e2 Standard Test Method [3]. Simulation results were validated against *in vitro* measurements.

The integrated M&S workflow on the cloud platform allows the user to upload the 3D geometry and the material properties of the orthopedic implant to be tested, automatically set up the standard testing scenarios, run simulations and process outcome, with the option to summarize the results in accordance with current FDA guidance on M&S reporting [4].

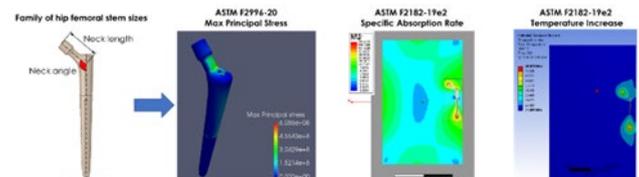

### Results and Discussion

The easy-to-use interfaces of InSilicoTrials tools run through commercial web browsers, requiring no specific expertise in computational methods or additional on-premises software and hardware resources, since all simulations are run remotely on cloud infrastructure.

**Figure 1:** Web interface of the CONSELF and NuMRis tools.

The integrated cloud platform can be used to evaluate design alternatives, test multi-configuration devices, perform multi-objective design optimization, and identify worst-case scenarios within a family of implant sizes, thus reducing the amount of physical testing to be conducted.

**Figure 2:** CASE EXAMPLE: Evaluate design alternatives and identify worst-case scenarios within a family of implant sizes.

### Conclusions

InSilicoTrials.com is the first cloud platform offering a collection of M&S tools to perform *in silico* standard testing for orthopedic implants. The proposed tools allow to easily assess mechanical safety and electromagnetic compatibility of generic and custom devices before prototyping, preventing risks and criticalities for the patient, and helping manufacturers and points-of-care to accelerate time and reduce costs of device development.

The proposed platform promotes the broader adoption of digital evidence in preclinical trials, supporting the device submission process and pre-market regulatory evaluation, and helping accelerate regulatory approval.

Email: alexandre.naaim@univ-lyon1.fr

### Summary

Soft tissue artefacts (STA) is one of the main limitations for using motion capture. Foot joint arthrodeses are frequently performed in end-stage osteoarthritis. Tibio-talo-calcaneal (TTC) arthrodesis consists to fuse the joints between the calcaneus, the talus and the tibia together. One may expect that motion recorded during gait between the segments of the calcaneus and the shank would result only from STA. Four subjects who underwent a TTC arthrodesis performed a gait analysis with a modified version of the Rizzoli foot model. Effects of STA found for the shank-calcaneus dorsi-plantar flexion were larger than that reported in previous studies. This might be due to major skin sliding over the calcaneus for these subjects. Studies assessing subjects with TTC arthrodesis should interpret kinematic data with caution.

### Introduction

Soft tissue artefacts (STA), the underlying movement between skin markers and their anatomical counterpart, remain one of the main limitations in using marker base motion analysis both in research and in clinical context [1]. Usually, STA can be evaluated using invasive protocols such as intracortical pins [2] or using imaging technology [3]. As a result, it might be difficult for a laboratory to evaluate how STA affect their measurements. A solution might arise for the ankle and foot joints. Foot joint arthrodeses are frequently performed in end-stage osteoarthritis. Tibio-talo-calcaneal (TTC) arthrodesis consists to fuse the joints between the calcaneus, the talus and the tibia. One may expect that motion recorded between the segments of the calcaneus and the shank would result from STA as the joints are fused. In this first feasibility study, the 3D kinematics of shank-calcaneus (Sha-Cal) joint of subjects with TTC arthrodesis was evaluated.

### Methods

Three male and one female subjects (age:  $46.5 \pm 6.5$  years, BMI:  $31 \pm 8 \text{ kg.m}^{-2}$ ) with a TTC arthrodesis participated in this study. One subject had the surgical procedure at both feet. At least 12 months post-operatively, they performed a gait analysis. The participants were asked to walk at self-selected speed barefoot over a 10 m walkway.

Inter-segment foot kinematics were obtained using a motion-capture system of 10 Miquis cameras (Qualysis, Goteborg Sweden) at a 200Hz frequency. An adaptation of the Rizzoli foot model proposed by Deschamps et al. [4] was used. This model allowed to consider the Sha-Cal joint as the movement between the tibia and the calcaneus.

The effect of the STA was quantified as the mean range of motion (RoM) about the three joint axes during the five most

homogeneous trials (based on walking speed) and compared to the fluoroscopic results of Kessler et al. [2].

### Results and Discussion

**Table 1:** Mean Range of Motion (RoM) in degree of the Sha-Cal joint during a gait cycle for all subjects

Subject	Mean RoM Dorsi-plantar flexion	Mean RoM Inversion-Eversion	Mean RoM Abduction-Adduction
S1 Left	7.1°	3.4°	1.7°
S2 Left	6.1°	1.4°	1.0°
S3 Right	7.2°	1.5°	0.2°
S4 Left	9.5°	3.6°	1.8°
S4 Right	9.3°	3.8°	2.1°
Mean (n = 5)	7.8°	2.8°	1.3°
StD (n = 5)	1.5°	1.2°	0.8°
STA in Kessler et al. [2] (n = 9)	2.5°	3.6°	4.3°

Surprisingly, our results differ from the findings of Kessler et al. [3] who used bi-plane fluoroscopy on asymptomatic subjects. In contrast to their results, this study found the largest effect of STA for dorsi-plantar flexion (STA effect appears 2 to 3 time larger). For the two other joint axes, the effect tends to be lower in our study.

During gait, STA is mainly due to skin sliding as opposed to muscle contraction or inertial effects. A possible explanation for this amplified effect found on dorsi-plantar flexion might be a major skin sliding over the calcaneus, with the TTC arthrodesis acting as a large “wrapping object” for the skin. As the movement of the other mobile joints occurs mainly in dorsi-plantar flexion, the STA effect tends to be larger about this joint axis.

### Conclusions

A larger than expected effect of the STA on hindfoot joint kinematics was found in our study. It seems that Sha-Cal joint arthrodesis does not represent an efficient method to assess the effect of STA on the joint kinematics. In addition, studies assessing foot joint kinematics after TTC arthrodesis should interpret their results with caution as large STA were found for the hindfoot.

In future work, it could be interesting to evaluate this method on a larger sample and other fused foot joints.

### Summary

Assessing interventions for mobility disorders in children using real-life movement is still an unsolved problem and the possibility to transfer gait analysis to the real world conditions to prevent children postural alterations is attracting attention in the literature [1]. The aim of the study was to evaluate the reliability and repeatability of a methodology for forming movement analysis for mobility disorders assessment in children in real world conditions. To this extent commercial video-cameras and automatic tracking of features techniques were used. Results are encouraging as good reliability and repeatability were observed.

### Introduction

Gait analysis is a process of instrumented measurement and evaluation of walking ability in patients, recognized as a useful assessment tool and a support in medical decision-making [2]. Standard gait analysis is performed within a gait laboratory by means of stereophotogrammetric systems. Recently great attention has been given to the possibility of assessing children's motion for gait and posture evaluation purposes, in real world conditions [1]. The aim of this study was to evaluate the reliability and repeatability of a methodology for gait and posture assessment in real world conditions by means of commercial video-cameras and automatic tracking of features techniques in children. This approach could be exploited in ambulatory conditions, in school or sport facilities, for the prevention of postural alterations in children with foot deformities [3], scoliosis [4] and temporomandibular disorders [5].

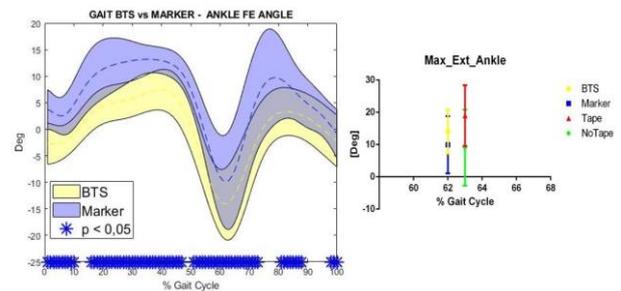

### Methods

Eleven subjects (mean±SD age 9.7 ± 2.6 years, BMI 20.6 ± 3.5 kg/m<sup>2</sup>) were acquired simultaneously with a stereophotogrammetric system (6 TVC, 60-120 Hz, BTS) and 4 GoPro Hero 7 cameras. Each subject performed several gait cycles and 4 different set-up were adopted: reflective markers on anatomical landmarks ("BTS"), markers made with double colored tape ("Tape") [6], without applying any marker ("NoTape"). Reflective markers were applied as in [7] and trajectories were reconstructed through stereophotogrammetry ("BTS") or video tracking ("Marker"), using Track on Field (BBSof, S.r.l), based on a self-developed tracking of feature algorithm [6]; in the other 2 conditions (Tape and NoTape), a simplified version of [7] was applied and only video tracking was used to reconstruct anatomical landmarks trajectories. Joints angles were determined as in [6] for "BTS" and "Marker" set up, while

only sagittal plane kinematics was retrieved for "Tape" and "NoTape". Comparison among the four set-up was performed through the estimation of the mean root mean square distance (RMSD) and Wilcoxon signed-rank test ( $p < 0.05$ ). For the inter-trial variability, the Coefficient of Multiple Correlation ("CMC") [8] was calculated for each biomechanical variable. Normative bands were created, for each condition, including only trials with a CMC > 0.7 [9]. To verify the inter-operator variability the Standard Error ("SE") [9] was calculated (2 operators).

### Results and Discussion

Although statistically significant differences were observed, results showed that the 4 set up were comparable in terms of occurrence of the joint angles peak within the gait cycle (Fig. 1, right) and range of motion (Fig.1, left). Good inter-operator repeatability was found.

**Figure 1:** Left side: Ankle Flexion-Extension Angle, "BTS" & "Marker" asterisks indicate statistically significant differences; right side: Ankle Extension Angle Peaks

### Conclusions

Results are encouraging toward the adoption of a wider use of motion analysis in real world conditions as in sport or rehabilitation facilities, and schools.

## Summary

In recent years, high-density surface electromyography (HD-sEMG) is gaining more popularity. In this study, reliability of electrical activities of ankle dorsi-/plantar-flexors measured by HD-sEMG are evaluated during isometric contraction. Furthermore, multiple features are extracted from the collected signals to characterize the major muscles around the ankle. Measurements were conducted with different angle and percentages of the maximum voluntary contraction (MVC). Results show reliability of less than 10% variance. Features such as mean average value (MAV) and zero crossing (ZC) could be potentially useful to indicate muscle characteristics in clinical applications.

## Introduction

HD-sEMG has been more and more applied to quantify spatial and temporal muscle activity [1-2], which can provide insights into new muscle characteristics. The aim of this study is to evaluate the reliability of HD-sEMG recordings of major ankle muscles during isometric contraction and extract features from the collected signals that can be used to characterize the muscles.

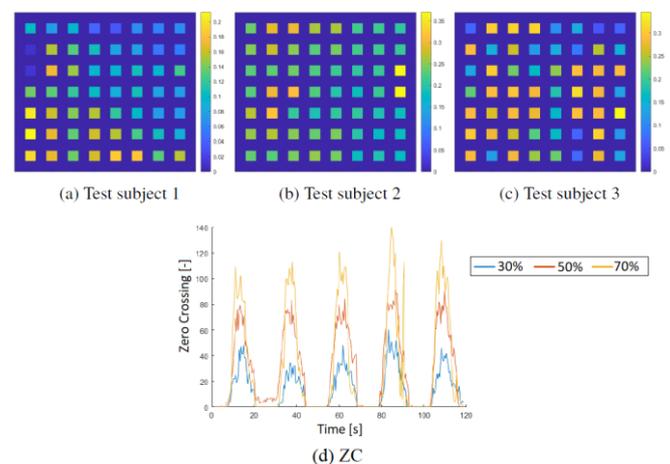

## Methods

An experimental protocol was designed to collect HD-sEMG data (Quattrocento, OT Bioelettronica) from five muscles (medial and lateral gastrocnemius, soleus, peroneus longus and tibialis anterior) of the right lower leg of five healthy subjects (3F/2M, age:  $28.6 \pm 5.4$  yrs, height:  $169.0 \pm 8.9$  cm) at 30%, 50% and 70% MVC in plantarflexors and dorsiflexors, respectively. The grid was placed on each muscle according to a standardized protocol. The participants were asked to follow a trapezoidal force profile with 5 repetitions on the display with  $\pm 10\%$  error allowed and 5s rest between each repetition. The torque was measured simultaneously using an ankle dynamometer. Each test constituted of 4 ankle angles in a randomized order (a neutral position at  $0^\circ$ ,  $7.5^\circ$  and  $15^\circ$  plantarflexion and  $10^\circ$  dorsiflexion). To determine the reliability of the experimental setup, relative variance between measurements in two different days were evaluated. To investigate the characteristics of the muscles during the sub-MVCs, heatmaps of muscle activation were created and two common EMG features, namely MAV and ZC, were extracted.

## Results and Discussion

The preliminary results of reliability show intra-subject variance as low as 1% for tibia anterior (TA). The highest variance of 9% was found for gastrocnemius medialis (GM). Heatmaps of the measured average differential EMG signal

in each electrode of the grid provide visual information on the spatial distribution and magnitude of activation in the muscles over the measured area (Fig 1a-c). Different subject recruit different part of the muscle to produce the same level of the MVC. The extracted MAV of tibia anterior was found to correlate with ankle angle, increasing from the dorsiflexion to plantarflexion positions. Moreover, analyzing the signal in frequency domain with ZC feature, we observed that the peaks of ZC slightly increased from the first to the last sub-MVC attempt (Fig 1d). The increased ZC could indicate a correlation between the frequency of the signal and MU temporal recruitment as well as possible fatigue.

**Figure 1:** (a-c) Visualization of the spatial muscle activation of TA during isometric dorsiflexion (70% MVC and  $0^\circ$ ). (d) ZC change of GM during isometric plantarflexion at  $15^\circ$  with sub-MVCs

## Conclusions

Our preliminary study shows promising results in terms of intra-subject reliability. Multiple features were extracted from the collected signals and identified as a possible indicator for muscle characteristics such as muscle fatigue, activation, and spatial distribution of activation. This can be a helpful tool to assess the muscle contraction in different population and identify compromised areas of the muscles amongst others.

## Summary

We propose a method to compare healthy and pathological statistical shape models (SSM) of the pediatric talus. The proposed approach, based on a vertex-wise Bhattacharya metric, provides clinically relevant local similarity assessment and allows an evaluation of the musculoskeletal disorder impact on different bone regions. Experiments conducted on pediatric cohorts of healthy and equinus ankles illustrate the clinical potential of the methodology.

## Introduction

The Bhattacharya coefficient, which measures the similarity between probability distributions, has already been used to compare SSM built from the same dataset but with different point-set registration algorithms [1]. A global overlap was computed on point-based probability distributions, and the returned value ranged from 0 (dissimilar) to 1 (similar).

However, in clinical practice, it is needed to compare two separate populations (healthy and pathological) and to assess the local modifications in shape conveyed by the disorder. Hence, rather than comparing the global shape distributions arising from the healthy and pathological populations, we propose to employ a vertex-wise Bhattacharya metric on selected bone regions.

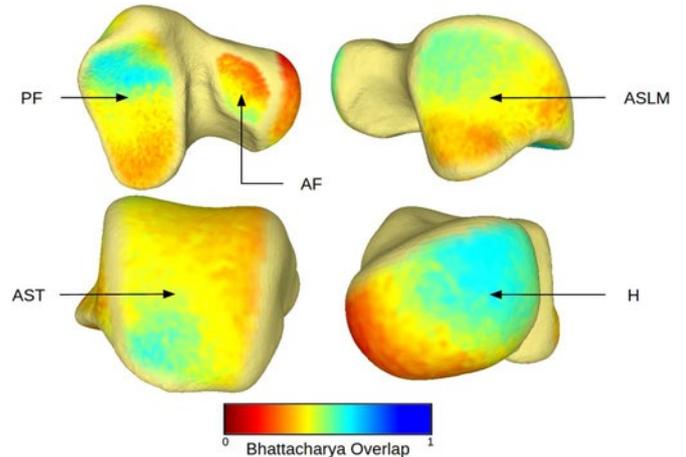

## Methods

MR images of 20 pediatric ankles (10 healthy and 10 equinus) were acquired using a 3T scanner after acquiring parental consent. An expert manually segmented the images to obtain the 3D meshes of the talus bone. A non-rigid alignment algorithm was used to obtain point-to-point correspondence between the 20 shapes [2]. We then created two SSMs, one each from the healthy and equinus populations, using the established correspondences [2]. The two SSMs were thus in point-to-point correspondence, and each point, in each SSM, was defined by a 3D distribution.

We selected 5 regions on the mean healthy talus bone (Fig. 1): posterior facet (PF), anterior facet (AF), articular surface for tibia (AST), articular surface for lateral malleolus (ASLM) and head (H). For each vertex in these regions, we computed the Bhattacharya overlap between the healthy and pathological 3D Gaussian distributions, based on their respective means and covariance matrices. Then for each region, we determined the mean, standard deviation (STD), minimum and maximum of the vertex-wise coefficients.

## Results and Discussion

The obtained mean Bhattacharya overlap ranged from 0.36 to 0.41, indicating medium similarity between healthy and pathological SSM (Tab. 1). The minimum similarities were observed in region AF (0.19) and H (0.12), while the maximum appeared in region PF (0.63) and H (0.62). The visualization (Fig. 1) further illustrated that regions AF and H were the most impacted by the pathology.

**Figure 1:** Visualization of the vertex-wise Bhattacharya overlap between healthy and pathological SSM on the 5 talus regions.

However, while the results appear promising, the proposed methodology is limited by the low sample size, which is due to the scarcity of pediatric datasets.

## Conclusions

We presented a method, based on SSM and vertex-wise Bhattacharya metric, to assess the impact of the equinus pathology on the shape of the pediatric talus.

## Validation of kinematic models of the human whole body centre of mass

Charlotte Le Mouel<sup>1</sup>,

<sup>1</sup>Movement Science, University of Münster, Münster, Germany

Email: charlotte.lemouel@normale.fr

### Summary

Characterising human movement and balance requires estimating the position of the whole body centre of mass (CoM). This is typically done using kinematic models, whose validity during dynamic movement is not known. During running, when the body is in the air, the acceleration of the CoM is equal to gravity. This study compares this ground truth to the CoM acceleration obtained from three different kinematic models. The state-of-the-art model has a mean error of 2.4 m/s<sup>2</sup>. The simplified models have a larger error, up to 4.8 m/s<sup>2</sup>. This error may be improved by combining kinematic and force plate recordings.

### Introduction

To characterise human movement and balance, the external forces and torques acting upon the human body need to be estimated. The force and torque exerted by the ground reaction can be directly measured using force plates. To determine the torque exerted by weight however, the position of the whole body CoM must be estimated. This is typically done with kinematic recordings. The body is divided into segments and a model is used to determine the weight and CoM of each segment, which are then combined to obtain the whole body CoM.

The state-of-the-art kinematic model requires measuring the position of 38 markers [1], which is cumbersome and time consuming. Therefore, simplified versions of this model have been proposed. This study compares the accuracy of three kinematic models during dynamic movement.

### Methods

Three kinematic models of the CoM were compared: 1. the state-of-the-art model, requiring 38 markers [1], 2. a simplified version requiring 13 markers [2], 3. the hip midpoint, requiring 4 markers.

The CoM position was reconstructed during running, smoothed using a Savitzky-Golay filter of order 3, and differentiated twice to obtain acceleration. Only the flight phases of running were analysed.

### Results and Discussion

During the flight phase of running, the acceleration of the CoM is equal to gravity, i.e. null in the horizontal plane and downwards of amplitude 9.81 m/s<sup>2</sup>. However, the mean acceleration calculated from all three kinematic models had a bias both in the vertical direction and in the horizontal plane. Downwards acceleration was overestimated by 0.7 m/s<sup>2</sup> for the full model, and by 1.2 m/s<sup>2</sup> for both the simplified and hip models. The bias in the forwards direction was largest for the hip model (-3.0 m/s<sup>2</sup>), followed by the simplified model (0.8 m/s<sup>2</sup>) then the full model (0.3 m/s<sup>2</sup>). The mean net error was also largest for the hip model (4.8 m/s<sup>2</sup>), followed by the simplified model (3.7 m/s<sup>2</sup>) then the full model (2.4 m/s<sup>2</sup>).

The state-of-the-art kinematic model of the CoM does not provide an accurate estimate of the CoM acceleration during

running. Simultaneous recordings of kinematics and ground reaction forces could provide improved estimates of CoM position.

### Conclusions

The estimation of CoM position from kinematics has a mean error in acceleration of at least 2.4 m/s<sup>2</sup> during running. This error may be improved by combining kinematic and force plate recordings.

### Summary

Principal Component Analysis (PCA) has been extensively used to reduce hand kinematics because hand joints have coordinated movements (kinematic synergies). However, synergies are task-dependent and the variety of tasks the hands can perform during daily life is vast. The aim of this work is to identify a small set of tasks representative of the hand kinematic synergies during activities of daily living (ADL) by using an iterative PCA method. Kinematic synergies were extracted from 16 hand joint angles recorded to 24 healthy adults while performing 24 varied ADL. As a result, 6 ADL could be enough to obtain kinematic synergies with high level of similarity to those considering a wide set of varied ADL, and with little loss of range of movement.

### Introduction

PCA has been extensively used to reduce hand kinematics in many fields, such as in prosthesis design, based on the fact that hand joints have coordinated movements (kinematic synergies) [1]. These synergies are obtained from the analysis of hand kinematics during the performance of some tasks. However, the variety of tasks the hands can perform during daily life is vast. The aim of this work is identifying a small set of tasks representative of the hand kinematic synergies during ADL.

### Methods

Hand kinematics data from [2] were used (16 joint angles of 24 right-handed healthy adults while performing 24 varied ADL). A first PCA (eigenvalues, varimax rotation, standardized data) was applied to all the data to identify the kinematic synergies (<sup>24</sup>PCi). Then, an iterative method was followed: in each step, the kinematic data was reduced by removing each ADL data one-by-one, and the resulting N datasets were used as input in N PCA (one PCA per each ADL, N=24-k, in the k-th step). In this case, a non-standard scaling was applied, using the mean and SD of the original

matrix. In each step, the dataset explaining highest variance was selected as input for the next step. This iteration was repeated until one ADL remained (k=23). Finally, the similarity between the synergies in each step (<sup>24-k</sup>PCi) and the original ones (<sup>24</sup>PCi) was checked by means of the angles between the vectors that represent both set of synergies, and the comparison of the scores of <sup>24-k</sup>PCi respect to <sup>24</sup>PCi.

### Results

Five synergies (<sup>6</sup>PCi) representative of all the ADL were obtained from the first PCA (with 73.1% of the variability of the original data). Figure 1 (Left) shows the % of variance of the original data explained in each step of the iterative ADL removal, where a slight decrease is observed until arriving to a set with only 6 ADL. The 5 synergies (<sup>6</sup>PCi) from this set of 6 ADL explained 71.9% of the original data variance, and were quite similar to the original ones and with similar ranges in the coordinated movements (Figure 1, Right).

### Discussion

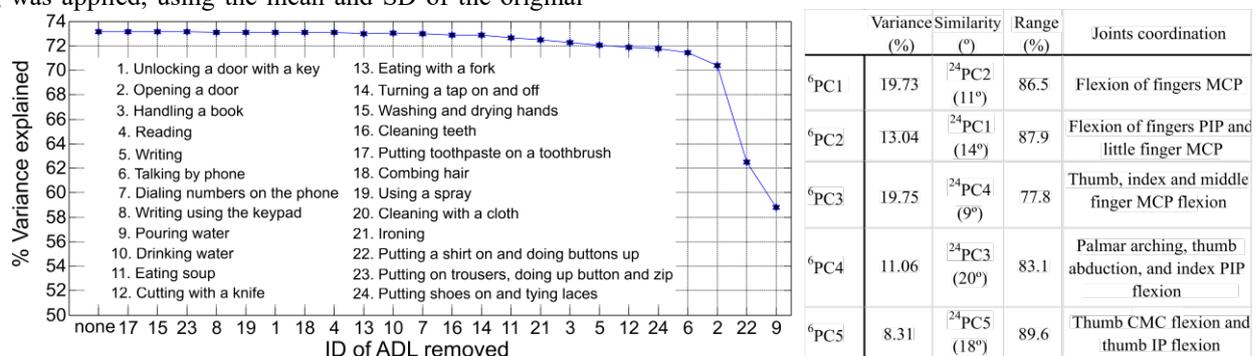

The results suggest that a set with only 6 ADL (cleaning with a cloth, pouring water, putting a shirt on and doing buttons up, opening a door, talking by phone and putting shoes on and tying laces) could be enough to obtain the kinematic synergies underlying ADL, with high level of similarity to those considering a wide set of varied ADL and with little loss of range of movement. Some ADL provided high inter-subject variability. Therefore, it might be interesting to investigate the sample size required to obtain representative results of global population.

## Falling heads biomechanical and neuromuscular responses to head-neck perturbations

Isabell Wochner<sup>1</sup>, Lennart Nölle<sup>1</sup>, Oleksandr Martynenko<sup>1</sup>, Syn Schmitt<sup>1</sup>

<sup>1</sup>Institute for Modelling and Simulation of Biomechanical Systems, Stuttgart Center for Simulation Science, University of Stuttgart, Germany

Email: [isabell.wochner@simtech.uni-stuttgart.de](mailto:isabell.wochner@simtech.uni-stuttgart.de)

### Summary

In this study, we conducted perturbations experiments (called ‘falling heads experiments’) to the head-neck complex to understand the involved reflexive responses. The volunteers were placed on a table with an additional trapdoor supporting the head. This trapdoor was suddenly released, leading to a free-fall movement of the head until the muscles’ reflexive responses stopped the downwards movement. We report the experimental results and enhance them by performing simulations with a reflex controller. The experimental dataset [1] can be used as a benchmark test to compare different muscle control strategies and validate existing human body models.

### Introduction

Head and neck perturbations can lead to injuries in many different situations ranging from sports-related impacts to car accident scenarios. Such injuries are widely recognized as a significant public health concern [2,3]. They are induced by biomechanical forces such as contact or inertial forces that are transmitted to the brain, head or upper body. To better understand the underlying phenomena, we set up experiments perturbing the head-neck complex for two force directions (flexion and extension) with healthy participants of different ages and genders.

### Methods

In the experiments, 17 volunteers were placed on a table in a supine and prone position. The subject’s head was supported by a trap door, which was unexpectedly released leading to the heads’ free-fall movement (see Fig. 1). We recorded the heads’ kinematic trajectory and the electromyographic signal of the *sternocleidomastoideus* and the *trapezius* muscle. Furthermore, we performed simulations matching this ‘Falling Head’ experiment using a simple stretch-based reflex controller.

### Results and Discussion

First, we show a large difference in the individual reflexive responses between participants: The maximal falling height between participants varies between 3.2-14.9 cm, and latency times range between 17.67-86.67 ms (in the supine case). Second, the reflexive behavior depends on the directions of the perturbation force: in the prone case the participants tend to fall less (range between 0.5 – 8.3 cm vs 3.2-14.9 cm), and they display smaller linear and rotational peak accelerations (average rotational peak of 44.4 rad/s<sup>2</sup> vs 62.4 rad/s<sup>2</sup>). Third, we show that our neuro-musculoskeletal simulations using a reflex controller can predict similar responses compared to the experiments. Furthermore, this response can be modulated by simple control parameter adjustments (e.g. reflex thresholds). Based on this controller variation, we show that a higher sensitivity in the neuronal state (e.g. a higher threshold) reduces acceleration peaks, which might reduce injury risks.

### Conclusions

The findings based on the experimental results of our study will help to improve existing and to develop potentially better Human Body Models and muscle control strategies.

## New approach on constitutive modeling of the pure titanium thermoplastic deformation

Jakub Bańcerowski<sup>1</sup>, Marek Pawlikowski<sup>1</sup>

<sup>1</sup> Warsaw University of Technology, Institute of Mechanics and Printing, Poland

### Summary

Commercially pure titanium was compressed in high temperatures and under various strain rates in order to increase its strength by grain fragmentation. However, to fully control this complex thermomechanical process, proper constitutive equation had to be implemented. The experimental data was fitted to Arrhenius, Johnson-Cook, Khan-Huang-Liang and Anand equations to determine which model would be most useful in further work.

### Introduction

Commercially Pure (CP) titanium as a biomaterial requires controlled plastic deformation processing to increase its strength [1]. This process is complex and dependent on many factors such as strain rate, temperature, coefficients of strain hardening and softening and others [2]. To ensure stability and repeatability of this process, constitutive equation must be applied [3]. In order to find the most accurate model for our process, several equations were selected and fitted to the data.

### Methods

CP titanium (Ti) samples were compressed at elevated temperatures (775 K ÷ 875 K) at different strain rates ( $\dot{\epsilon} = 10^{-2} \div 10^1$ ) to the constant strain  $\epsilon = 0.6$  in a Gleeble thermomechanical simulator. The data from the experiment were used in the constitutive model constants identification.

According to literature the most commonly used constitutive equations were Arrhenius model (1), Johnson-Cook eq. (JC) (2) and Khan-Huang-Liang eq. (KHL) (3). Due to viscoplastic character of the deformation the Anand model (4) (usually employed for the solder processing modeling) was also chosen.

- Arrhenius model:

$$\dot{\epsilon} = A[\sinh(\alpha\sigma)] \exp\left(-\frac{Q}{RT}\right), \quad (1)$$

where  $\dot{\epsilon}$  [ $s^{-1}$ ] - strain rate,  $A$ ,  $\beta$ ,  $n_1$ ,  $n$ ,  $\alpha = \beta/n_1$  - material constants,  $Q$  [ $kJmol^{-1}$ ] - activation energy of plastic strain,  $R$  - universal gas constant,  $T$  [K] - temperature,  $\sigma$  [MPa] - flow stress;

- Johnson-Cook eq.:

$$\sigma = (A + B\epsilon^n)(1 + C \ln \dot{\epsilon}^*) (1 - T^{*m}), \quad (2)$$

where  $A$ ,  $B$ ,  $n$ ,  $m$  are material constants.

- Khan-Huang-Liang eq.:

$$\sigma = \left[ A + B \left( 1 - \frac{\ln \dot{\epsilon}}{\ln D_0^p} \right)^{n_1} (\epsilon^p)^{n_0} \right] \left( \frac{\dot{\epsilon}}{\dot{\epsilon}^*} \right)^C \left( \frac{T_m - T}{T_m - T_r} \right)^m \quad (3)$$

where  $A$ ,  $B$ ,  $C$ ,  $m$ ,  $n_1$  are material constants,  $D_0^p$  is upper bound strain rate (arbitrarily chosen),  $T_m$  is melting temp.,  $T_r$  is reference temp. (arbitrarily chosen).

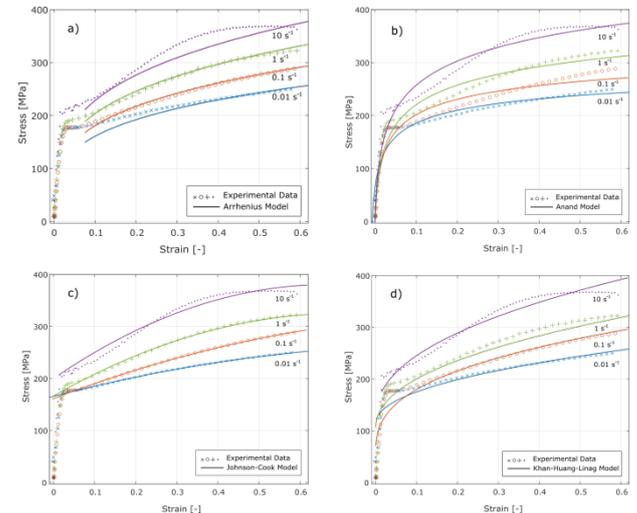

- Anand eq.:

$$\dot{\epsilon}_p = A \exp\left(-\frac{Q}{RT}\right) \left[ \sinh\left(\xi \frac{\sigma}{s}\right) \right]^{\frac{1}{m}} \quad (4)$$

where  $s$ ,  $\xi$ ,  $m$  are material constants. The common symbols in equations (1), (2), (3) and (4) denote the same quantities.

### Results and Discussion

Models were fitted to data with the varying degrees of success. The Anand, JC and KHL models provide a good fit. The Arrhenius one is less adequate (Fig. 1). It is worth noticing that only Anand model is able to represent the whole range of deformation.

**Figure 1:** Stress-strain graphs and Arrhenius (a), Anand (b), JC (c), KHL (d) models for the 775 K deformation process.

### Conclusions

The applied models provide precise fit in plastic deformation zone. JC is the most accurate for the higher strain rates. KHL model is the most precise one in plastic zone. Arrhenius model is the least precise. The most promising is however Anand model, due to its ability to predict material behavior during both, elastic and plastic deformation. The further work will include the finite element modelling of the titanium processing in order to find the best input parameters leading to desired material properties.

# Does Multibody Kinematic Optimization Increase Reliability of Knee Joint Angles and Moments Between Thigh Marker Clusters in High Knee Flexion?

Jessa M. Buchman-Pearle, Stacey M. Acker

Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada

Email: [jessa.bpearle@uwaterloo.ca](mailto:jessa.bpearle@uwaterloo.ca)

## Summary

This study explored the sensitivity of peak knee joint angles and moments in high knee flexion to thigh marker cluster location and multibody kinematic optimization (i.e., constraining joint degrees-of-freedom). Peak knee flexion, abduction, and adduction angles and moments were calculated using six different thigh marker clusters, with and without multibody optimization for fifty participants in squatting and kneeling. The effect of marker cluster location (quantified by the effect size,  $\eta^2$ ) decreased, however within-subject repeatability (quantified by the intraclass correlation coefficient, ICC(2,1)) increased. These findings suggest that, in high knee flexion, multibody optimization may not effectively compensate for thigh marker cluster-specific soft tissue artifact on an individual basis.

## Introduction

Select marker placements [1] and data processing techniques, such as multibody kinematic optimization [2], have been shown to impact soft tissue artifact. The objective of this study was to explore if multibody optimization reduced differences in peak knee joint angles and moments from marker clusters localized to six different areas of the thigh in high knee flexion. An increase in within-subject reliability would suggest that multibody optimization may partially compensate for cluster-specific soft tissue artifact.

## Methods

Motion of the lower limb and ground reaction force data during squatting and kneeling (Figure 1) were recorded from fifty participants. Six marker clusters were used on the thighs (Figure 1) and one on the shank. The peak knee flexion, abduction, and adduction angles and moments were calculated using each thigh marker cluster with and without multibody optimization. Multibody optimization was implemented in Visual 3D by applying translational constraints to the ankles, knees, and hips, as well as frontal and axial rotational constraints on the ankles. Effect sizes, to determine the effect of marker cluster location for each task and multibody optimization condition, were evaluated with the partial eta squared ( $\eta^2$ ). Intraclass correlation coefficients [ICC(2,1)] were also calculated using a two-way mixed effects model to assess agreement across the marker clusters.

**Figure 1:** Heels-up squat (HS), dorsiflexed knee (DK), and plantarflexed knee (PK) and thigh marker cluster placement.

## Results and Discussion

Of the 18 effect sizes calculated without multibody optimization, 3 were classified as medium (0.07-0.09) for the flexion moments and all others were classified as large (0.16-0.50). With multibody optimization, effect size classification decreased to small for the flexion moments (0.02-0.03), and medium for angles in HS (0.12-0.13) the abduction moment in HS (0.11), and the adduction moment in PK (0.06). All other effect sizes remained classified as large ( $>0.14$ ).

Of the thirty-six ICCs, 21 were classified as poor, 13 as moderate, 1 as good, and 1 as excellent (Table 1). Multibody optimization improved ICC classification for the flexion angle in HS and PK (Table 1).

**Table 1:** ICC for peak knee joint angles and moments with (MO) and without (no MO) multibody optimization. Bolded ICCs were classified as moderate to excellent ( $>0.50$ ).

Task	Flexion		Adduction		Adduction	
	No MO	MO	No MO	MO	No MO	MO
<i>Peak Angles</i>						
HS	<b>0.75</b>	<b>0.92</b>	<b>0.60</b>	0.38	<b>0.57</b>	0.20
DK	<b>0.52</b>	<b>0.67</b>	<b>0.72</b>	0.42	<b>0.52</b>	0.33
PK	0.45	<b>0.66</b>	<b>0.70</b>	0.37	<b>0.59</b>	0.34
<i>Peak Moments</i>						
HS	<b>0.63</b>	<b>0.60</b>	0.38	0.45	<b>0.64</b>	0.49
DK	0.40	0.38	0.46	0.32	<b>0.61</b>	0.33
PK	0.45	0.42	0.43	0.48	0.46	0.06

## Conclusions

Large effect sizes and poor reliability with different marker cluster placements highlights the importance of consistent marker placement within and between subjects. Multibody optimization improved effect size classifications (decreased  $\eta^2$ ) for 8 variables and improved reliability classification (increased ICC) for 2 variables. Collectively, these findings suggest that while multibody optimization may decrease differences in knee joint angles and moments between marker clusters across a sample, multibody optimization does not compensate for cluster-specific soft tissue artifact for a given participant. This is particularly apparent when evaluating tasks which elicit greater range of motion at multiple joints (i.e., DK and PK) [3] and outcomes in the frontal plane.

## Periodic median filter for power line interference in force plate and bioelectric recordings

Marc [□□□de Lussanet](#)<sup>1,2</sup>, Charlotte le Mouel<sup>1</sup>

### Summary

Power line interference (“hum noise”) is a common source of noise in recorded biological data. It has a frequency of 50 or 60 Hz with harmonics and temporal fluctuations in frequency, amplitude and wave shape. Various filters have been proposed, but these fluctuations often present severe problems, such as deformations. Also, steps in the data, e.g., in force plate recordings tend to produce “ringing” artifacts. We propose a periodic median (PM) filter to reliably remove hum of any harmonic composition. We compare the performance of this filter to that of two state-of-the-art filters on a combination of recorded and simulated force plate and EMG data. Our filter is robust to fluctuations in line frequency and unstable harmonics. It does not introduce border artifacts or ringing. The filter is validated on recorded and artificial data. The PM filter thus outperforms the best hum filters currently in use.

### Introduction

Power line interference (“hum noise”) presents an old and well-known problem in diverse biological recordings, including bioelectric (EEG, ECG, EMG), biomagnetic (MEG) and kinetic (force plates) signals. In addition to the classical “Notch” filter, a large number of numerical filters for hum have been proposed. Modern filters exist, that do cope quite well with the typical instabilities of the hum noise, which are fluctuations in frequency, amplitude and harmonic composition. However, they introduce distortions of the signal during transient steps in the data, at the start and end of the recording and during sudden changes in the noise amplitude. For example, landing on a force plate will cause a sudden rapid change in the measured signal, and hum filters typically introduce Gibbs rippling or “ringing artifact” in the vicinity of the transient.

### Methods

To remove the hum from a signal, the waveform of the hum over each period of the hum noise is estimated. First, a high-pass filter is applied to the signal (20 Hz cut-off, 4th order two-way Butterworth). The waveform of the filtered signal is then averaged on a sliding window of 50 successive periods of the hum frequency. For averaging, we take the median rather than the mean to improve robustness. This Periodic Median is then subtracted from the signal.

The Periodic Median filter (PM) is compared to two modern ones (gold standard), i.e., the Spectrum Interpolation (SI) filter [1] of FieldTrip [2] and the Fourier Decomposition Method (FDM) [3].

We compared the performance of the 3 filters on 1. artificial signals with a realistic frequency spectrum and hum, 2. hum-free EMG recordings (ground truth) with superimposed power line hum (recorded from non-loaded force plates), 3. force plate recordings of jumping (with hum).

### Results and Discussion

All three filters had similar steady-state performance for removing a hum with constant amplitude from artificial signals. The performance of SI and FDM deteriorated at the beginning and end of the signal, and at sudden changes in the amplitude of the hum, whereas that of our novel PM filter did not. On the EMG recordings with added hum noise, the FDM filter showed considerable errors, particularly during strong muscle contraction. Both the SI and the PM filters performed well, with the PM showing slightly better performance than the SI during low muscle contraction, and slightly worse during large muscle contraction. During large muscle contraction, the error of the PM filter nevertheless remained below the amplitude of the hum and was negligible with respect to the amplitude of the signal.

When applied to force recordings of jumps, both SI and FDM showed substantial ringing in the vicinity of the jumps (for the FDM, the ringing amplitude was as much as four times the hum amplitude). The novel PM filter showed no ringing at all, and no increase of the error.

### Conclusions

The here proposed novel PM filter is highly stable and highly reliable in all tested conditions, and performed equally well or outperformed both reference filters in almost all tests. We recommend its use for biological recordings with power line hum.

Matlab and Python scripts are made available on Github [4].

Email: pauline.morin@ens-rennes.fr

## Summary

External forces and joint torques have been jointly minimized in a motion-based external force prediction method. The prediction of external forces during a fencing lunge demonstrates the interest to consider joint torques during static phases of movements.

## Introduction

In motion analysis studies, classical inverse dynamic methods require ground reaction forces and moment (GRF/M) to compute internal forces. Predicting GRF/M from motion capture makes it possible not to measure them. In such a prediction method, contact is handled through multiple points, making the inverse dynamics problem undetermined. Physiological assumptions (like minimizing external forces) in an optimization approach enable to determine the most plausible solution from the mathematical variety of force distribution solutions [1]. This abstract presents a pilot study questioning the implication of the internal forces (considering joint torques) in external forces prediction during a fencing lunge.

## Methods

The present study is a pilot study considering 10 lunges executed by one fencer (1.86m, 78.6 kg) issued from [2]. Lunge motion consists in an explosive extension of the front leg accompanying an extension of the sword arm. It admits a static (preparing the attack) and a dynamic phase (the lunge itself). Motion capture markers (46 on standardized anatomical landmarks) were recorded with an optoelectronic motion capture system Qualisys (200Hz). The external forces were recorded with two AMTI force platforms (2000Hz). The GRF/M were predicted from an optimization approach considering a set of discrete contact points. The cost function was a combination of a quadratic sum of external forces  $\|F\|^2$  and a quadratic sum of joint torques  $\|\tau\|^2$  as follow:

$$\min_F \left( w_{ext} \frac{\|F\|^2}{F^{norm2}} + w_{int} \frac{\|\tau(F)\|^2}{\tau^{norm2}} \right)$$

At each frame, the quadratic sum of external forces was normalized by the square of the norm of the global external force  $F^{norm2}$  (computed from the inverse dynamic equilibrium). The quadratic sum of joint torques was normalized by the quadratic sum of joint torques considering equal to zero the external forces. The two terms were balanced by:

$$(w_{ext}, w_{int}) \in [0,1] \text{ s. t. } w_{ext} + w_{int} = 1$$

This method has been implemented in the CusToM Matlab toolbox [3].

The external forces were predicted for different values of  $(w_{ext}, w_{int})$ : (1, 0), (0.75, 0.25), (0.5, 0.5), (0.25, 0.75) and (0,1). The efficiency of those predictions was evaluated comparing predicted GRF/M and force platforms data varying, in terms of RMSE. The results are presented for the static and the dynamic phases, detected visually on each trial.

## Results and Discussion

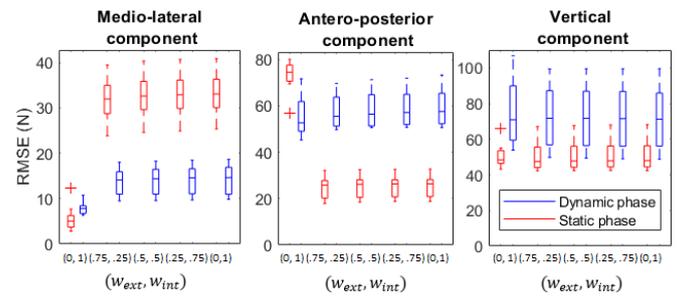

Figure 1: RMSE of the external force prediction for different  $(w_{ext}, w_{int})$  values with a dynamic and static phase distinction.

The RMSE statistical repartition is presented in the Figure 1 for each resultant component. All non-zero values of  $w_{int}$  led to similar predictions in shape and amplitude. Considering joint torques in the prediction improved the antero-posterior component prediction and deteriorated the medio-lateral component prediction during the static phases. Considering joint torques in the cost function did not impact prediction during the dynamic phases. The studied motion admitted two easily identifiable phases (static and dynamic), and we may assume that joint torques were minimized during the static phase to let the fencer being relaxed before the assault. Any other motion may present specificities to be considered to find the best combination between internal and external forces to be minimized in the prediction.

In conclusion, minimizing joint torques and external forces in a motion-based external forces prediction method seems relevant for static phases of motions. A larger cohort should be considered to validate these preliminary results. Other motions presenting specific dynamical characteristics should also be considered.

### Summary

This pilot study introduces an innovative signal processing pipeline for a markerless motion capture system. In the proposed approach, the three-dimensional space pose and the joints angles are the results of a cascade of classifiers based on convolutional neural networks (CNN), which are applied to a set of time-synchronized video streams. This method is also applied to underwater (UW) data acquisitions, a challenging environment due to internal reflections and high levels of noise. In this analysis, lower limb joints flexion-extension angles are presented and compared with a state-of-the-art marker-based technique.

### Introduction

Nowadays, clinically accepted optical systems are mostly marker-based. Despite the high accuracy they can achieve, there are some open issues: expensive instrumentation is required, markers can prevent the subjects from preserving a natural motion, occlusions and an overall long processing time can affect trajectories reconstruction. To overcome these problems, markerless techniques are gaining more and more relevance. In this study, we propose a deep learning-based motion capture pipeline as deep neural networks have been widely applied to images and video processing domains with success.

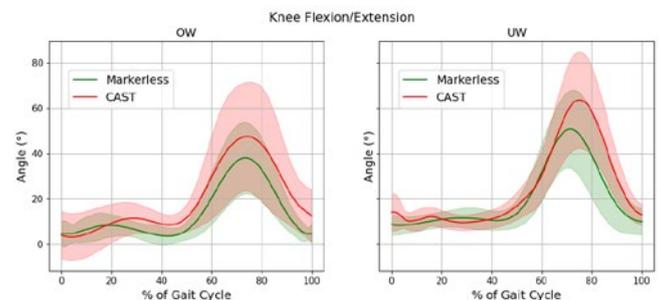

### Methods

The proposed pipeline is highly modular, and flexible for future innovations. A set of synchronized cameras is placed around the scene and the data stream can be managed both online and offline. The former case tends towards a real-time application: the synchronized new frames are processed as soon as they are available. Whereas, in the latter case, the trials are assumed to be completed and the processing can exploit the information from the whole videos in order to improve accuracy. After the preprocessing step that extracts and undistorts the video frames, a cascade of a person detector [1] and a pose estimator [2] are applied to a set of synchronized frames. The result is a heatmap per each joint expressing the probability map of finding that particular joint on the 2D image. Then the 3D subject pose is triangulated and refined matching the anatomical constraints imposed by a subject-specific model acquired by laser scan. The final step calculates planar angles between the anatomical segments. The system was tested on 42 gait trials performed by 3 subjects (mean age  $27.3 \pm 5.5$  years, mean BMI  $21.3 \pm$

$2.6 \text{ kg/m}^2$ ) acquired both in a laboratory environment (out-of-water, OW) and underwater (UW) in a swimming pool. Six synchronized UW color analog wide-angle cameras (720×576 resolution TS-6021PSC), were used and synchronized automatically with a custom-made application [3]. Calibration of the intrinsic parameters was performed OW, filming a black and white checkerboard and then corrected for UW condition [3]. A 12-control points calibration grid (2 m×1.1 m×1.1 m) was used for extrinsic calibration [3]. In order to assess reliability of the proposed approach, the same gait trials were processed by automatically tracking anatomical landmarks (Track on Filed, BBSOF S.r.l.) marked on the subjects skin with a black marker, according to [4]. Mean and Standard deviation, across trials, of each planar angle were computed for each technique and compared (Paired T Test  $p < 0.05$ ).

### Results and Discussion

No significant differences were observed between the two methods both OW and UW (Fig.1).

**Figure 1:** Knee flexion-extension angles during gait, same subject in different environments. Total number of gait cycles: markerless 12 (OW) and 31 (UW), CAST 4 (OW) and 9 (UW)

### Conclusions

Despite the pose estimator was trained for non-clinical purposes, the joints' kinematics was reconstructed with remarkable accuracy.

## Evaluating methods of calculating jump height from force plate data

Rendán L. Pinto, Jack P. Callaghan

Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada

Email: [blpinto@uwaterloo.ca](mailto:blpinto@uwaterloo.ca)

### Summary

Jump heights calculated from force plate data using take-off velocity (TOV) and TOV summed with take-off displacement (TOV+s) were compared to whole body displacement measured by a single kinematic marker. This provided a criterion that matched the assumption of point mass made by the force plate calculation methods while directly recording representative whole body displacement. Conversely, estimating centre of mass (COM) from a rigid link model (RLM) would not match these assumptions. Results indicate that the TOV+s method provides greater accuracy and precision.

### Introduction

Jump height can be calculated from force plate data using projectile motion equations. The TOV and TOV+s methods are preferred over the time in air method, which is influenced by landing posture [1,2]. Results from TOV and TOV+s methods have been compared to COM displacement derived from a kinematic RLM. However, COM from the RLM is sensitive to changes in body posture during flight, whereas the projectile motion calculation using force plate data assumes the body as a point mass. The purpose of this investigation was to compare the calculate jump height from the TOV and TOV+s methods to a kinematic criterion that matches the assumption of point mass made by the projectile motion calculation, while directly measuring actual whole body vertical displacement.

### Methods

A single marker on the third lumbar vertebrae was used to record vertical displacement. This captured the displacement of the torso while limiting the influence of limb, ribcage and pelvis posture. This approach entailed fewer assumptions than the RLM while directly recording the vertical point mass displacement that the TOV and TOV+s methods attempt to estimate from the force plate data.

Thirty-four counter-movement jumps from 12 participants (6 female; mean  $\pm$  SD age  $24 \pm 4$  years; mass  $73.4 \pm 17.6$  kg; height  $1.74 \pm 0.08$  m) were used to calculate the limits of agreement (LOA) between each force plate calculation method and the kinematic criterion. A linear mixed effects model was used calculate the variance components while accounting for the multilevel data structure [3].

### Results and Discussion

The TOV+s method provided the best agreement with the kinematic criterion as the mean bias (dashed line Figure 1) was closer to the criterion (solid line at 0 cm Figure 1), with narrower limits of agreement (dotted lines Figure 1). However, this method still underestimated the criterion by up

to 4 cm and appears to be influenced by the magnitude of the jump as indicated by the slight negative trend with increasing jump magnitude (Pearson's  $r = -0.59$ , Figure 1).

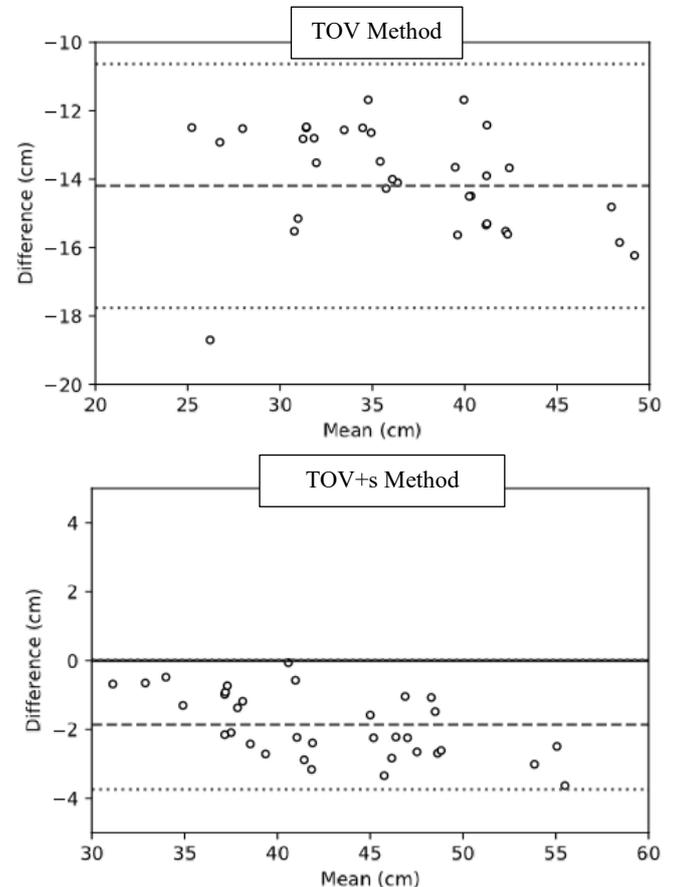

Figure 1: Bland and Altman plots for each method's agreement with the kinematic criterion.

### Conclusions

Accounting for displacement at take-off using the TOV+s method provides higher accuracy and precision compared to the TOV method. Further investigation is required to assess the persisting error, towards developing improved estimates of jump height from force plate data.

### Summary

While many methods have been proposed to quantify the systematic error of stereophotogrammetric (SP) systems, they are underutilised and not commonly reported due to their complexity and need for additional equipment. In response, a simple spot-check has been designed adopting previously proposed methodology. This study demonstrates the use of this method and presents preliminary results of the systematic error quantified for three different SP systems.

### Introduction

SP systems are widely used for the quantification of gait features and for estimating joint kinematics and kinetics. The laboratory set-up, capture volume, as well as the outcome of calibration procedures are critical aspects in the accuracy of a SP system [1]. Consequently, monitoring the accuracy and reliability of these systems is crucial to deploy laboratory quality assessment. Current practice on reporting systematic errors varies between manufacturers and usually does not entail the provision of easily readable feedback to compare errors on different days of use and between different systems. Although previous studies have assessed the error of different systems [2], a quick and cost-effective approach that could be easily performed before each use and can provide information about both linear and angular errors, is not yet available. To this end, this study aims to demonstrate the use of a simple spot-check to estimate the systematic error of different SP systems across multiple testing.

### Methods

After calibration, following the manufacturers guidelines, the proposed spot-check was performed on three SP systems: SP1: 14 Canon cameras, capture volume 5x4m; SP2: 10 T160 cameras, capture volume 7x4m; SP3: 12 Qualisys Miquis cameras, capture volume 6x4.5m.

Two trials were recorded using a wand comprising markers: 1) Static: a 5 s recording of the wand placed in the centre of the capture volume and 2) Dynamic: a recording of the operator moving the wand exploiting the full capture volume. Both trials were reconstructed and labelled following

manufacturers guidelines. The uncertainties ( $Uncertainty = SD_E \times k$ , where  $SD_E$  is the standard deviation of the error and  $k$  is the coverage factor,  $k=3$ ) for the distances ( $D_1$  and  $D_2$ , Figure 1) and angles ( $\theta_1$  and  $\theta_2$ ) were calculated for the static trials. The root mean square errors of each distance and angle were calculated for the dynamic trials [3].

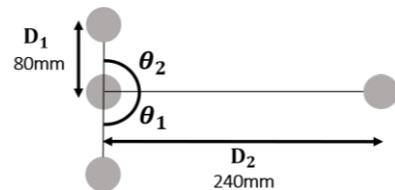

Figure 1: Distances and angles calculated from the active markers.

### Results and Discussion

Table 1 summarises the results of the spot-checks performed on each system on 10 different days of data collection. Errors observed both within and between systems were low overall, with the error for the distances always under 2mm and 1.8° for the angles.

### Conclusion

This study demonstrates the adoption of a simple method to monitor the level of systematic error in SP systems, regardless of manufacturer, number of cameras, capture volume and operators. This preliminary study is part of an ongoing data collection with a more comprehensive analysis of this method to be shared with the research community once completed, together with the computational tools that will ensure it may be embedded routinely within standardised protocols.

### Summary

While biological neural networks (NN) function under states of excitatory to inhibitory (EI-)balance, the number of neurons and their connections are not the same for these two groups. We investigated whether reservoir computing artificial neural networks (RC-NNs) also perform better with inequalities between the excitatory and inhibitory populations. Results show that networks generally perform better when inhibitory neurons have the upper hand.

### Introduction

NNs function under states of EI-balance, meaning there is a relatively constant ratio between excitatory and inhibitory inputs to neural cells. This phenomenon has been theorized to be a mechanism to keep networks both stable as well as temporally irregular and chaotic. In firing rate RC-NNs [1,2], pools of neurons are randomly created without distinction between excitatory and inhibitory populations, with their connections in an even distribution around zero. The aim of this study was to assess the effect of fluctuating the E:I ratio of (1) neuron number, (2) connection percentage, and (3) connection strength, on the performance of RC-NNs. Based on the findings in nature, we expect that such maps should not be symmetrical in relation to the main diagonal.

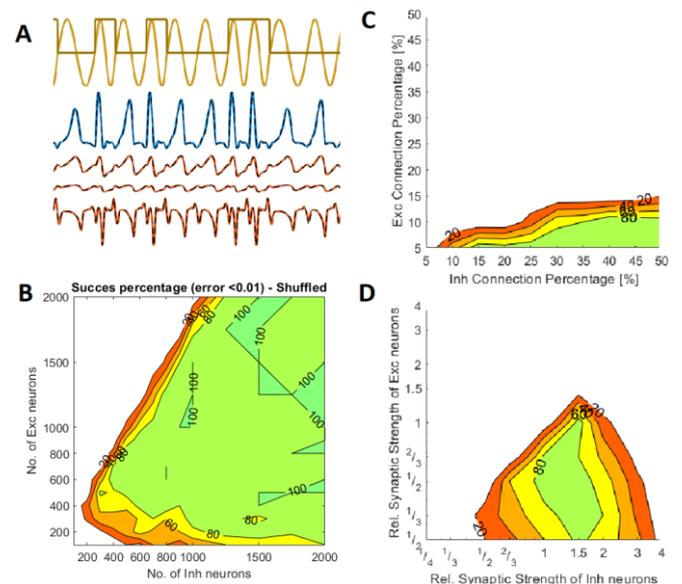

### Methods

All networks were trained and tested using locomotion data: slow walking, fast walking, and running. Kinematics and ground reaction forces were measured and, using the inverse dynamics option of the 3D muscle model called *Myonardo* (Predimo GmbH, Münster, Germany), transformed into spinal cord afferent and efferent signals, that functioned as the target signals (see Figure 1A). The network input was a context signal specifying the type of activity (binary signal) and the step frequency (via a sinusoid). The network was trained using FORCE [2]. For both populations, neuron number varied from 100-2000, connection percentage from 5-50% and connection strength from a factor of 0.25 to 4. Connection percentage and strength were tested for a combination of E:I ratios (4:1, 3:1, 2:1, 1:1 and vice versa).

### Results and Discussion

Networks performed better if they had a higher number of inhibitory than excitatory neurons. A clear cut-off line between successful and non-successful networks was found ranging from a E:I of 2:1 for smaller networks and a slightly smaller ratio for larger networks (Figure 1B). For the connection percentage, a similar phenomenon was found

(Figure 1C). Here, the slope of the cut-off line gets steeper, increasing the number of successful networks, as the fraction of inhibitory neurons increases. For the connection strength, a relatively small island of success was found (Figure 1D). Networks performed better when excitatory strength was no higher than a factor 1, while inhibitory strength could be scaled up. General trends show that networks perform better when the inhibitory neurons have more influence. At first glance, this seems to go against what we see in nature, since the cortex might have four times as many excitatory than inhibitory neurons [3]. However, networks with a biologically relevant 4:1 ratio have been found to be successful in this study given that either the inhibitory connection percentage or connection strength is high enough.

**Figure 1:** Example output of a successful network (A) and success percentages for varied number of neurons (B), connection percentage (C) and connection strength (D). Results in C and D are from a network with 1200 excitatory and 300 inhibitory neurons.

### Conclusions

RC-NNs function better when the excitatory and inhibitory network number, connection percentage and connection strength are not equal, reflecting what we see in the human nervous system.

## Relationship between neck flexion in neurodynamic tests and lower limb muscle activity

Dirk Möller<sup>1</sup>, Harry von Piekartz<sup>1</sup>, Kevin Maliszewski<sup>1</sup>, David Snowdon<sup>1</sup>

<sup>1</sup>Department of Movement and Rehabilitation Science, University of Applied Sciences, Osnabrück, Germany  
Email: d.moeller@hs-osnabrueck.de

### Summary

Neck flexion has a proven effect on the mechanosensitivity of neurodynamic tests of the lower limb, but it is not clear whether this can be explained by an increased (intra-neural) tension of the neural tissue and/or by a protective reflex mechanism of the motor system. The aim of this study was to evaluate the relationship between range of neck flexion and muscle activity changes in the lower limb during neurodynamic tests.

All included subjects performed the neurodynamic straight leg raise test and slump test. Muscle activity of the hamstring, quadriceps and calf muscles and range of motion of the neck flexion were measured during these tests and correlations were calculated.

The study results substantiated an overall-segmental influence of passive neck flexion on muscle activity in the lower limb. The patterns potentially indicate a protective muscular mechanism in end of range neurodynamic positions.

### Introduction

Neck flexion is a sensitizing maneuver for neurodynamic tests of the lower limb. It has a proven effect on the mechanosensitivity of these tests, but it is not clear whether this can be explained by an increased intra-neural tension and/or by a protective mechanism of the motor system. Previous research showed a relationship, but the muscular response of the lower limb on neck flexion is still not clear.

The aim of this study was to evaluate the relationship between range of neck flexion and muscle activity changes in the lower limb during neurodynamic tests.

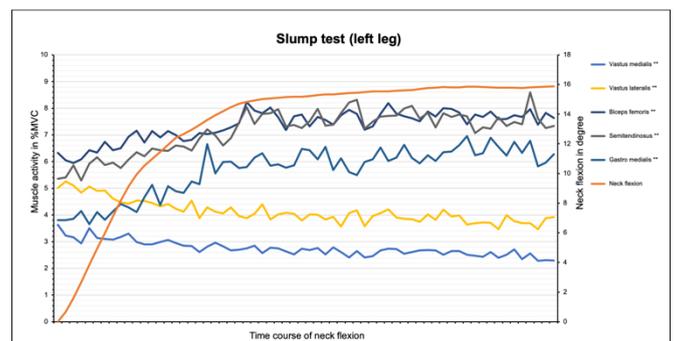

### Methods

Muscle activity (measured with electromyography) of the hamstring, quadriceps and calf muscles was measured in 30 healthy participants during neck flexion (measured with an inertial sensor system) in two neurodynamic tests (straight leg raise and slump). Correlations were calculated between increasing neck flexion and muscle activity during these tests.

### Results and Discussion

Increasing neck flexion was significantly correlated to muscle activity during straight leg raise test ( $r_s = -.61 - .76$ ; hamstrings > quadriceps > calf) as well as during slump test ( $r_s = -.34 - .94$ ; hamstrings > calf > quadriceps) (tab. 1). Negative values represent muscle activity declined with increasing neck flexion. Figure 1 illustrates the time course of neck flexion and muscle activity during the slump test.

These results support the hypothesis of a complex protective mechanism based on reciprocal inhibition to protect the neural structures [1,2,3].

**Figure 1:** Activity of different muscles in the time course of the passive neck flexion during the slump test (left muscles,  $**p < .01$ )

### Conclusions

Neck flexion in neurodynamic tests seems to have an influence on muscle activity of the lower limb. These muscle activity patterns during neck flexion supports clinical findings of an increase of symptoms and passive resistance in the lower limb during neurodynamic tests.

### Summary

We aimed to investigate whether painful electrical stimulation alters vastus medialis (VM) and lateralis (VL) motor unit recruitment strategies during isometric knee extension contractions. Twelve asymptomatic participants performed three 30s-long isometric knee extensions at 20% of their maximal voluntary contraction. In the middle 10s of each contraction, sinusoidal electrical stimulation at 4 Hz was delivered over the infrapatellar fat pad to induce a pain intensity of 4/10 (verbal analog scale). The firing rate of 51 single motor units was identified from surface high-density electromyographic recordings and averaged before, during, and after the painful stimulation. Friedman tests identified no difference in torque ( $p=0.368$ ), but motor unit firing rate decreased during the painful part of the contraction compared to before ( $p=0.001$ ) and after pain ( $p=0.011$ ). Similar to injections of hypertonic saline solution in the infrapatellar fat pad, painful electrical stimulation alters VM and VL motor unit recruitment.

### Introduction

A decrease in VM and VL motor unit firing rate is commonly observed when experimental knee pain is induced by injecting hypertonic saline solution in the infrapatellar fat pad [1]. Recent evidence shows that low-frequency sinusoidal electrical stimulation applied with surface electrodes over the infrapatellar fat pad elicits stable perception of pain over at least 60s, while allowing the recording of surface EMG with minimal artefacts [2]. We aimed to investigate if pain induced by low-frequency sinusoidal electrical stimulation replicates the alteration in motor unit recruitment strategies observed after injection of hypertonic saline solution as this could provide an alternative, non-invasive experimental pain model.

### Methods

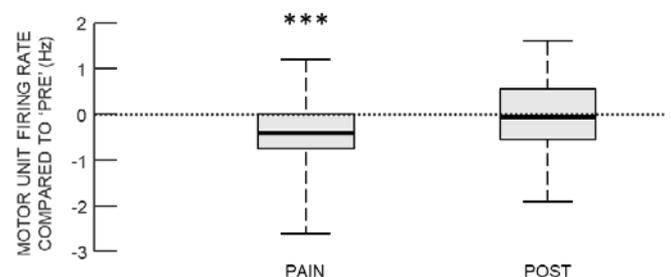

Twelve asymptomatic participants (2 women  $27 \pm 5$  years old  $176 \pm 6$  cm  $76 \pm 8$  kg) participated in the study which was approved by the local ethics committee. Stimulation electrodes were placed over the medial and lateral sides of the infrapatellar fat pad. Electrical stimulation was delivered as a 4 Hz sine wave [2] at an intensity that induced a pain intensity of 4/10 on a verbal analog scale. Knee extension torque was measured using a Biodex dynamometer. High-density surface EMG signals were recorded from the VM and VL using a Sessantaquattro (OT Bioelettronica, Italy) and grids of 8x4 electrodes with 10 mm inter-electrode distance. Participants performed three 30s-long isometric knee extensions at 20% of their maximal voluntary

contraction. Painful electrical stimulation was delivered during the middle 10s of each contraction.

Single motor unit firings were identified using the Convolution Kernel Compensation algorithm [3]. Torque and firing rate of the identified motor units were averaged in epochs before (pre), during (pain), and after (post) the painful stimulation, and averaged across contractions. Friedman tests and Bonferroni-corrected Wilcoxon tests were used to identify differences between pre, pain and post.

### Results and Discussion

Knee extension torque did not change during pain ( $p=0.368$ ). Of the 51 single motor units identified across all participants, 40 fired continuously throughout the contraction. The firing rate of motor units was, on average, lower during pain compared to pre (0.43 [0.02, 0.74] Hz  $p=0.001$ ) and post (0.26 [0.02, 0.74] Hz  $p=0.011$ ), with no difference between pre and post ( $p=1.00$ ). Additionally, 6 new motor units were recruited during pain, 4 were de-recruited, and 1 was recruited only after the end of the painful stimulation.

**Figure 1:** Change in motor unit firing rate between pre and pain, and between pre and post  $p < 0.001$ .

Similar to what has been observed after injection of hypertonic saline solution, we observed recruitment and de-recruitment of motor units. The smaller reduction in firing rate (0.4 Hz vs 1.2 Hz) compared to other studies [1] may be due to lower pain intensity or differences in the type and location of targeted receptors.

### Conclusions

Pain induced with low-frequency sinusoidal electrical stimulation of the infrapatellar fat pad alters motor unit recruitment strategies of the vastus medialis and lateralis.

# The Efficacy of Surface EMG Decomposition to Detect Motor Unit Firing Rates of the Lower-Limb Muscles During High Cadence Cycling

## Summary

Advances in surface EMG decomposition have allowed a better understanding of motor unit firing rates during dynamic movement. However, the application has been limited to movements at relatively slow contraction speeds. The preliminary results presented here demonstrate the efficacy of surface EMG decomposition to detect motor unit firing rates of the lower limb muscles during whole limb dynamic movement at fast contraction speeds during cycling.

## Introduction

Surface EMG decomposition provides useful insight into neuromuscular control. The application of surface EMG decomposition to the study of dynamic movement has been limited to relatively slow contraction speeds [1]. During dynamic motion, with relatively fast contraction speeds, there is a greater displacement of the surface EMG sensor relative to the underlying muscle fibers [2]. This additional motion may limit motor unit firing rate detection accuracy, subsequently reducing motor unit yield. For example, motor unit firing rates for the vastus lateralis during slow walking at 40 and 60 steps per minute were  $13 \pm 9$  and  $10 \pm 7$  respectively [1]. Whereas for isometric contractions of the vastus lateralis at 50%MVC, motor unit yields of up to 31 motor units per contraction have been reported [3]. To the authors knowledge limited research has attempted to detect motor unit firing rates during highly dynamic movements with faster contraction speeds beyond tasks such as bicep curls and level walking.

The aim of this preliminary investigation was to explore the efficacy of surface EMG decomposition for motor unit firing rate detection of multiple lower-limb muscles during high-cadence cycling activity.

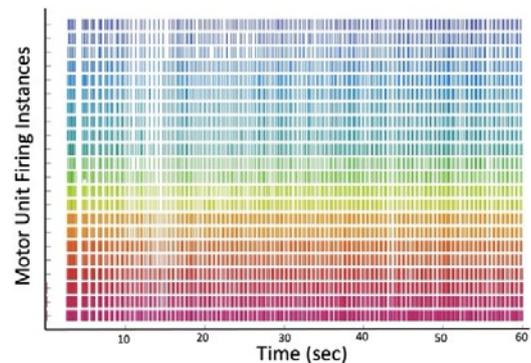

## Methods

Following informed consent and institutional ethical approval two recreationally active men (participant 1: age 37, height 175 cm, mass 67kg; participant 2: age 33, height 170 cm, mass 60 kg) completed 60 seconds of submaximal cycling at cadences of 60, 75, 90 and 105 RPM on an SRM ergometer. Surface EMG data was recorded for three bi-articular muscles (rectus femoris, biceps femoris and gastrocnemius medialis) and three mono-articulate muscles (vastus lateralis, semimembranosus and tibialis anterior) using Galileo surface EMG sensors (Delsys, Boston, USA).

Maximal power was determined with a 10 second sprint test at each cadence. During submaximal cycling participants were asked to match the target power of 40% max placed on a screen in front of them. Processing of the surface EMG data was conducted using proprietary decomposition algorithms (Delsys, Boston, USA). Accuracy of the algorithm was determined using the DSDC method [4].

## Results and Discussion

Motor unit yields were successfully obtained for a number of muscles at higher cadences (Table 1). Data for the biceps femoris and semimembranosus was not successfully collected for participant 2 due to the sensors being dislodge during the trial. Motor unit yields for the lower-limb muscle are comparable at 60, 75, 90 and 105 RPM with a motor unit firing rate detection accuracy of > 90%.

**Figure 1:** Motor unit firing instances for the rectus femoris during isokinetic cycling at 105 RPM and 40% max power for 60 seconds.

## Conclusions

The preliminary results demonstrate the efficacy of surface EMG decomposition to accurately detect motor unit firing rates of the lower limb muscles during high cadence cycling. Motor unit yields presented here demonstrate that surface EMG decomposition can indeed be applied to highly dynamic activities for the assessment of neuromuscular control strategies.

### Summary

Knee extension training has been typically used to gain strength in the quadriceps muscles and is frequently used in muscle building routines. The analysis of vastus medialis (VM) and vastus lateralis (VL) activity during knee extension exercises has been widely reported due to their role in the rehabilitation of conditions such as patellofemoral pain and ACL injury. Therefore, the aim of this study was to explore the effect of speed, load and contraction phase on motor unit behaviour in VL and VM using surface EMG decomposition (dEMG) during knee extension tasks in healthy subjects. The results obtained indicated that the motor unit firing rates increased with both load and speed, and were also greater during the concentric phase.

### Introduction

Knee extension training has been typically used to increase strength in the quadriceps muscles [1] and is frequently reported due to its implications to musculoskeletal conditions at the knee [2]. With respect to the influence of the speed of movement on EMG activity, the amplitude of signals has been shown to increase in VM and VL at faster speeds during the eccentric phase of knee extension [3]. Although differences were seen between concentric and eccentric phases at lower speeds, no such differences have been observed at faster speeds (60°/s) [3]. The use of surface EMG decomposition (dEMG) to describe motor unit behaviour within muscles has previously been restricted to isometric tasks [5], however this has been recently reported during cyclic dynamic contractions [6]. The aim of this study was to explore the effects of speed, load and contraction phase on the motor unit firing rates in VM and VL during knee extension training tasks.

### Methods

Twenty-three healthy adults (10 females and 13 males) volunteered and participated in this study. The average (standard deviation) age was 31 (9.0) years, height 1.79 (0.1) m and weight 78.5 (14.6) kg. Surface EMG signals were recorded at a frequency of 2222 Hz using two four-channel dEMG Trigno Galileo wireless sensors (Delsys Inc., Boston, USA). The dEMG sensors were attached to the skin using hypoallergenic double-sided tape over the VM and VL of the dominant leg of each participant. An additional two IMUs sensors (Trigno Avanti, Delsys Inc., Boston, USA) were attached to the skin on the thigh to record angular velocity at a frequency of 148Hz.

A knee extension machine (Technogym UK Ltd., WP, United Kingdom) was used to complete knee extension

training tasks with loads of 10% and 20% of body weight (BW), at 15 and 25 repetitions per minute (RPM). NeuroMap software v.1.1.0 (Delsys Inc., Boston, USA) was used to decompose the EMG signals from VM and VL into their constituent motor units. Motor units over an 80% accuracy threshold were then combined with the segment angular velocity data and imported into Visual 3D. The mean, maximum, and tertiles (upper, middle and lower) of the firing rates were then calculated for the different loads and speeds for both the eccentric and concentric phases of the knee extension training tasks. A three factor repeated measures ANOVA was used to explore the effects of load, speed and contraction phase, and any significant interactions were explored using post hoc paired t-tests. The statistical significance level was set to  $p < 0.05$ .

### Results and Discussion

The repeated measures ANOVA showed that both muscles had significantly higher firing rates as both load and speed increased, approximately 13% and 8% respectively ( $p < 0.001$  and  $p < 0.05$ ), with the VM showing the greatest firing rates and changes (Figure 1). In addition, the concentric phase showed approximately 5% and 10% higher firing rates than the eccentric phase across all measures in the VL and VM respectively ( $p < 0.001$ ). However, significant interactions were seen between load and contraction phase, and speed and contraction phase for the firing rates. Post hoc tests revealed significant differences between speeds across both loads in VM, whereas VL only showed significant differences between speeds at 20% BW. The higher firing rates indicate an increase in neuromuscular demand as load and speed are increased, which is also higher during the concentric phase, with VM showing the greatest changes to the different conditions.

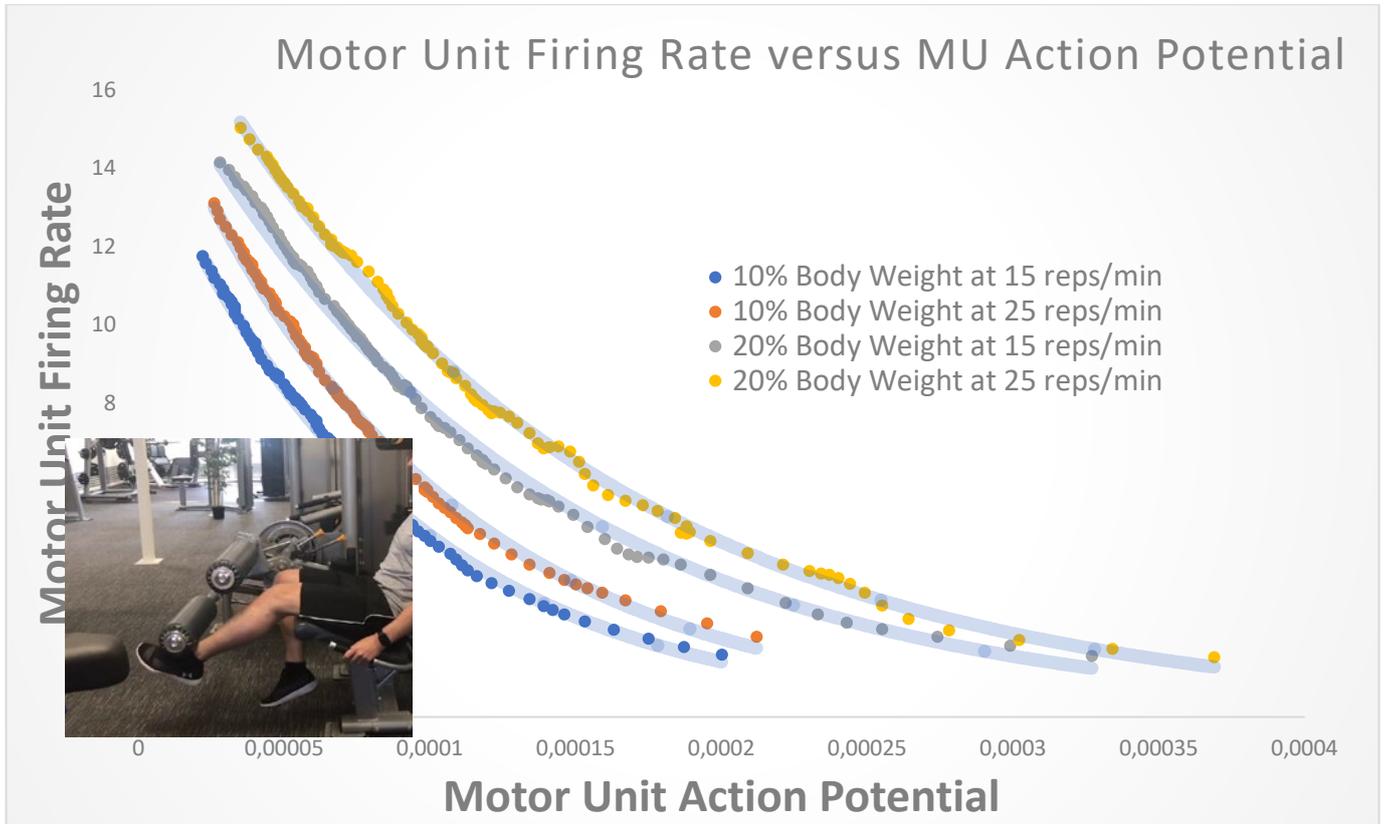

### Conclusions

These findings highlight previously unreported effects of load, speed and contraction phase during knee extension exercises. These may yield important information on changes in motor unit behaviour and how such movements are controlled during different rehabilitation exercises.

### Summary

This study aimed to measure mechanical properties of *gastrocnemius medialis* (GM) muscle-tendon unit following heat exposure (HOT, 46-50°C), increasing core and muscle temperature, compared to control environment (CON, 26°C). Rate of force development (RFD) in the early phase (*i.e.*, <100 ms) was faster in HOT than CON while late RFD was unchanged. Peak fascicle shortening velocity was unaffected, joint force-velocity relationship shifted to the right while fascicle force-velocity properties remained similar between both conditions. Passive muscle stiffness and active Achilles tendon stiffness decreased with hyperthermia. These results could explain the change in early RFD in hot environment.

### Introduction

Explosive force is commonly evaluated through the RFD, which is dependent of neural drive transmission, propagation of the action potential, excitation-contraction coupling processes and muscle force transmission [1]. RFD has been shown to increase with increasing core temperature [2]. This study aimed to evaluate the effect of hyperthermia on GM fascicle force-velocity relationship, passive muscle stiffness and active tendon stiffness to understand the localized mechanisms potentially involved in improved skeletal muscle contractility.

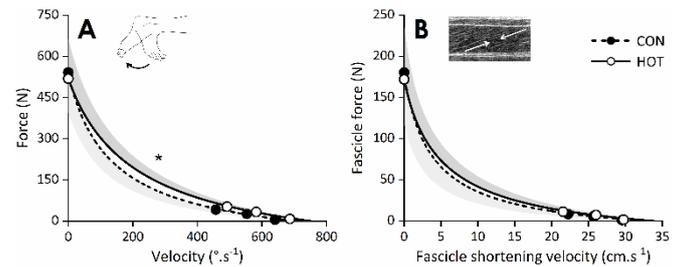

### Methods

Sixteen young recreationally active participants performed two testing sessions in CON and then in HOT condition, core and muscle temperature reaching 38.4±0.3°C and 37.0±0.6°C in HOT. Participants laid prone with their knee fully extended and their ankle flexed at 90°. Mechanical and ultrasound data were collected across four procedures: electrically-evoked and maximal voluntary contractions (MVC), ballistic contractions, at 0, 1.5 and 3kg, and isometric ramp contractions from 0 to 90% of MVC peak force. Resting shear modulus was measured in GM in neutral ankle position.

### Results and Discussion

Core and muscle temperature values were higher in HOT than CON (+1.42±0.5 and +3.0±1.0, respectively;  $P < 0.001$ ). MVC

force showed a trend to be lower in HOT and voluntary activation was lower in HOT (Table 1). RFD increased in the early phase (RFD<sub>0-100</sub>) while late RFD (RFD<sub>100-200</sub>) was unchanged (Table 1). Peak fascicle shortening velocity ( $V_F$ ) during electrically-evoked and voluntary contractions was not different between conditions (Table 1). Joint velocity at a given force was higher in HOT (Figure 1). Fascicle force-velocity properties relationship was unchanged (Figure 1). Muscle stiffness and active tendon stiffness decreased in HOT (Table 1).

**Figure 1:** Mean joint force-velocity relationship (A) and mean fascicle force-velocity relationship (B) in CON and HOT. \*, main effect of condition ( $P < 0.05$ ).

Hyperthermia does not modify muscle contractility (*i.e.*, fascicle shortening velocity), but decreases the stiffness in soft tissues. The increase in RFD is potentially linked to upstream mechanisms such as the speed of nerve conduction [3].

### Conclusions

The hyperthermia-induced increase in early RFD, is not related to changes in muscle contractility as reflected by similar force-velocity properties and reduced stiffness of soft tissues. The present study provides information on the determinants of human muscle performance in the heat.

### Summary

Children with cerebral palsy (CP) may undergo significant morphological and compositional alterations during growth that make their muscles smaller and weaker [1]. In the current study, we quantified 3D muscle morphological parameters and intramuscular fat fraction (IFF) in typically developing (TD) children and children with CP. The observed alterations in fascicle length (FL) and IFF can provide valuable information to evaluate musculoskeletal function in children with CP.

### Introduction

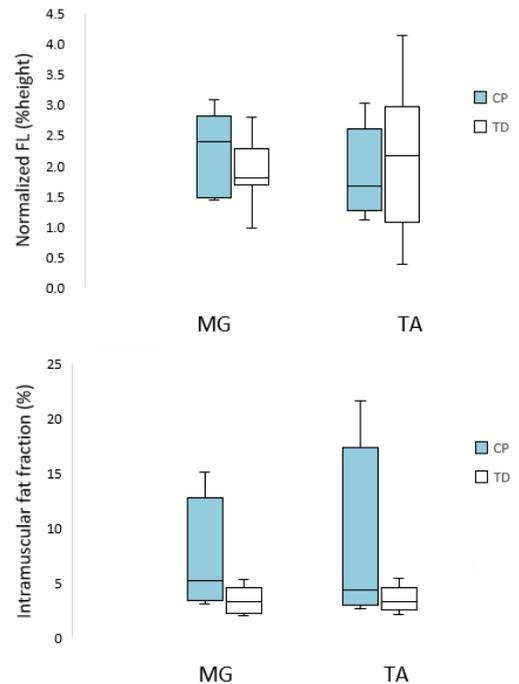

Physical activity is limited among children with CP, thus IFF may rise compared to TD children, which has important impact for physical performance [2]. The aim of this study was to compare 3D morphological parameters, i.e., FL, and IFF of lower leg muscles in CP and TD groups.

### Methods

Five children with CP (2M/3F, age  $10.3 \pm 3.1$  yrs, height  $138.1 \pm 10.7$  cm, weight  $31.8 \pm 6.9$  kg) and eight TD children (3M/5F, age  $9.3 \pm 2.4$  yrs, height  $134.2 \pm 13.4$  cm, weight  $30.4 \pm 6.4$  kg) voluntarily participated in the study approved by the local ethics committee. All the participants were scanned using a 3T MRI scanner (Siemens Trio) in a supine position, with  $20^\circ$  knee flexion and  $10^\circ$  ankle plantar flexion. T1-weighted, diffusion tensor (DT) and mDixon images were acquired for the lower legs. Muscle fascicle reconstruction was performed based on a previously reported pipeline [3] consisting of manual T1-weighted image segmentation, DTI registration, fiber tracking and parameter identification. IFF of all voxels in a muscle were calculated using the ratio of water and fat signal intensities [4]. For children with CP, quantification was made on the more affected side. For TD children, one side was randomly selected. Due to the low image quality and movement artifacts, mDixon images of three TD children and one child with CP were not included in the analysis.

### Results and Discussion

The FL and IFF of medial gastrocnemius (MG) and tibialis anterior (TA) are summarized in Figure 1, where FL was normalized with respect to the body height. Compared to the TD group, the FL of MG was found 17.8 % longer in children with CP but 11.3 % shorter in TA. As expected, compared to the TD group, children with CP have higher IFF in both muscles, which was in line with a previous study [2].

**Figure 1:** Normalized FL (top) and IFF (bottom) in MG and TA in children with CP (affected side) and TD group.

### Conclusions

DTI and mDixon images were used to investigate FL and IFF in the lower leg muscles of children with CP. The preliminary results showed that children with CP had a longer FL in MG but shorter in TA. Higher IFF was found in both MG and TA in the CP group. Further analysis is needed to determine whether the morphological and compositional changes are related to muscle strength and overall joint function.

## Summary

We tested the between-day reliability of diffusion tensor imaging (DTI) measurements of muscle fibre lengths in regions of varying size in the medial (MG) and lateral (LG) gastrocnemius muscles. The reliability increased with increasing size of muscle regions in which median lengths were measured, and varied considerably between individuals. These results should be taken into account when using DTI to measure local variations in muscle architecture.

## Introduction

The architecture of a muscle, particularly the fibre length, contains important information regarding the muscle’s force generating capacity. DTI is a promising technique to non-invasively quantify *in vivo* muscle fibre lengths in 3 dimensions at high spatial resolution. While the technique has been shown to provide reliable measures of the average muscle fibre length and other architectural parameters in whole muscles [1], the reliability has not yet been tested for smaller muscle regions.

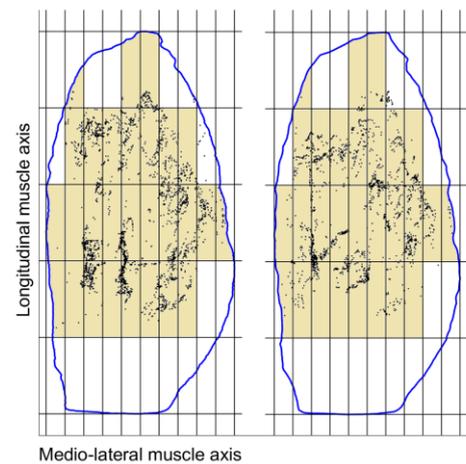

## Methods

Previously published data from the MG and LG [1], collected in four women and four men was used in this study. Each participant was scanned on two separate days to obtain both T1-weighted and DTI MRI scans of the left lower leg on each day. Segmentations of MG and LG from the T1 MRI scans were used to define the muscle boundaries. On average,  $4436 \pm 1185$  (MG) and  $2755 \pm 902$  (LG) fibre tracts were fitted on the DTI with third-order polynomials and then linearly extrapolated to the muscle boundaries.

A grid of rectangles was overlaid on the muscle’s (local) frontal plane (Fig. 1). Three rectangle sizes were used: small, medium, and large, with heights of 20%, 25%, 25% of muscle length and widths of 10%, 20%, 33.3% of muscle width, respectively. Median fibre lengths of all fibres with midpoints inside a given rectangle were calculated and compared between days. The mean intra-class correlation (ICC) and standard error of measurement (SEM) between days were computed for each rectangle size and muscle.

## Results and Discussion

An increasing rectangle size resulted in an increasing ICC for the median fibre lengths between days, in both muscles (Table 1). The mean ICC values ranged from moderate to good. However, we found a relatively large range of individual ICC values, with poor reliability in some participants. SEM values for both muscles followed a similar trend of decreasing values with increasing rectangle size. This suggests that with the largest rectangle sizes (□ 55 x 24 mm for the participant shown in Fig. 1), local median fibre lengths can be measured, on average, with good reliability.

**Figure 1:** Frontal view of the same MG muscle on day 1 (left) and day 2 (right), with the small rectangle size overlaid. Muscle boundaries are outlined in blue □ black dots show fibre midpoints □ shaded rectangles contain midpoints in both scans and were used to determine the ICC and SEM of median fibre length measurements.

## Conclusions

The reliability of DTI-based measurements of regional muscle architecture depends on the size of the region, with larger regions giving higher reliability. These results should be taken into account when using DTI to measure highly local variations in muscle architecture.

## Effect of muscle length on performance enhancement in a stretch-shortening cycle of the quadriceps femoris

Martin Groeber<sup>1</sup>, Arnold Baca<sup>1</sup>

<sup>1</sup>Department of Biomechanics, Kinesiology and Computer Science in Sport, Centre for Sport Science and University Sport, University of Vienna, Vienna, Austria  
Email: martin.groeber@univie.ac.at

### Summary

The present work disputes the influence of the muscle length on the stretch-shortening cycle (SSC) performance enhancement. The focus of this work is on the history-dependent properties of this muscle action. 25 healthy adults have been tested at an isokinetic dynamometer, parameters of interest were the mechanical work during shortening and the steady-state isometric force after the dynamic phase.

### Introduction

The isometric force or torque following eccentric or concentric muscle action is smaller (residual force depression, rFD) or greater (residual force enhancement, rFE) compared to an isometric reference contraction at the same muscle length and activation level [1]. rFE occurs at all muscle lengths but seems to be greater at long muscle lengths [2]. The contribution of rFE to a more relevant muscle action like the stretch-shortening cycle (SSC) should therefore also be greater at long muscle lengths. Thus, the focal point of this study was to examine the influence of different muscle lengths (meaning different angular positions) on the SSC performance enhancement.

### Methods

Torque of 25 healthy young adults was measured during SSC conditions, shortening conditions (CON) and isometric reference conditions (ISO) using an isokinetic dynamometer. The tests were conducted at the quadriceps femoris of the right leg. Electrical stimulation was used for all contractions. Current was increased until 35% of maximal voluntary contraction was reached, this current was used for the whole experiment. The angular velocity and range of motion were always fixed to 60°/s and 30° respectively, but angular positions varied (CON: 50 - 20°, 80 - 50° or 110 - 80°/SSC: 20 - 50 - 20°/50 - 80 - 50°, 80 - 110 - 80°). Full extension of the knee joint was defined as 0°.

Two-way ANOVA was used, the interaction (condition × angular position) and main effect was examined for the mechanical work during the shortening phase and the steady-state torque after the dynamic phase. The effect size was assessed with partial eta squared ( $\eta^2$ ).

### Results and Discussion

For mechanical work, no significant interaction (condition × angular position) was found ( $p = 0.544$ ,  $\eta^2 = 0.25$ ). Main effect for condition ( $p < 0.001$ ,  $\eta^2 = 0.435$ ) and angle ( $p < 0.001$ ,  $\eta^2 = 0.408$ ) revealed significant higher mechanical work with greater knee flexion angle and for the SSC condition. The percentage increase of mechanical work was nearly identical

at all different angle ranges (50 - 20°: 8.1%, 80 - 50°: 8.5% and 110 - 80°: 8.6%).

Two-way ANOVA revealed a significant interaction (condition × angle) ( $p = 0.033$ ,  $\eta^2 = 0.127$ ) for the steady-state torque. Main effect of angle was significant ( $p < 0.001$ ,  $\eta^2 = 0.636$ ), as well as the main effect for condition ( $p < 0.001$ ,  $\eta^2 = 0.296$ ). Further comparison with Bonferroni post hoc correction showed significant higher torque for the SSC condition compared with the CON condition at the greatest dynamometer angle ( $p = 0.043$ ) (Figure 1). No statistical difference was found between CON: 50-20° and SSC: 20 - 50 - 20° ( $p > 0.05$ ) and between CON: 80-50° and SSC: 50 - 80 - 50° ( $p > 0.05$ ).

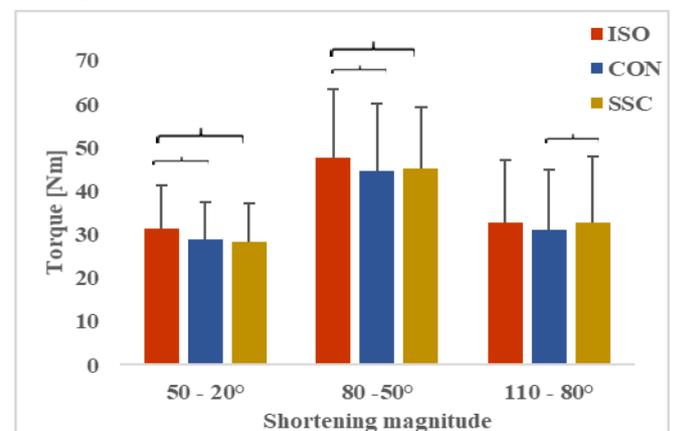

Figure 1: Steady-state torque of all tested contractions. Brackets indicate significant differences ( $p < 0.05$ ).

The results imply, that mechanisms related to rFE are responsible for the less depressed steady-state torque after the SSC with the greatest angular position.

### Conclusions

In conclusion, reduced rFD after the SSC contraction was only found at the condition with the greatest knee flexion angle (meaning longer muscle length). However, the percentage increase of mechanical work was independent of the angular position.

## Summary

We assessed the in vivo Achilles tendon (AT) strain, loading and strain energy during walking and running using a novel experimental approach. The AT length behavior was measured by integrating ultrasound and kinematics. The curved-shape of the AT was assessed by small reflective skin-markers placed on the path of the AT from origin (notch in calcaneus bone) to insertion (junction to medial gastrocnemius). The misalignment of the myotendinous junction to the skin surface and potential displacement of the skin insertion marker relative to the bone were considered. The tendon loading and strain energy during gaits was assessed by fitting a quadratic function to the experimentally measured AT force-elongation curve obtained from maximum voluntary ramp contractions. We found the AT strain during running lower than reported thresholds for an effective stimulus for tendon adaptation, which may explain the lack of adaptation following running training reported earlier. Moreover, we found a recoil of AT strain energy in the early stance phase of running, which we suggest to be functionally relevant.

## Introduction

The AT can adapt to external mechanical loading by increasing its stiffness. AT strain levels between 4.5 to 6.5 % were found to be effective to stimulate AT adaptation [1]. Previously, reported AT strains during running were in the suggested range of strain for tendon adaptation (i.e. 4.6 to 9 %). However, most studies that compared runners and untrained controls could not detect significant differences in AT stiffness [2]. The discrepancies between these findings might be the result of methodological limitations using simple planimetric model. Tendons feature elastic properties, enabling the storage and release of strain energy during gaits in favor of energy conservation and locomotor economy. Komi et al. (1990) [3] reported a reduction of the AT force in the early stance phase of running, suggesting an energy recoil of the AT after touchdown. This energy recoil might be functionally relevant for human running but has not been directly investigated yet.

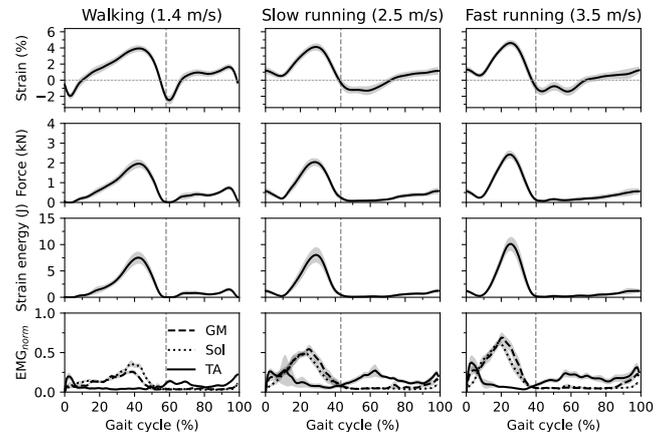

## Methods

Eleven participants (height =  $177 \pm 6$  cm, body mass =  $74 \pm 9$  kg, age =  $29 \pm 3$  years) walked and ran at 1.4, 2.5 and 3.5 m/s on a treadmill. AT length was defined as a curve-path from the insertion at the calcaneus (notch) that follows a line of reflective markers placed on the skin above the AT to its origin at the gastrocnemius myotendinous junction (MTJ).

The MTJ was captured during gaits using ultrasound and tracked by a self-developed semi-automatic algorithm. The tracked positions were firstly projected to skin surface and then projected to the global coordinate system. The potential skin-to-bone displacement of the calcaneus skin marker (insertion) was assessed separately during a passive rotation of the ankle joint and ultrasound. AT force and strain energy during gaits were calculated by fitting a quadratic function to the separately experimentally measured AT force-elongation curve obtained from maximum voluntary ramp contractions.

## Results and Discussion

The contribution of skin-to-bone displacement and projection of MTJ to the skin surface significantly affected AT length ( $p < 0.05$ ). The maximum AT strain ranged from 4.0 to 4.9%, indicating an insufficient strain magnitude to induce adaptation, which can explain the lack of adaptive changes in AT stiffness of runners. We found an elastic energy recoil between 7.8 J (walking) and 11.3 J (running) during the propulsion phase. We further found a recoil of elastic strain energy by AT in the early stance phase of slow and fast running in order of  $1.7 \pm 0.6$  J and  $1.9 \pm 1.1$  J, respectively, which might be functionally relevant for running efficiency.

**Figure 1:** Achilles tendon strain, force and strain energy, as well as EMG-activity of the gastrocnemius medialis (GM), soleus (Sol) and tibialis anterior muscle (TA).

## Conclusions

We found the AT strain during running is lower than previously reported and inadequate to initiate an adaption and provided the first evidence of elastic strain energy recoil in the early stance phase of running.

<sup>3</sup>Radiology Department, Virgen del Rocío University Hospital, Sevilla, Spain

Email: [s.wolfram@tees.ac.uk](mailto:s.wolfram@tees.ac.uk)

### Summary

This study investigated muscular adaptations of the residual and sound limb of transfemoral amputees compared to able-bodied controls. We found a decrease in muscle thickness in the residual limb compared to the sound limb and controls but no change in muscle stiffness.

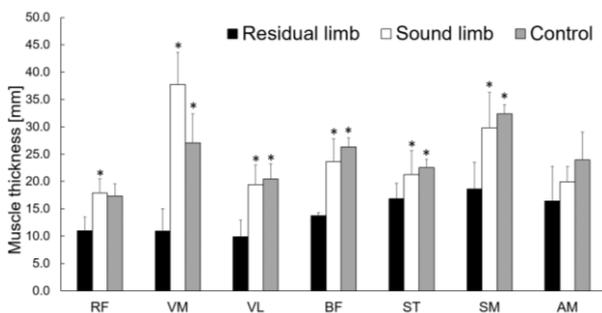

### Introduction

Transfemoral (TF) amputation involves disinsertion of distal ends of thigh muscles and reinsertion to non-physiological sites. As a result, amputees must adapt to a new muscular state. Loss of muscle mass has been reported for some thigh muscles of the residual limb [1] but nothing is known about changes in muscle material properties.

The purpose of this study was to conduct a thorough investigation into thickness of the major thigh muscles and subcutaneous fat of TF amputees and to obtain a measure of muscle stiffness using shearwave (SW) elastography.

### Methods

Thigh muscles of the residual limb (RES) and sound limb (SND) of six established TF amputees (3 males, 39.00 ± 6.22 years) and the left thigh of four able-bodied, age-matched controls (CON; 3 males, 38.75 ± 6.87 years) were studied. Participants provided informed consent and the study was approved by the ethics committee of Hospital Universitario Virgen del Rocío. Muscle thickness, subcutaneous fat thickness and SW velocity were measured from the mid-belly region of rectus femoris (RF), vastus medialis (VM), vastus lateralis (VL), adductor magnus (AM), biceps femoris (BF), semitendinosus (ST) and semimembranosus (SM). Muscle thickness, subcutaneous fat thickness and SW velocity were compared between RES, SND and CON with a One-Way ANOVA and Tukey's post-hoc test, where appropriate.

**Figure 1** Muscle thicknesses of residual limb, sound limb and control. Error bars represent standard deviations. \*Significant difference to residual limb ( $p < 0.05$ ).

### Results and Discussion

In agreement with previous studies [1,2], muscle thickness was significantly smaller for all RES muscles compared to SND and CON except AM (Figure 1), which may be due to muscle atrophy but could also be a result of surgical technique. The thickness of subcutaneous tissue did not differ for any of the areas between RES, SND and CON.

Interestingly, we did not find differences in SW velocity between the RES, SND and CON for most muscles. Only SW speed of BF was found to be significantly greater in CON compared to RES (Table 1). These findings indicate that muscle material stiffness is not related to muscle atrophy as was shown for the elderly [3]. Rather, changes in SW speed may reflect adaptations of muscle connective tissue.

**Table 1:** Shearwave velocities (with standard deviations) for all muscles. \*Significant difference to residual limb ( $p < 0.05$ )

Muscle	Shearwave velocity [m/s]		
	Residual limb	Sound limb	Control
Rectus femoris	2.34 (0.41)	2.18 (0.26)	2.38 (0.68)
Vastus lateralis	3.27 (0.89)	2.42 (0.88)	2.32 (0.46)
Vastus medialis	2.78 (0.72)	2.23 (0.54)	2.49 (1.11)
Biceps femoris	<b>2.54 (0.74)</b>	3.47 (1.23)	<b>3.47 (0.42)*</b>
Semitendinosus	2.04 (0.34)	2.43 (0.45)	2.96 (0.78)
Semimembranosus	2.39 (0.58)	3.00 (0.9)	4.12 (1.04)
Adductor magnus	4.03 (0.88)	3.66 (0.84)	4.71 (0.25)

### Conclusions

Muscular adaptations in TF amputees occur for the residual limb through a reduction in muscle size rather than a change in muscle material properties. These adaptations seem to affect the residual limb only but not the sound limb.

### Summary

Human muscle function is often evaluated using indirect measures such as net joint torque. We therefore used a new non-invasive technique known as shear-wave tensiometry to estimate the *in vivo* human quadriceps muscles' force-angle relationship at various muscle activity levels using patellar tendon wave speed measurements and net joint torque measurements. Preliminary data shows that tensiometry is more sensitive to changes in both passive and active muscle tension across knee joint angles.

### Introduction

A muscle's force capacity depends on its length as described by its force-length relationship (F-l-r). When estimating the F-l-r of human muscles *in vivo*, muscle force cannot be measured directly. Often, external net joint torque is used as a substitute and force is estimated using lever-arm functions [1]. However, these approaches are problematic as subject-specific lever arms are often unknown and because net joint torque is influenced by gravitational forces and forces generated by agonist and antagonist muscles.

Recently, it has been shown that non-invasive tensiometry [2] might be able to overcome these problems. Tensiometry allows tendon load to be estimated by calculating the speed of a shear wave that is induced by a tap on the tendon. By assuming that tendon load is proportional to muscle force, the F-l-r can then be estimated based on more direct estimates of muscle force from tendon wave speed measurements. The aim of this study was to compare the submaximal F-l-r of the quadriceps obtained from both net joint torque and tendon wave speed measurements.

### Methods

Preliminary data was recorded from one healthy participant who performed nine fixed-end ramp contractions at knee angles ranging from 30 to 110° of knee flexion (0° refers to extension) at 10° increments. Their right shank was fixed to the lever arm of a dynamometer (IsoMed2000, DOR Ferstl GmbH, GER) while they sat with 90° hip flexion. Contractions were based on the summed muscle activities of vastus lateralis (VL), vastus medialis (VM) and rectus femoris (RF), which was provided as a real-time visual biofeedback signal. During the contractions, the participant had to linearly increase their quadriceps activity such that after 3-s they matched 50% of their maximum activity observed during maximum voluntary contraction (MVC) at 70° knee flexion.

Torque and crank arm angle were recorded at 2 kHz. Muscle activity was recorded at 2 kHz by surface EMG (NeuroLog System NL905, Digitimer Ltd, UK). Patellar tendon wave

speed was calculated from the time delay of the shear wave induced by a piezoelectric stack actuator (PK4J-P2, Thorlabs, USA), as measured by two accelerometers (Model 352A26, PC Piezotronics, USA) attached over the skin nine millimeters apart. Accelerometer data was sampled at 100 kHz and synchronized with all other signals using a 16-bit A/D converter (Power1401, CED, UK).

Submaximal torque-angle and wave speed-angle relationships ( $T-\theta$ -r and  $Ws-\theta$ -r) for 5–50 % MVC EMG levels were constructed from the nine fixed-end contractions. The summed quadriceps activity was normalized to its maximum recorded at each angle during the ramp contractions up to 50% MVC and submaximal torque and wave speed were taken at the corresponding time points from 10–100% of the normalized signal (resulting in 5–50% activity). Torque and wave speed were measured at rest from the first 250ms of each fixed-end contraction and subtracted at each angle. The  $T-\theta$ -r and  $Ws-\theta$ -r data were fitted with a second order polynomial.

### Results and Discussion

First results indicate a steep rise in wave speed at rest from 90° knee flexion, which was not observed using torque measurements. While passive torque is dominated by gravity acting on the leg attached to the dynamometer, wave speed at rest should reflect the tension in the quadriceps muscle-tendon units (MTUs). When considering the muscle and tendon as perfectly in series, this could indicate that beyond 90° knee flexion the passive tension of the muscle increases substantially.

The amplitude of the  $Ws-\theta$ -r largely exceeded the amplitude of the  $T-\theta$ -r. At 50% EMG activity, the lowest wave speed at 30° knee flexion equaled only 13% of the maximum wave speed at 70° knee flexion, whereas the minimum torque at 30° knee flexion equaled 60 % of the maximal torque at 70° knee flexion. One possible explanation could be related to joint geometry and the muscle's lever arm function that transforms tendon force into joint torque.

### Conclusions

Our preliminary data suggest that standard measurements of net joint torque potentially do not reflect patellar tendon load and therefore the tension generated by the quadriceps' muscles.

<sup>3</sup>Centre Hospitalier de Luxembourg, 1210 Luxembourg, Luxembourg

\*Corresponding author: [ahmed.soliman@uni.lu](mailto:ahmed.soliman@uni.lu)

### Summary

It was the objective to analyze the influence of personalization of musculoskeletal models (MS) on muscle and contact joint forces for frequent daily movements. For normal gait cycle, we detect approximately 20% for some muscles attached to the pelvis, as well as for maximum hip-joint contact force.

### Introduction

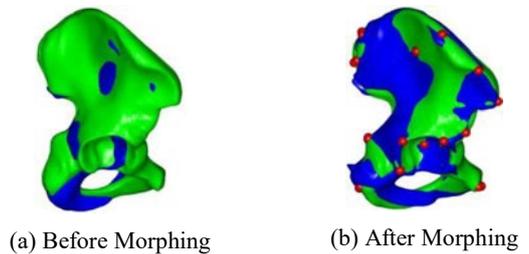

Over the past decades, numerous biomechanical studies were performed in order to investigate pelvis charging under physiological loading. Musculoskeletal Models (MS) proved already to provide precise muscle and contact forces. The latter were validated by measurements of instrumented implants [1], for this reason the muscles' forces can be assumed to be correct. However, an interesting question is the influence of personalization. The calculated muscles and joints contact forces may be utilized to predict stress states in pelvis bones and implants by using finite element (FE) software. In our study, the generic MS model of AnyBody software [2] is customized by matching the pelvis to the individual geometry ("morphing") of the SawBone pelvis [3]. As a result, muscle attachment points and joints centers shifted and results are compared.

### Methods

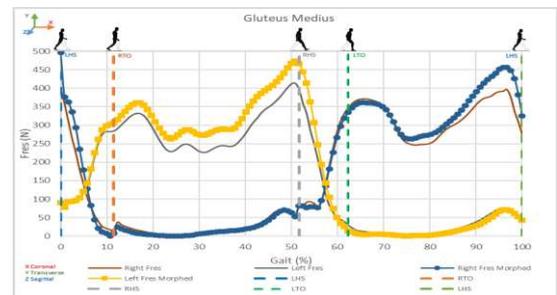

In order to digitize the 4<sup>th</sup> gen. SawBones artificial pelvis, computed tomography (CT) was conducted and 593 Digital Imaging and Communications in Medicine (DICOM) images of 0.5 mm thickness were imported into ITK-SNAP [4] and a 3D model of the pelvis was segmented. The total number of 28 corresponding anatomical landmarks (red dots in Figure 1) on both pelvises are selected using Meshlab [5]. The landmark coordinates are used in anybody to scale the morphing. For the gait movement, the inverse dynamics analysis was done twice, once for the generic MS and then for the personalized model.

### Results and Discussion

Figure 1(a), (b) show the two pelvises prior to and after morphing, respectively. As an example, the force of Gluteus Medius muscle for both models during normal gait is shown in Figure 2, which is considered as one of the most significant muscles of the lower limb. Though the pattern for both models is similar, there are deviations up to 24% for Left Heel Strike (LHS). The resulting Hip Joint Contact (HJC) force for both models show similar deviations up to  $\approx$  20% for Right Heel Strike (RHS), well in line with experimental studies of Bergman et al. [1].

**Figure 1:** Illustration of the differences between the generic and the morphed Anybody pelvis in MS models. AnyBody pelvis in blue, Sawbones pelvis (Target) in green, Controlling landmarks in red

**Figure 2:** Force (Fres) of Gluteus Medius muscle of left and right leg for both generic and morphed AnyBody MS model

### Conclusions

MS models allow full insight on muscle and joint contact forces. The personalized MS model shows similar shape of the calculated forces with clearly detectable deviations at distinct moments of the gait cycle. Hence, personalizing MS models can provide better results for individual biomechanical studies and for personalized implants.

## Towards more effective training: A biomechanical comparison of three hamstring exercises

Bas van Hooren<sup>1</sup>, Panayiotis Teratsias<sup>1</sup>, Paul Willems<sup>1</sup>, Sam van Rossum<sup>2</sup>, Benedicte vanwanseele<sup>2</sup>, Kenneth Meijer<sup>1</sup>, Maarten Drost<sup>1</sup>

<sup>2</sup>Human Movement Biomechanics Research Group, Department of Movement Sciences, KU Leuven, Leuven, Belgium  
 Email: basvanhooren@hotmail.com

### Summary

This study aimed to characterize and compare lower-limb muscle forces, muscle activation, and biceps femoris muscle fascicle behavior between three hamstring exercises: the Nordic hamstring exercise (NHE), the single-leg Roman chair (RCH), and the single-leg deadlift (DL). Increases in fascicle length were largest in the NHE, followed by the DL and RCH. Peak knee joint moments were highest for the NHE, followed by the RCH and DL while peak hip joint moments did not differ.

### Introduction

Risk factors for hamstring injuries include low hamstrings strength, short biceps femoris fascicles, and altered intermuscular coordination between the medial and lateral hamstrings [1]. A variety of exercises is being used to modify these risk factors in an attempt to prevent hamstring injuries and improve performance. Knowledge about the muscle forces, relative load and activation of each muscle, and fascicle behavior during exercises is essential as this allows practitioners and researchers to target specific adaptations to maximize the effectiveness of the exercises. However, there is currently little evidence available on these aspects across different exercises. The aim of this study is therefore to characterize and compare lower-limb muscle forces, muscle activation, and biceps femoris muscle fascicle behavior between three hamstring exercises: the Nordic hamstring exercise (NHE), the single-leg Roman chair (RCH), and the single-leg deadlift (DL).

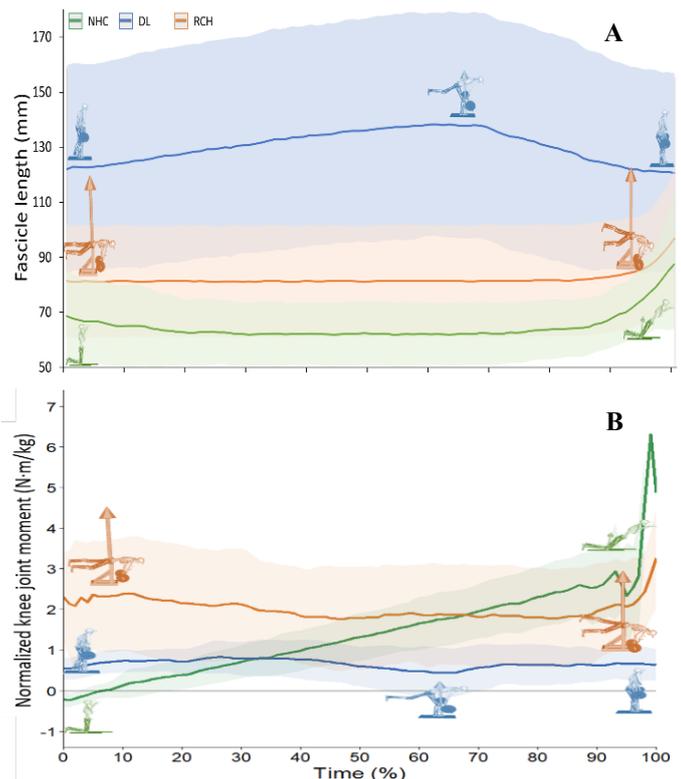

### Methods

Ten male participants performed the NHE, RCH and DL in a randomized order with a 1RM load, while full-body kinematics, ground reaction forces, lower-limb surface muscle activation (EMG) and biceps femoris muscle fascicle behavior were measured. Joint moments and muscle forces were determined using OpenSim [2]. Linear-mixed models were used to compare outcomes between exercises.

### Results and Discussion

Biceps femoris fascicles remained quasi-isometric before actively lengthening during the NHE and RCH, while they lengthened and subsequently shortened in the DL (Figure 1A). The increase in fascicle length was sig. larger in the NHE (30.8 ± 11.7 mm), compared to the DL or RCH (18.5 ± 5.2 and 17.8 ± 7.9 mm, respectively). Mean fascicle length was largest in the DL, followed by the RCH and NHE (130.1 ± 39.6, 92.8 ± 26.1 and 72.4 ± 14.6 mm, respectively), with all pairwise comparisons being significant. Peak knee joint

moments were highest for the NHE, followed by the RCH and DL (6.6 ± 1.2, 3.8 ± 1.3, 1.0 ± 0.4 N·m/kg, respectively (Figure 1B)). Peak hip joint moments and peak surface muscle activation did not significantly differ. Preliminary results indicate that the peak muscle forces for all hamstring muscles are highest in the NHE, followed by the RCH and DL.

**Figure 1** (A) Biceps femoris long head fascicle length, and (B) normalized knee joint moment during the NHE, RCH, and DL. Solid lines depict individual data, shaded areas between-subject SD.

### Conclusions

The larger increase in fascicle length during the NHE suggests this exercise may be most effective to trigger fascicle length adaptation. The higher peak hamstring muscle forces in the NHE suggest this exercise may be most effective to increase strength in these muscles.

### Summary

This project uses a forward-dynamics tracking approach to compute muscle as well as knee joint forces from measured gait data using a musculoskeletal model combining rigid body bones, line actuators, and finite element meniscus bodies. This model will allow us to investigate meniscal loading during highly dynamic movements as well as the effect of meniscal injuries on knee loading.

### Introduction

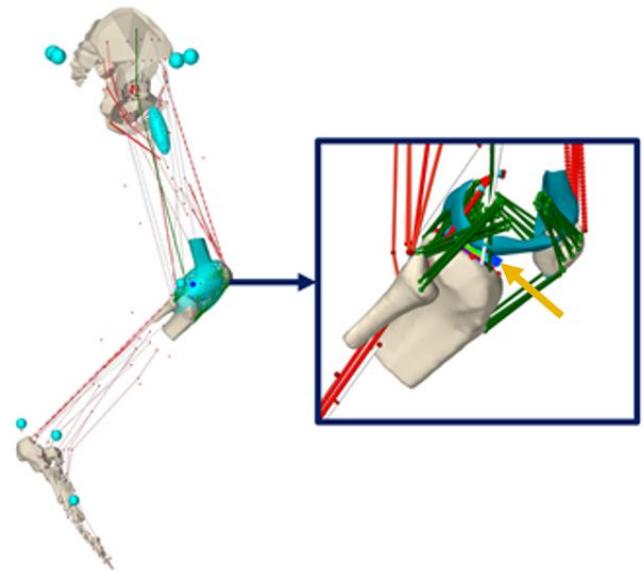

Dynamic musculoskeletal simulations using motion analysis data are a common tool in lower extremity biomechanics and have been used to investigate knee loading for a variety of tasks and disorders. Typically, these models use idealized rigid body joints to represent the knee, which does not allow for easy inclusion of deformable meniscus bodies. On the other hand, FE studies on meniscal loading are often computationally expensive and are mostly used for static or quasi-static investigations. In this project, we strive to use a rigid body model with included FE menisci to run forward-dynamics tracking simulations of various lower extremity tasks. This will allow us to investigate meniscal and articular cartilage loading during dynamic tasks from realistic, *in vivo* loading conditions.

### Methods

We built a combined rigid body-FE body model of the knee that included femur, tibia, patella, and menisci bodies connected by six-degree-of-freedom joints, ligaments, and articular contact. Bone, cartilage, muscle, and ligament geometries as well as tissue parameters were taken from an existing OpenSim model [1] and imported into ArtiSynth [2] ([www.artisynth.org](http://www.artisynth.org)). The lateral and medial menisci were modeled as FE bodies using a linear material model. Articular cartilage was modeled as elastic contact foundation layers. The Artisynth tracking controller [3] was first employed to run a muscle-driven forward-dynamics tracking simulation of a simple knee flexion task. The controller is currently being improved to track measured motion capture trajectories and ground reaction forces during a full gait cycle to investigate meniscal loading. To examine the effect of a meniscus tear we virtually resected the FE mesh and repeated simulations. Ultimately, we aim to visualize the effect of tears on the von Mises and maximum principal stresses of the menisci and the contact pressures of the cartilage.

### Results and Discussion

Preliminary results computed for a dynamic knee flexion indicate increased loading of the anterior cruciate ligament and articular cartilage layers in knees with a torn meniscus and greater deformations in the meniscal bodies.

**Figure 1:** Dynamic leg model and detailed view of knee model; inset shows detailed knee set-up including FE meniscus (location indicated by a gold arrow)

### Conclusions

We use a forward-dynamics tracking approach to perform muscle driven gait simulations that include FE representations of the meniscus. Simulations of meniscal tears can provide insight into surgical repair techniques and the role of meniscal damage in osteoarthritis.

## Estimated Hamstring Muscle Function During Sprinting is Sensitive to Modeling Methods

Carlie J. Ede, Glen M. Blenkinsop, Sam J. Allen

School of Sport, Exercise and Health Sciences, Loughborough University, UK

Email: c.ede@lboro.ac.uk

### Summary

Musculoskeletal modelling of hamstring (HS) muscle function during the swing phase of sprinting was matched via three optimisation methods. Fibre length and velocity were similar in all methods, but increased muscle force during the early swing phase was found during dynamic optimisations.

### Introduction

Musculoskeletal models are a valuable tool to investigate HS muscle function and injury risk during sprinting. Multiple methods are available to estimate muscle function, each with differing complexity. Static Optimisation (SO) solves the muscle indeterminacy problem by matching joint torques from inverse dynamics at discrete time steps, assuming a rigid tendon. Dynamic optimisations such as, Computed Muscle Control (CMC) and the newly released OpenSim Moco (0.4.0) employ forward dynamics approaches. CMC combines feedforward and feedback controllers to track experimental kinematics, while Moco utilises direct collocation. Previously, similar results have been reported between static and dynamic optimisations during walking and slow running [1], though the effects of these methods on estimated muscle function during dynamic activities is yet to be compared.

### Methods

One male participant ran at  $8 \text{ m}\cdot\text{s}^{-1}$  on an instrumented treadmill following informed consent and university ethical approval. Synchronised force (1000 Hz) and motion capture (250 Hz) data were recorded for 10 strides.

A generic OpenSim model [2] was scaled to the participant and modified to form a 2D planar model, reducing the size of the optimisation and focusing on primary muscle groups. The model had 14 degrees of freedom and comprised: 20 segments, 30 muscle-tendon actuators and 5 ideal torque actuators to control the torso and upper limbs. The optimal fibre length was adjusted to match the angle at maximum isometric force identified by Anderson [3]. Maximum isometric force was adjusted based on muscle volumes from

Miller [4], and the maximum contraction velocity was set at  $20 \text{ fibre lengths}\cdot\text{s}^{-1}$ .

Inverse kinematics was performed in OpenSim before force and kinematics were low pass filtered (20 Hz), cropped to a single representative swing phase, and inputted into SO, CMC and Moco. For all problems, residual actuators at the pelvis were added to account for dynamic inconsistencies and coordinate actuators were used to support the function of the lower limbs.

### Results and Discussion

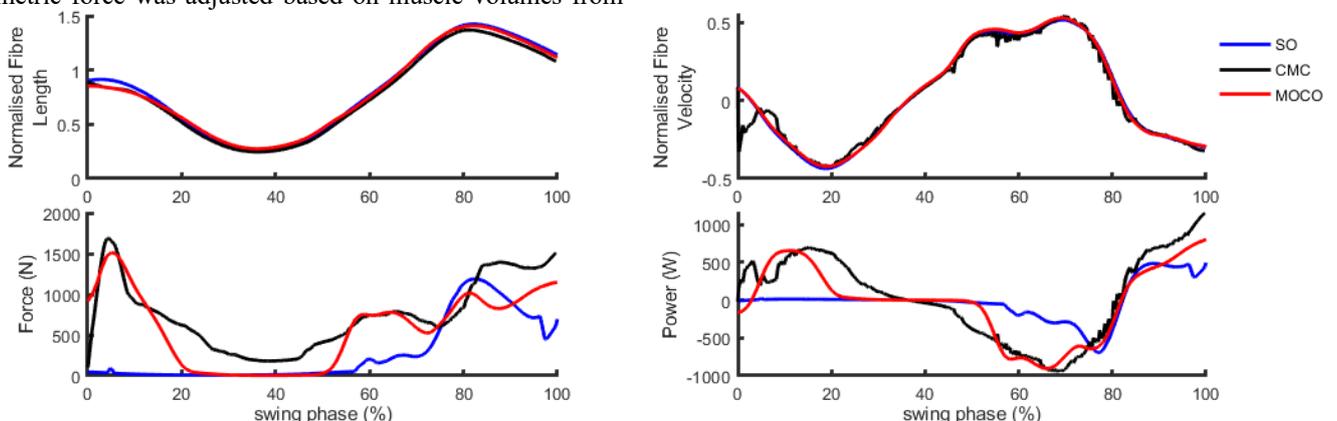

CMC required the highest coordinate reserves (combined RMS: 55.1 Nm), followed by SO (19.5 Nm) and Moco (2.0 Nm). Normalised fibre length was similar across methods, with a slightly lower peak in CMC (1.37) compared to Moco (1.40) and SO (1.42). In line with Thelen [5], peak fibre length, velocity and power were reported in late swing for all methods (figure 1). SO showed a peak force of 1189 N at 82% of swing, but almost zero force for the first 50%. Both CMC and Moco produced similar peak values in late swing, but peak force occurred within the initial 10% (CMC: 1689 N, Moco: 1515 N). This difference is likely due to increased co-contraction at the hip and knee after toe-off, which has been demonstrated with EMG data [6].

### Conclusions

Force output from the three methods showed varied results. Algorithms that support muscle dynamics and co-contraction may provide better estimates of HS function during dynamic tasks such as sprinting.

## Musculoskeletal Models for Assessing Surgical Indications and Outcomes in Cerebral Palsy

Claude Foyford<sup>1</sup>, Emma Pratt<sup>2</sup>, Claudia Mazzoli<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering & Insigneo Institute for in silico Medicine, University of Sheffield, United Kingdom

<sup>2</sup>Sheffield Children's Hospital NHS Foundation Trust Gait Laboratory, Ryegate Children's Centre, United Kingdom

Email: cfhayford1@sheffield.ac.uk

### Summary

Some surgical indications and outcomes in CP are based on joint kinematics derived from the conventional gait model and direct kinematics. Global optimization has however been proven to be more accurate. Using clinical gait analysis data of CP patients who underwent femoral derotation osteotomies, this study investigates three transverse plane kinematic measures (pelvic rotation, hip rotation, and foot progression angle) in addition to the Gait Profile Score and suggests that global optimisation with constrained models can equally quantify and predict relevant clinical changes and outcomes for use in clinical decision-making.

### Introduction

Femoral Derotation Osteotomies (FDO) are used to correct torsional deformities such as excessive anteversions in children with cerebral palsy (CP). Outcomes are judged based on changes in transverse plane kinematics over stance such as pelvic rotation (PRot), hip rotation (HRot), and foot progression angle (FPA) [1]. Similarly, the Gait Profile Score (GPS) is used to quantify overall lower limb gait quality. These metrics are predominantly obtained from clinical gait analysis (CGA) using the conventional gait model (as implemented in the Plug-in-Gait model (PiG)). Global optimisation has been shown to be more accurate due to reducing skin tissue artefacts [2]. This is typically associated with musculoskeletal (MSK) models having additional joint constraints with respect to the PiG. This study hypothesized that using such a model and the global optimisation approach, clinical information equally relevant to that provided by the traditional gait analysis model can be obtained when looking at outcome quantification and prediction. This would support the case for adopting these MSK models, allowing to also estimate internal muscle and joint contact forces, in clinical protocols to improve decision-making.

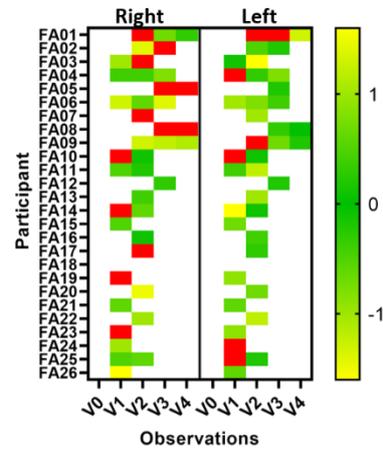

### Methods

Retrospectively collected CGA data for controls (n = 34) and CP patients with excessive femoral anteversion (FA, n = 26) were investigated. Each subject had at least 3 dynamic gait trials and FA had pre- and one or more post-surgery visits. PiG model (DoF: 3 at hip and knee, 2 at ankle) joint kinematics for all subjects were processed per the clinical protocol in Vicon Nexus. Scaled gait2392 models (Gen, DoF: 3 at hip, 1 at knee and ankle) were created for each subject and simulated in OpenSim 3.3 to estimate joint angles. Mean of PRot, HRot and FPA were calculated over stance. GPS was calculated per Baker et al, 2009. These metrics were summarised as mean and standard deviation. Additionally, correlation analysis between PiG and Gen estimates were

performed. Changes ( $\Delta$ ) in these metrics between visits were also compared.

### Results

PRot, FPA and GPS scores of all limbs and observations were highly correlated ( $R^2 > 0.7$ ) between PiG and Gen. Similarly, there was a greater than 89% (n = 81, all limbs) agreement between PiG and Gen estimates of positive or negative changes in GPS between observations.

**Figure 1:** Differences between  $\Delta$ (GPS) estimated by Gen and PiG. Red squares indicate values exceeding  $1.6^\circ$  (minimal clinically important difference in GPS) as the limit of agreement between models.

Results showed great correlation and similarity between joint kinematics estimated by PiG and Gen as previously reported [3]. The exception to this was HRot where the Gen tended to estimate more externally rotated hip angles compared to the PiG observable as an offset between model estimates. This affected Gen GPS estimates and when HRot was omitted from the calculation, the percentage of agreement in estimates of change ( $\Delta$ (GPS), Figure 1) increased. The decreased correspondence at the hip may be due to the Gen's inability to capture the different degrees of anteversion and further analysis is ongoing to understand this important aspect for this population. Overall, the Gen was able to detect the direction of change in metrics although magnitudes could be different.

### Conclusion

These results suggest MSK models can be used to approximate changes in indications and outcomes after FDO in CP, similar to estimates from using the PiG model.

### Summary

Reliable computational ligament-skeletal models are essential for the comprehension of the human ankle biomechanics. Although, a good level of approximation with respect to experimental data is reported, current models still need further improvements. This study reports a development of a validated in-silico model by including MRI-based mapping of a number of critical ligaments poorly investigated in the relevant literature. Comparisons in terms of load-displacement curves between standard and updated anatomical mapping revealed considerable improvements in simulation-to-measurement comparisons.

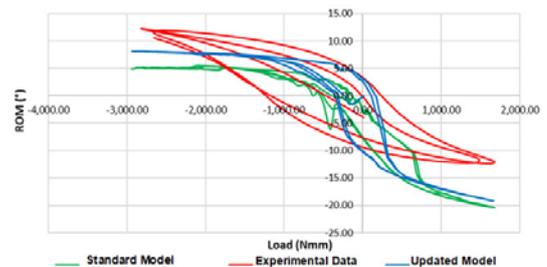

### Introduction

A thorough comprehension of the stabilizing role of the ligaments at the Ankle Joint Complex (AJC) is important in biomechanics [1] and in clinics, for reliable diagnosis and personalized surgical treatments. Several subject-specific computational models have been developed, but only a few with a strong validation against experimental data [2]. Unfortunately, model inputs in terms of bone-ligament attachment mapping still employ improper information, especially in the case of structures of difficult identification. More subject-specific models should derive from more precise overall mappings data from state-of-the-art Magnetic Resonance Imaging (MRI). The aim of this study was to further enhance a validated ankle computational model by using subject-specific morphological data, including bones derived by Computer-Tomography (CT) and critical ligament attachments areas as by MRI. For the same model, resulting joint load-displacement curves will be compared with the corresponding from standard procedures. The effects deriving from the removal of one of these ligaments at a time are also analyzed.

### Methods

Morphological data of ankle bones were obtained from CT (DE Rev HD 1700 GSI, GE; 0.6 mm slicing space and thickness) of one normal cadaver leg. Corresponding bone-ligament attachment areas were reconstructed from 3.0 T MRI (750W GEM ENAB, GE; Sag 3D cube). The following ligaments were mapped by an experienced radiologist: Anterior Talo-Fibular (ATFL), Posterior Talo-Fibular (PTFL), Calcaneo-Fibular (CFL), Anterior ATTL and Posterior (PTTL) Tibio-Talar, Tibio-Calcaneal (TCL), Tibio Spring (TSL), Interosseus Talo-Calcaneal (ITCL), and Cervical Ligament (CL), the latter two being of difficult access and here properly identified. AJC motion and load data, derived from imposed Internal-External (Int-Ext) and Inversion-Eversion (Inv-Eve) rotation torques were measured experimentally [3].

A validated computational ankle model [1,2] was utilized both in its standard ligament configuration, and after update via the above reported subject-specific ligament data. After proper cartilage compensations, 3D bone models were imported in ADAMS (MSC Software Corporation, USA-CA); all ligaments were modelled as tension-only force elements, whose number depends on the ligament size, with non-linear strain [1]. Int-Ext and Inv-Eve loads necessary to run dynamic simulations were extracted from the corresponding experimental torque signals. Model predictions, in terms of AJC load and angular displacement, were derived from standard and updated ligament configuration. The latter was used also to analyze the effect of removal of one ligament at a time, this meant to mimic realistic ankle injuries.

**Figure 1:** Int-Ext load-displacement: curves from experimental measurements, and those from the two different model predictions, i.e. with standard and updated ligament configurations.

### Results and Discussion

When moving from standard to updated MRI-based ligament configuration, the difference in Int-Ext rotation range between model-based and experimental data dropped down by about ~50% (~40% in Int direction); marginal differences were observed in Inv-Eve range (~5%). Most of the observed changes are due to the mapping of ITCL and CL. Similarly between configurations, when ITCL is removed, Ext rotation increases of ~250%; when CL is removed Inv-Eve range increases of ~30% in both directions.

### Conclusions

The reported differences confirm how computational models may benefit further from more subject-specific ligament mapping, especially for the most critical ones. Since a closer replication of experimental AJC laxity may derive from such mapping, this must be carried out with appropriate care.

### Summary

Several circumstances in daily living require minimization of forces acting on a joint. To investigate the relation between muscle forces and joint forces, a direct measurement of these variables is desirable. Rather than using invasive methods to directly measure joint forces, they can also be approximated using musculoskeletal models. Here, we investigate the accuracy of predicted forces in a knee joint during walking and squatting based on a computational musculoskeletal model, by comparing the predicted data with the corresponding real-life data gained from knee prostheses capable of measuring internal joint forces.

### Introduction

Movement and non-movement related pain mostly influences the motor control and movement pattern of people with joint pain. Strategies to reduce pain involve, e.g., shifting the load to the non-painful leg, changing the gait pattern, or using gait assistant tools. To estimate the individual outcome of such strategies, it is desirable to know the joint and muscle forces as precisely as possible. However, for ethical reasons, a direct joint force measurement is problematic because of its invasiveness.

Here, we investigated the accuracy of predicted forces in a knee joint during walking and squatting based on a computational musculoskeletal model, by comparing the predicted data with the corresponding real-life data gained from knee prostheses capable of measuring internal joint forces [1]. Furthermore, we analyzed how different optimization strategies for neuromuscular activation patterns of bi- and uniarticular knee muscles can reduce knee joint forces.

### Methods

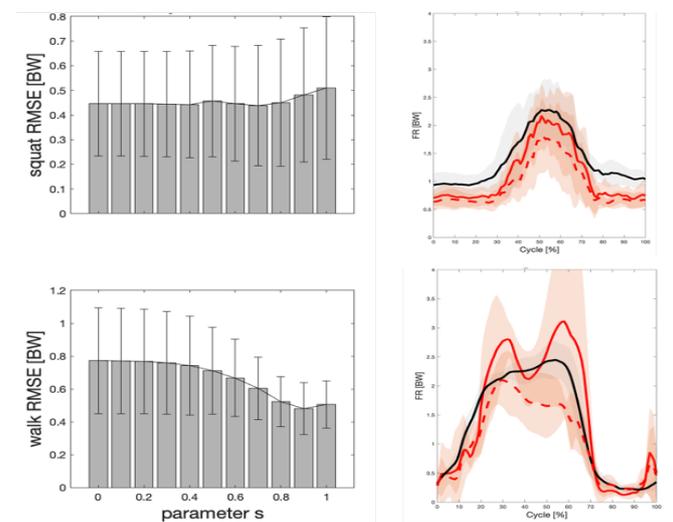

The experimental basis for the analyses of the present study was the CAMS-knee dataset [1], which encompasses kinematic data, ground reaction forces and measured joint forces in the knee prostheses of six patients. For the computational modeling, a full body musculoskeletal model called *Myonardo* (Predimo GmbH, Münster, Germany) was used. With *Myonardo* we calculated the net joint torques to predict the muscle forces acting on each joint. To calculate the net joint torques, the kinematics of the body segments and the external GRF acting on each foot were applied to the skeletal model.

Subsequently, we compared the influence of two different optimization criteria on the predicted joint forces, namely (1)

minimizing muscle forces, and (2) minimizing resulting joint force.

### Results and Discussion

The accuracy of the predicted knee joint forces depended on the optimization criterion, i.e. the optimization parameter  $s$  (Fig. 1, left). Minimum Root Mean Squared Error (RMSE) for parameter  $s$  was about 0.9. The standard deviations of the predicted and measured trajectories of the six patients were overlapping (Fig. 1, right).

**Figure 1:** Left: RMSE between measured and predicted joint forces during squatting (1<sup>st</sup> row) and level walking (2<sup>nd</sup> row), and different parameters  $s$  ( $s=0$  minimizes muscle forces,  $s=1$  minimizes joint forces). Right: Predicted knee joint forces ( $s=0$  red solid line,  $s=1$  red dashed line), and measured knee joint forces (black).

### Conclusions

We found that the accuracy of the predicted knee joint forces depends on the optimization criterion ( $0 < s < 1$ ). Patients may adapt their neuromuscular activation pattern to reduce joint forces during locomotion or everyday movements.

### Acknowledgments

We acknowledge the sources of the CAMS-Knee database (Laboratory for Movement Biomechanics, ETH Zurich, Julius Wolff Institute, Charité), and Predimo GmbH for providing the *Myonardo* software.

## A note on the influence of tendon speed in musculoskeletal inverse dynamics

L. Joakim Holmberg, Alexandra Roser, Jonas Stålhand

Solid Mechanics, Dept. Management and Engineering, Institute of Technology, Linköping University, Linköping, Sweden

Email: Joakim.holmberg@liu.se

### Summary

In the Hill model for muscle contraction, the split between the muscle and tendon is arbitrary and the problem lacks a unique solution. Commonly, a constant tendon length is assumed in simulation tools, but this assumption has not been thoroughly tested and may introduce unknown errors to the simulations.

We propose a new model that behaves like a friction clutch, includes an evolution law for the muscle length and non-zero tendon speed. Using a biceps curl simulation our model is compared to a state-of-the-art commercial muscle model (using zero tendon speed). Overall, the results are similar, but there is a difference in tendon speed of up to 3.3%.

### Introduction

In 1938 Hill [1] proposed a mechanical muscle model: a contractile element, representing the muscle, in series with a spring, representing the tendon. This Hill model comprise features like length and contraction speed dependence on the generated force. Hill-type muscle models are used in musculoskeletal simulation tools, e.g., AnyBody [2].

The speed-dependent properties of muscles together with the serial arrangement require a split of the total length and total speed of the muscle-tendon into separate parts for the contractile muscle and the tendon. The measurable quantities are usually the total muscle-tendon length and speed along with the tendon force. Thus, the split between muscle and tendon becomes arbitrary. Because a muscle's force-length-speed characteristics refer to muscle contraction, not total muscle-tendon length, the problem lacks a unique solution and is ill-posed. One solution is to reformulate the problem into a differential-algebraic equation and solve for a set of initial conditions. However, it is generally assumed that the speed of the tendon is negligible and that the contractile speed of the muscle is the total muscle-tendon speed, e.g. in AnyBody. The effect of this substitution has not been thoroughly tested for musculoskeletal inverse dynamics.

### Methods

We have previously proposed a modified muscle model where the contractile element behaves like a friction clutch [3,4,5] because of the similarity to the muscle contraction cycle; myosin heads attach to thin actin filaments, pull them inwards to the center of the sarcomere while the actin filaments also have a short and rapid outward slip. We have 3 elements in parallel: the contractile element; a passive element, modeled as a spring, that represents any stiffness in the muscle; and a viscous damper that represents any fluid in the muscle that would resist contraction. In series with these 3 elements is a spring representing the tendon. From the model's internal

mechanical power and the dissipation inequality we derived an evolution law for muscle contraction that facilitates the inclusion of tendon speed in the muscle model.

To assess the inclusion of tendon speed we compare results from our model with the Hill-type model in AnyBody using the brachialis muscle during an inverse dynamics simulation of a biceps curl. The external loading on the muscle, muscle properties and simulation times are the same or as close as possible. See Roser [5] for numerical and other details.

### Results and Discussion

For all tested cases, the tendon speed is small but non-zero throughout the motion using our model (Figure 1). Thus, there is a difference between our model and AnyBody, which expressed as a tendon speed error percentage ranges from almost zero to 3.3%. The tendon speed error generally increases with increased muscle contraction speed. The resulting differences for max muscle force and muscle work were up to 16.9% and 6.5% respectively.

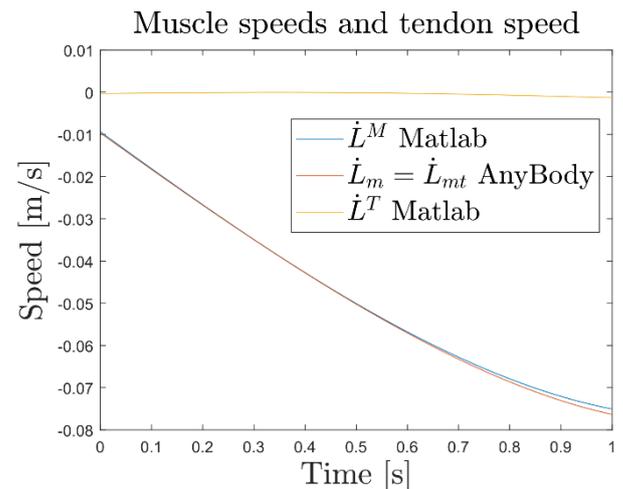

Figure 1: Speeds for our model (Matlab) and Anybody.

### Conclusions

The effect of including tendon speed seems to be small, but not necessarily always negligible as is generally assumed.

## A Musculoskeletal Parameter Study of Scapula Characteristics Affecting Rotator Cuff Muscle Forces

 Email: johanna.menze@sitem.unibe.ch

### Summary

A musculoskeletal shoulder model was applied to compare maximum rotator cuff forces (RC) during abduction and flexion to 120° with various scapula morphologies. Subscapularis (SB) and infraspinatus (IS) forces strongly increase with an upward glenoid inclination (GI) and acromion lateralization (AL) during abduction. Supraspinatus (SS) forces increase with an upward GI, but decrease with a higher AL.

### Introduction

Clinical observations and experimental studies have shown that morphological characteristics of the scapula affect the incidence of RC tearing [1]. Understanding the biomechanics could allow the identification of high risk patients for symptomatic RC injuries. Continuous overstraining of the rotator cuff might cause the high incidence of RC tearing for scapula geometries with an upward tilted glenoid and a laterally extended acromion, corresponding to a high Critical Shoulder Angle (CSA) [2]. However, a systematic parameter study comparing the influence of GI and AL on RC muscle forces calculated by inverse dynamics is lacking to date.

This musculoskeletal study aims at comparing the influence of the GI and AL on the maximum RC muscle forces during abduction and flexion.

### Methods

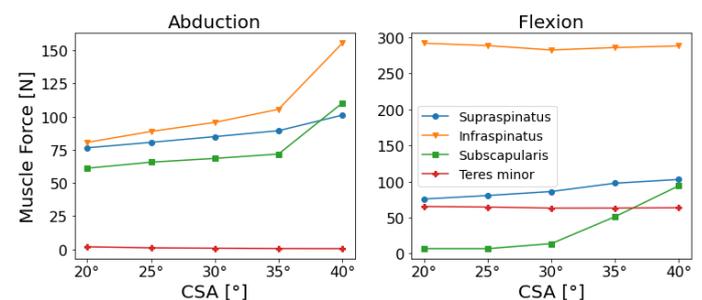

The musculoskeletal modeling was performed in Anybody 7.3 using the generic model (male, 75kg, 1.80m) of the repository AMMR v.2.3.1. Muscle forces were calculated based on inverse dynamics for shoulder abduction and flexion to 120° against a resistance of 25N and the maximum forces were subsequently compared. A parameter study was defined where the GI was altered while the AL remained unchanged, and vice versa. Both influence the CSA which was set to range from 20° to 40° to cover the population variations [3]. The chosen CSA range corresponds to a GI measure, the  $\beta$ -angle according to Maurer et al.(2012), from 64° to 91° for the first part and to an acromion index (AI) between 0.4 and 1.0 for the second part [4,5].

### Results and Discussion

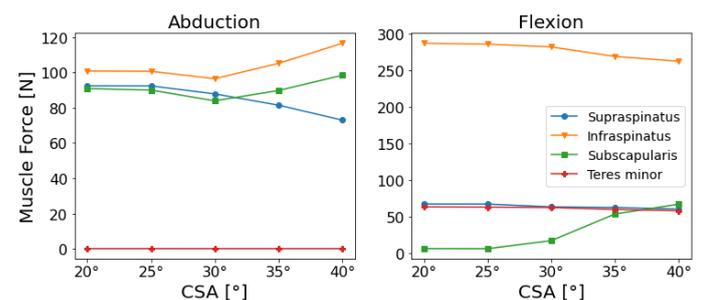

GI and AL variations have a stronger effect on RC forces during abduction than flexion (Figure 1 A, B). An increase of the CSA from 20° to 40° by GI changes, leads to a force increase of 93%, 67% and 31% in the IS, S $\square$  and SS, respectively (Figure 1A). While an acromion medialization does not influence the RC forces, an AL also increases the IS

and S $\square$  forces which suggests they might be crucial to provide shoulder stability [7]. The SS force during abduction decreases by 17% for a 40° CSA by AL (Figure 1 B) which accords with experimental studies showing that GI has a stronger effect on SS forces than AL [2].

#### A: Variation of glenoid inclination

#### B: Variation of acromion lateralization

**Figure 1:** Maximum RC muscle forces during abduction and flexion from 0° to 120° for a range of Critical Shoulder Angles (CSA) varied by changing the GI (A) and the AL (B)

### Conclusions

Using Anybody simulations it could be shown that S $\square$  and IS are most sensitive to changes in AL and GI. This could imply they are the key muscles for shoulder joint stability. An upward GI appeared to be more important for SS loading than AL. Glenohumeral translations will be included in further investigations.

## Assistance Level versus Metabolic Cost in a Biarticular Exoskeleton: A Simulation Study

Karthick Ganesan, Abhishek Gupta

Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, India

Email: karthick.ganesan@iitb.ac.in

### Summary

Finding how different assistance levels affect metabolic cost in exoskeleton assisted gait is an important goal in exoskeleton development. We used musculoskeletal simulation to explore the effect of different assistance levels in a biarticular knee-ankle exoskeleton for loaded walking. The results of this study can be used to choose appropriate assistance level in knee-ankle exoskeletons.

### Introduction

Exoskeletons can augment the capacity of humans and enhance mobility in the disabled. Often it is required to understand how varied levels of assistance affect the metabolic cost. Experimental studies investigated the effect of varied assistance on metabolic cost for different exoskeletons [1]. Simulations can complement experiments. Simulations have shown how actuator joint locations affect the metabolic cost and have provided optimal device torque profiles [2]. Here we investigate how different levels of assistance affect metabolic cost in loaded walking with a biarticular knee-ankle exoskeleton.

### Methods

We used OpenSim [3] for modeling and simulations. We used the scaled, mass adjusted musculoskeletal model and experimental gait data with load, without exosuit of one subject supplemented with the literature [2] for the simulations. The three dimensional musculoskeletal model has 39 degrees of freedom. Eight of the degrees of freedom were locked. For the simulations of loaded walking, the model has a 38 kg of load attached to the torso. We considered two cases: one with a monoarticular ankle exoskeleton and other with a biarticular knee-ankle exoskeleton. In case I, exoskeleton actuator was modeled as ideal torque actuator providing ankle plantar flexion torque and was implemented as CoordinateActuator in OpenSim. In case II, it was modeled as ideal force actuator producing force along a prescribed path, implemented using PathActuator. We used computed muscle control algorithm to estimate the muscle and actuator controls to track the experimental data. We used Umberger2010MuscleMetabolicsProbe to compute the metabolic cost.

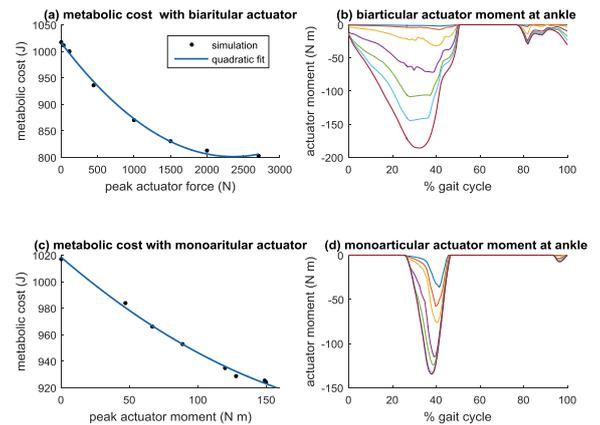

The force produced by actuator is given by

$$F = x F_{opt} \quad (1)$$

Where  $x$  is the control signal to the actuator, varying from 0 to 1 and  $F_{opt}$  is the optimal force, the maximum force/moment that the actuator can produce. Varied levels of assistance were achieved by varying the optimal force parameter of the actuator.

### Results and Discussion

With increased assistance, metabolic cost of walking reduces (Figure 1). Beyond a certain optimal force value, there is no significant decrease in metabolic cost. Minimizing the metabolic cost to the fullest extent may affect some other parameters such as joint loads or may alter the kinematics more. Designer can choose to provide a certain amount of assistance required to achieve a desired metabolic cost reduction based on constraints like device power, mass and cost. For different levels of assistance, optimal moment profile at ankle is shown (Figure 1). Here gait cycle begins with opposite toe off. Biarticular actuator produces more moment at the ankle compared to monoarticular actuator since it reduces the activity of gastrocnemius muscle in addition to soleus muscle. Biarticular actuator also increased activity of tibialis anterior muscle. Simulations with peak force values beyond the optimal value obtained from CMC simulations resulted in ankle reserve actuator producing more moment, giving unrealistic metabolic cost estimation.

**Figure 1:** Metabolic cost versus peak actuator force/moment and actuator torque profile for different levels of assistance.

### Conclusions

This abstract presents a framework for finding pareto optimal assistance profiles for exoskeletons. The results provide a reference for deciding the amount of assistance required and optimal torque profile for ankle and knee-ankle exoskeletons. This can be extended to other joints as well.

## Summary

A motion-based method to predict ground reaction forces and moments (GRF/M) in a moving and/or non-horizontal frame has been developed. The motion of a subject located on a moving hand pallet truck has been recorded. The moving structure has been equipped with a force platform to compare predicted and measured GRF/M.

## Introduction

Inverse dynamics methods are widely used in motion analysis studies to compute joint torques. The ground reaction forces and moments are required to solve the dynamic equilibrium of the subject studied. Measuring the GRF/M reduce the ecological aspect and constraint the movement area. Motion-based prediction methods are used to circumvent this limitation. All the existing methods regard the ground as a static and horizontal surface. In this abstract, an existing prediction method [1] is improved to expand its application to external forces coming from mobile and/or non-horizontal structures.

## Methods

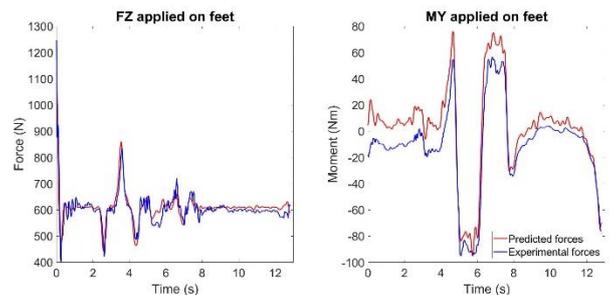

The force platform is composed of a 6-dofs force sensor (MCS10 5kN, 5000Hz, HBM) located between two steel plates. The motion capture data were recorded using an optoelectronic system (200 Hz, Qualisys). 43 reflective markers were placed on standardized anatomical landmarks of the human subject and 3 markers on the upper surface of the force platform. The force platform was laid down on a hand pallet truck. During a trial, the subject stood on the force platform, squatted once then successively lifted up each foot. During the subject's movement, an investigator pulled the hand pallet truck.

The GRF/M were predicted at each frame following two steps: contact detection and forces distribution. Firstly, a moving frame linked to the force platform was created using the 3D displacement of the 3 markers placed on it. Relative position and velocity thresholds between the moving contact surface and a set of discrete contact points under the subject's feet were tested. Secondly, the external forces applied on each prediction point were minimized with respect to the dynamic

equilibrium of the subject [1]. This method has been implemented in the CusToM Matlab toolbox [2].

## Results and Discussion

A comparison between predicted and measured force on vertical direction (Fz) and moment on antero-posterior direction (My) for a sample trial is presented below (Figure 1):

**Figure 1:** Predicted (red) and measured (blue) Fz (left) and My (right) applied on feet.

The RMSE errors between predicted and measured GRF/M curves for this trial are presented in the table below (Table 1). They are of the same order of magnitude as those obtained from the initial CusToM method [1]. The prediction method in moving frame presented here seems to open new applications to the initial one keeping the same accuracy. Nevertheless, more subjects and structure movements must be studied to draw suitable conclusion about this new method.

## Conclusions

A motion-based GRF/M prediction method in a moving and/or non-horizontal frame has been proposed. Preliminary results shows that this new method is promising and needs to be evaluated with more subjects and more challenging structure motions. Such a method may be useful for many applicative studies in sports or ergonomics.

### Summary

STAPLE (Shared Tools for Automatic Personalized Lower Extremity modelling) is an open source MATLAB toolbox that automates the creation of subject-specific models from three-dimensional bone geometries, normally obtained by segmentation of medical images. We compared automatic and manual models based on four anatomical datasets by quantifying the differences in their joint coordinate systems (JCS) and in joint angles and net moments calculated in gait analysis. Our findings suggest that the JCS of the automatic models were comparable to manual ones (within reported inter-operator variability) and differences observed in joint angles and moments for gait were due to JCS offsets and tibial mass estimation. The STAPLE toolbox is available at <https://simtk.org/projects/msk-staple>.

### Introduction

Predicting the effect of physical treatments has been made feasible by recent improvements in simulation techniques [1]. However, clinical applications, e.g. in orthopedics, very often require highly personalized anatomical models of the musculoskeletal system to virtually modify the patient anatomy according to planned interventions. Currently there are no fully automatic methodologies for generating these models, which are built by trained operators in several hours, so strongly limiting the adoption of modelling outside research environments. In this work we introduce a MATLAB toolbox called STAPLE that enables the generation of subject-specific skeletal models using fully automatic workflows and compare joint parameters and results of a gait analysis from automatic and manual models.

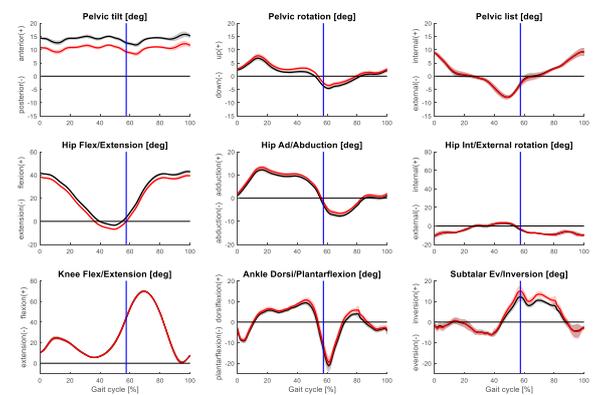

### Methods

Four anatomical datasets (age range: 14-85 yo, height: 1.71-1.8 m, mass: 45-87 kg, quality of segmented bone geometries: from excellent to low) were used as input to an automatic workflow consisting of a bone morphological analysis [2] streamlined with custom model-building scripts implemented in OpenSim 4.1 [3]. The models included five segments (pelvis, femur, tibia, talus and foot) and five joints (pelvis-ground: free joint, hip: spherical joint, tibiofemoral, talocrural and subtalar: hinge joints—12 degrees of freedom in total) defined as in [4]. Corresponding models were manually created by expert operators from the same anatomical datasets. Differences in JCS were quantified in terms of origin distance and axes orientation. For one of the datasets, joint angles and net joint moments were computed using OpenSim for six gait trials [5]. The resulting curves were compared using a two-tailed t-test (significance level  $\alpha=0.05$ ) implemented in the *spm1d* (<https://spm1d.org>)

package, plus correlation coefficients and root mean squared errors (RMSE) for each couple of corresponding curves.

### Results and Discussion

The automatic models were generated in less than 25s on a standard laptop. Differences of JCS origins ranged from 0.5 mm (hip joint) to 5.9 mm (subtalar joint), while the joint axes differed between 1° (knee joint) to 11° (subtalar joint). These values are comparable with inter-operator variability reported for manual models [6].

**Figure 1:** Comparison of gait kinematics estimated using an automatic (red lines) and a manual (black lines) lower limb model.

Correlation coefficients  $\approx 0.99$  ( $p < 0.0001$ ) and RMSE  $\approx 1^\circ$  were found for all joint coordinates except pelvis tilt and hip flex/extension, presenting  $3.4^\circ$  offset leading to significant differences in the t-test. The net joint moments differed prevalently in the swing phase of gait because of 25% difference in tibial mass estimation.

### Conclusions

The STAPLE toolbox automatically generates subject-specific lower limb skeletal models comparable to manual procedures in negligible processing time and offers a platform for further developments in personalized modelling.

# Evaluation of the impact of different scaling approaches in the model based muscle forces estimation during locomotion in Parkinson's disease subjects

Marco Romanato<sup>1</sup>, Francesca Colpin<sup>1</sup>, Daniele Colpe<sup>2</sup>, Simi Sawacha<sup>1,3</sup>  
<sup>1</sup>Department of Information Engineering, University of Padova, Padova, Italy  
<sup>2</sup>Fresco Parkinson Center, Villa Margherita, S. Stefano, Vicenza, Italy  
<sup>3</sup>Department of Medicine, University of Padua, Padua, Italy  
 Email: [romanato@dei.unipd.it](mailto:romanato@dei.unipd.it)

## Summary

The aim of our work was to apply the most appropriate musculoskeletal scaling approach in order to characterize differences between healthy and Parkinson's disease (PD) subjects.

## Introduction

PD is a progressive pathological condition characterized by a dopamine deficiency. Gait alterations are a well-known hallmark of PD patients [1]. Recently, the authors detected further signs of motor impairments in PD's neural strategies, as the timing of the muscle activation peak during the gait cycle and a difference in its amplitude [2] when compared with healthy subjects. Electromyography (EMG) is not representative of the subject's strength and currently, no studies investigated the possibility to assess strength in terms of muscle forces as a biomarker of disease progression in PD subjects. A possible way forward is the use of musculoskeletal modeling which allows the non-invasive estimation of muscle forces.

## Methods

Five control subjects ((CS), age=57.8±5.6 years, BMI=27.3±3.9 kg/m<sup>2</sup>) and five PD subjects (age=62.8±11.4 years, BMI=27.1±2.9 kg/m<sup>2</sup>) were acquired with a 6-camera motion capture system (60Hz, BTS), synchronized with 2 force plates (960Hz, Bertec) and an 8-channels EMG system (1000Hz, BTS) that recorded bilaterally the activities of 4 muscles: Rectus Femoris, Biceps Femoris, Gastrocnemius Lateralis (GL) and Tibialis Anterior (TA). Data were processed in OpenSim and two different scaling approaches were considered: the standard linear scaling (LS) and the muscle optimizer (MO) scaling [3]. For the latter, two different sets of muscles were used during the process, one including all the muscles of the model (MO\_FULL), and one including muscles only spanning knee and ankle joints (MO\_MIN). Three different scaled models were obtained for each subject, then inverse kinematics, and static optimization were performed. RMSE between CS predicted and experimental EMGs was computed to assess the physiological

validity of the models. Muscle forces were compared via Wilcoxon Signed Rank test, as no evidence of normality assumption was verified.

## Results and Discussion

RMSE (Table 1) reported a comparable physiological behavior of the investigated models, suggesting no significant loss of information between the approaches. Muscle forces obtained for LS and MO\_MIN models denoted statistically significant differences in GL and TA (Figure 1).

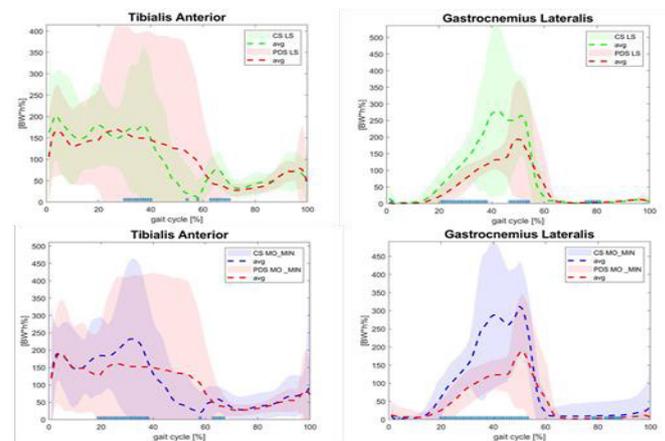

Figure 1: TA and GL muscle forces for CS and PD generated both for LS and MO\_MIN scaling approaches.

## Conclusions

The MO scaling approach resulted in an enhanced method to detect subject-specific modifications in the lower limb strength production in PD when compared to CS, thus no loss of physiological information was noticed. Further studies are needed to generalize these outcomes.

<sup>2</sup>High Performance Center (CAR), Sant Cugat del Valles, Spain

Email: apveloso@fmh.ulisboa.pt

### Summary

Most of the high-level sports movements are related to accelerations, or decelerations of the body, to produce direction changes. The aim of this work is to estimate muscle contributions to the knee bone-on-bone forces during a maximal forward braking and backward acceleration in elite athletes. Scaled generic musculoskeletal models, consisting of 12 segments, 23 degrees of freedom, and 92 musculotendon actuators were used in OpenSim. Anterior, compressive, and medial knee bone-on-bone forces occur during this task. The *vasti* are the main contributors to these forces along all three directions. The results of this work present a preventive approach to understand the injury mechanisms of knee injuries during deceleration tasks.

### Introduction

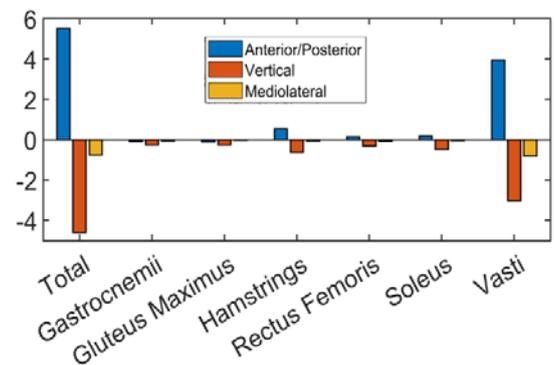

Improving joint stabilization during high-impact tasks plays a key factor to be accounted for in training programs that increase muscle coordination and strength. In addition to this, knowledge about how joint kinematics and muscle forces affect knee joint loading, whilst performing ballistic tasks remains scarce. The use of computational modeling allied with non-invasive experimental techniques to study injury mechanisms is an advantageous approach. To this end, the main purpose of this study is the identification of the main muscle contributors to the bone-on-bone forces exerted at the knee joint whilst performing a maximal forward braking and backward acceleration in elite athletes.

### Methods

Fourteen elite male team-sports injury-free athletes participated in this study (age:  $22 \pm 4$  years, height:  $185 \pm 4$  cm, weight:  $77 \pm 11$  kg). Kinematic and kinetic data were collected using 8 infrared cameras (Qualisys) working at a frequency of 300Hz and 2 force plates (Kistler). Muscle and joint contact forces were attained through OpenSim [1]. The musculoskeletal model was manually scaled to match each subject's anthropometry. A residual reduction algorithm (RRA) step was used to minimize errors related to kinematic inconsistencies and modelling assumptions. Muscle forces were estimated using a Static Optimization (SO) optimization technique. The forces obtained from SO and the adjusted kinematics from RRA were used for this analysis. Muscle contributions to the bone-on-bone forces were estimated based on [2].

### Results and Discussion

As expected from this task, the joint reaction forces at the knee are the highest along the A/P direction, being applied anteriorly on the tibia. These forces along the fore – aft direction recorded at the knee, are related to the fact that the muscles that exerted the most force in this task, *vasti*, are inserted in this joint. In addition to this, the hamstrings act as a minor contributor to the anterior bone-on-bone forces. Compressive forces along the vertical directions are applied at the knee joint. Once again, compressive force contributions by the *vasti* are also predominant. Slight contributions by the *soleus* are also of note. Along the mediolateral direction, at the knee joint, the medial bone – on – bone forces are key to the realization of the task, as they help maintaining the knee in a neutral position. Along this direction, the *vasti* are the main contributors.

**Figure 1:** Main muscle contributions to bone-on-bone forces at the knee joint, given in terms of body weight.

### Conclusions

The results from this work show that the main knee extensors are the primary producers of the knee bone-on-bone forces. Since the loadings at the knee joint and their contributions are interesting unknowns, their estimation is an important step to better understand the mechanisms behind an abrupt A/P deceleration task.

### Summary

This study presents a new numerical approach based on skin markers and fluoroscopy-based knee joint kinematics to estimate soft tissues stiffness of the thigh and of the shank segments during a squat movement.

### Introduction

Modelling the interface between the lower limb segments and a socket, orthosis or exoskeleton is of crucial importance for the design, modelling, control and the assessment of such devices. For that purpose, soft tissues stiffness is a key parameter. It has been estimated in static condition [3] and for given anatomical loading direction [2]. In dynamic conditions, the soft tissue stiffness is more generally studied to model the so-called *wobbling mass effect* [1]. In this context, this study aims to estimate translational and rotational soft tissues stiffness at the thigh and shank levels during a squat movement, a daily living dynamic activity, by extending the vibrational analysis method called smooth orthogonal decomposition (SOD), a method already developed for soft tissue artifact (STA) analysis in [1].

### Methods

Fluoroscopy-based implants and skin markers positions for 6 patients (5 males and 1 female,  $68 \pm 5$  years,  $88 \pm 12$ kg,  $1.73 \pm 0.04$ m) with knee prostheses have been recording at 25Hz and 100Hz, respectively. One trial per subject of a squat movement was analyzed [4]. Data was down sampled to 25Hz. The SOD method [1], was extended here in order to compute the rotational stiffnesses in the 3 Dofs of the anatomical coordinate system of the thigh or the shank.

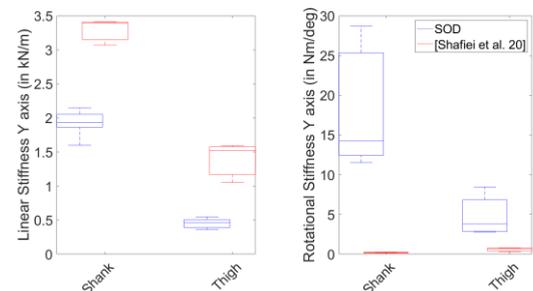

### Results and Discussion

In average, and for all subjects in the 3 anatomical directions, the translational and rotational stiffness coefficients were respectively equal to  $2.2 \pm 0.3$ kN/m (median and IQR) and  $17 \pm 6.5$ Nm/deg for the shank. The results for the thigh segment are much lower i.e.  $0.5 \pm 0.1$ kN/m and  $5.2 \pm 2.3$ Nm/deg. Figure 1 represents the stiffness coefficients along the longitudinal directions of the segments. The translational stiffness estimated by the SOD method are lower than the one computed experimentally with instrumented exoskeleton cuff [3] (see Figure 1). These differences could be due to the type of tissue involved by the STA that represents mainly the behavior of the skin while other methods may involve deeper tissues. Rotational stiffness coefficients computed in this study revealed to be

higher than from literature [3]. This may be due to different muscular contraction levels and external loadings (static condition vs. squat movement).

The main limit of the proposed methodology relies on the experimental setup (number and location of the skin markers) and on the retained imaging method (mono-plane fluoroscopy).

Nevertheless, the SOD method used in this study is a new numerical approach in soft tissues characterization during dynamic activities. The main benefit over traditional approach is to obtain task dependent stiffness coefficients. Investigating such approach paves new ways to deal efficiently with the increasing amount of fluoroscopic data for various activities and various devices (STA and socket or orthosis studies). Moreover, the results derived from the proposed stiffness estimation method could improve external devices conception, modelling and evaluation.

**Figure 1:** Translational and rotational stiffness coefficients along the longitudinal direction, with SOD method during squatting compared with literature report [3]

### Conclusions

This study extends the approach of Dumas et al. [1] by adding the computation of rotational soft tissues stiffness of both thigh and shank segments during squatting. When compared to the literature [3], the estimated stiffness coefficients were lower for the translational stiffness and higher for the rotational ones. This may be due to different tissue and/or different loadings involved during squatting. Nevertheless, this dynamic estimation of soft tissues stiffness seems to be promising in the context of human interface modelling with external devices.

## Summary

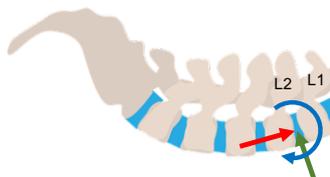

The quadratus lumborum (QL) is a deep muscle whose activity is difficult to record. A parametrized musculoskeletal model allowed to study its influence on the lumbar spine efforts for a prone back extension exercise. Activating more QL fascicles increased the normal and shear forces at each intervertebral lumbar level and modified the orientation of the disc internal fibers.

## Introduction

Musculoskeletal models allow to improve the knowledge of the human body. Using models gives the possibility to study the influence of one or several parameters for which there is few or no data. In this study, the parameter is the activation fraction of the quadratus lumborum (QL) muscle whose activity is difficult to assess via non-invasive measurements.

## Methods

On the basis of a fully articulated thoracolumbar spine and rib cage model published previously [1], a model of a 25-year-old man (height 175cm and mass 78 kg) was developed for a prone back extension exercise carried out in the Sorensen test posture [2]. The model included lumbar (LP), dorsal paravertebral (DP) muscles and the QL muscle [3]. A deterministic muscle distribution based on maximal isometric forces was used. The activated QL fraction can be modulated from 0 to 40%, reducing *de facto* the activation of both LP and DP muscles. The model can consequently be parametrized via the activated QL fraction.

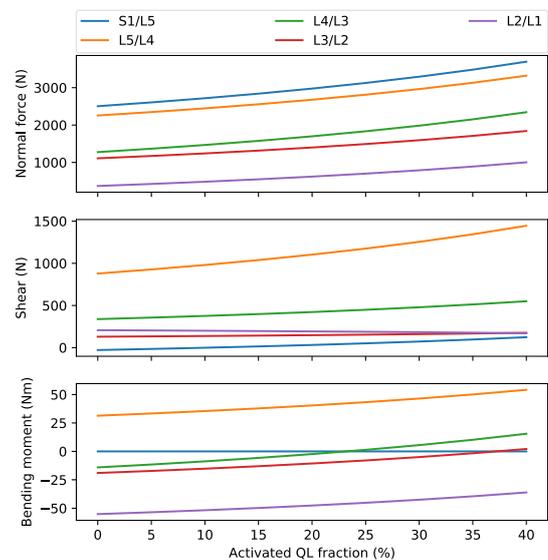

**Figure 1:** Intervertebral resultant efforts – normal force in red, shear in green and bending moment in blue – from L2 to L1 vertebral segment. Drawn arrows define positive values.

Efforts – forces and torques – (Figure 1) produced at each lumbar (Lx) intervertebral disc (IVD) levels were computed.

## Results and Discussion

For a given activated QL fraction, the normal force (Figure 2 top) at each IVD increases when coming closer to the pelvis. It is due to the greater number of muscles in the lower area of the lumbar spine, which induces a larger force resultant from those muscles. Shear (Figure 2 middle) does not show any logical sequence. It is found mainly at L5/L4 level. The bending moment reflects how internal fibers in each IVD are

oriented. For a QL fraction below 20% (Figure 2 bottom), the positive bending moment at L5/L4 level indicates that the posterior fibers of the IVD are in compression while the anterior fibers are in traction. For all the other levels, the negative bending moment induces the opposite trend. A possible explanation is that most of muscles involved in the model act at L5/L4 level which results in pulling L4 upwards. Above L5/L4 level, each segment might be seen as a cantilevered beam.

**Figure 2:** Efforts at each IVD in the lumbar spine.

When the activated QL fraction increases, normal and shear forces increase in most of the IVD levels reflecting the larger force resultant from the QL muscle, itself due to shorter lever arms of its fascicles. The bending moment decreases in cantilevered segments which results in less forces in IVD internal fibers. The positive bending moment at L5/L4 level is reinforced, involving greater forces in IVD fibers.

## Conclusions

This study showed the influence of the QL muscle on the lumbar spine efforts during a prone back extension exercise. Further work will focus on the possible experimental validation.

### Summary

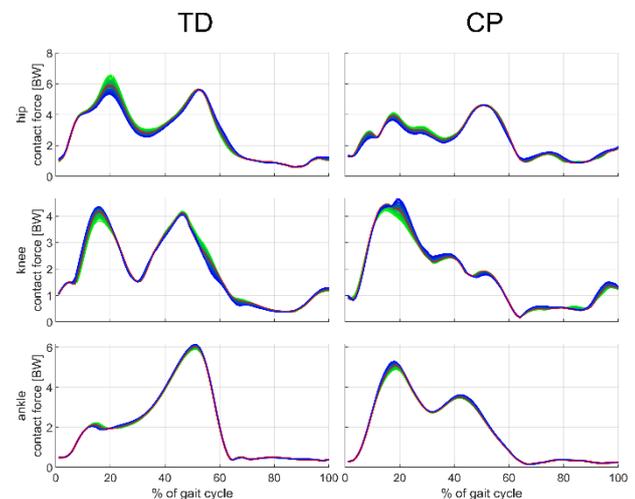

Musculoskeletal simulations are widely used in the research community. Marker-based scaling approaches include errors due to inaccuracies in marker placements. The aim of this study was to evaluate the influence of scaling errors due to a misplaced lateral epicondyle marker on simulation results in a systematic and comprehensive way. Magnetic resonance images from a child with cerebral palsy and a typically developing child were used to create a subject-specific reference model for each child. These reference models were modified to mimic scaling errors. Subsequently, musculoskeletal simulations with OpenSim were performed with all models. Joint kinematics, joint kinetics, muscle forces and joint contact forces were compared between the reference and altered models. Observed scaling errors influence simulation results at all joints due to the global optimization approach used in musculoskeletal simulations. Our findings can be used to estimate potential errors due to marker-based scaling approaches in previous and future studies.

### Introduction

Musculoskeletal simulations are widely used in the research community [1,2]. The locations of surface markers are mostly used to scale a generic model to the participant's anthropometry. Marker-based scaling approaches include errors due to inaccuracies in marker placements [3,4]. The aim of this study was to evaluate the influence of scaling errors due to a misplaced lateral epicondyle marker on simulation results in a systematic and comprehensive way.

### Methods

Motion capture data and magnetic resonance images from a child with cerebral palsy (CP) and a typically developing (TD) child were used to create a subject-specific reference model for each child. These reference models were modified to mimic scaling errors due to inaccurately placed lateral epicondyle markers, which are frequently used to scale the thigh and shank segments. The thigh length was altered in 1% steps from the original length and the shank length was accordingly adjusted to keep the total leg length constant. Thirty additional models were created, which included models with an altered thigh length of  $\pm 15\%$ . Subsequently, musculoskeletal simulations with OpenSim were performed with all models (Figure 1). Joint kinematics, joint kinetics, muscle forces and joint contact forces (JCF) were compared between the reference and altered models by analyzing the waveforms and computing the root-mean-square-error.

**Figure 1:** Comparison of joint contact forces of the TD (left column) and the CP child (right column) including all modified models. The red line shows the mean waveforms of the reference model. Green lines represent the models with shorter femur length while blue lines show the models with increased femur length.

### Results and Discussion

The investigated scaling error influenced joint kinematics and joint kinetics by up to  $9.4^\circ$  (hip flexion angle) and  $0.15 \text{ Nm/kg}$  (knee flexion moment), respectively. Maximum muscle and JCF differences of 46% (medial gastrocnemius) and 72% (hip JCF) bodyweight, respectively, were observed between the reference and altered models. Scaling errors mainly changed the magnitude but not the shape of most analyzed parameters. The influence of scaling errors on simulation results were similar in both participants.

### Conclusions

Scaling errors due to misplaced lateral epicondyle markers influence simulation results at all joints due to the global optimization approach used in musculoskeletal simulations. Our findings can be used to estimate potential errors due to marker-based scaling approaches in previous and future studies.

## Predictive simulations of step initiation to study origins of age-related changes in weight shifting

Wouter Muijres<sup>1</sup>, Maarten Afschrift<sup>1,2</sup>, Friedl De Groot<sup>1</sup>

<sup>1</sup>Human Movement Biomechanics Research Group, KU Leuven, Leuven, Belgium

<sup>2</sup>Robotics, Automation and Mechatronics, KU Leuven, Leuven, Belgium

Email: wouter.muijres@kuleuven.be

### Summary

Incorrect body weight shifts are a common cause of falls in elderly. Here, we used predictive simulations of stepping to study the effect of muscle weakness on weight shifting strategies. The backward center of pressure (COP) excursion when preparing to step decreases with age. In contrast, the simulated backward COP excursion increased when weakening the model. Hence, our simulations suggest that weakness is not the main cause of age-related changes in weight shifting.

### Introduction

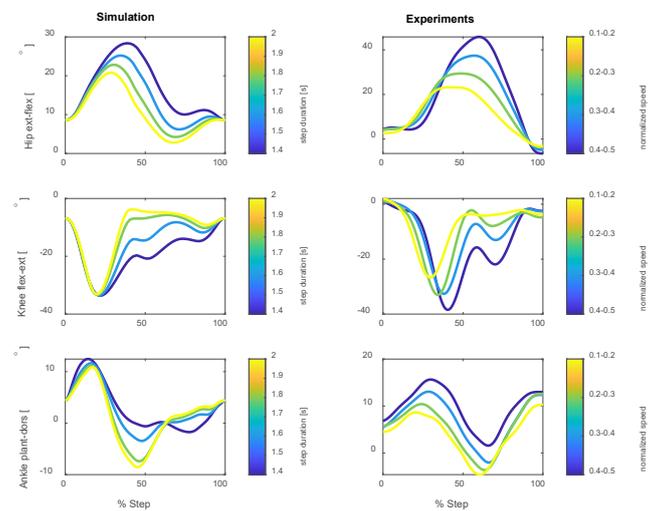

One out of three older adults fall each year. A common cause for falling in older individuals is incorrect body weight shifts. Step initiation is a suitable task to study weight shifting since successful initiation of a step prerequisites a series of well described weight shifts, such as the backward movement of the COP when preparing to step. With age, weight shifting strategies change. Older adults initiate steps with smaller ankle torques and decrease backward COP excursion [1]. The relative contribution of different age-related changes in the neuro-musculoskeletal system, such as muscle weakness and decreased sensory acuity, to altered weight shifting remains unclear. It is hard to study these relative contributions experimentally since aging affects different factors simultaneously. However, in computer simulations, model parameters can be altered to mimic age-related changes and their isolated influence on movement can be evaluated. Here we apply a previously developed gait simulation framework [2] to step initiation. We demonstrate that (1) simulated stepping captures main features of experimentally observed stepping and (2) how the framework can be used to study the effect of muscle weakness, which is common in aging.

### Methods

To simulate step initiation, we used a 2D OpenSim model with 10 degrees of freedom. Ankles, knees, and hips were actuated by 18 Hill-type muscles. The metatarsal and back joints were torque-actuated. Foot-ground contact was modeled by 3 Hunt-Crossley contact spheres per foot. Stepping was simulated by solving for muscle and torque controls that optimized performance [see 2] while imposing the initial and final states and step duration. At the initial and final times, the model was in a static upright position and the final state was translated 0.4 m forward with respect to the initial state. We evaluated the effect of (1) speed by varying step duration and (2) muscle weakness by reducing the maximal isometric force of all muscles by 30%.

### Results and Discussion

We compared simulated kinematics for different step durations (Figure 1) with experimental data on gait initiation at different speeds as experimental data on stepping at different speeds was not available [3]. Simulated and experimental hip, knee, and ankle angle trajectories were qualitatively similar. Both in experiments and simulations, hip and knee angle amplitude increased with increasing speed. In agreement with observations, weakening the model resulted in reduced peak ankle torques. In contrast with observations, simulated backward COP excursion increased. Hence, our simulations suggest that age-related changes in weight shifting strategy are not due to weakness. We will extend our model to test whether increases in sensory noise or changes in task-level goals, e.g. prioritizing stability over effort, explains age-related changes in weight shifting.

**Figure 1:** Simulated and experimental (reproduced from [3]) swing leg joint angles of the hip, knee, and ankle. In experiments, speed was normalized by  $\sqrt{\text{body height } x \text{ g}}$ .

### Conclusions

Our previously developed framework to simulate gait also captures important features of other tasks such as gait initiation, and is a potentially powerful tool to explore causal relationships between age-related changes in the neuro-musculoskeletal system and weight shifting strategies.

**Summary**

We estimated muscle excitations based on motion capture data of walking at seven speeds using three musculoskeletal models that differed mainly in parameters that define isometric muscle strength and passive muscle forces. We compared estimated muscle excitations to recorded EMG signals for eleven muscles. The *Lai-Arnold* model that combined high muscle strength with low passive muscle forces best captured changes in muscle activity with speed. None of the models estimated EMG patterns in hamstrings, rectus femoris or gluteus muscles accurately.

**Introduction**

Several musculoskeletal models have been refined to study human locomotion in recent years [1]-[4]. Hamner et al. modified the default OpenSim model [1] to simulate running [2]. Rajagopal et al. modified muscle parameters based on MRI data from healthy individuals and elderly cadavers [3] and Lai et al. further improved this model to compensate for excessive passive forces at knee and hip joints as observed in cycling [4]. These modifications might yield different muscle excitation predictions using the same experimental motion data and muscle redundancy solver [5], yet this hypothesis has not been tested at various walking speeds. This study aims to evaluate which model most accurately predicts muscle excitations at different walking speeds.

**Methods**

Marker trajectories (icon 16), ground reaction forces (AMTI Optima), and electromyography (EMG) were collected from 10 able-bodied subjects walking at 55%, 70%, 85%, 100%, 115%, 130% □ 145% of their preferred walking speed. EMG signals were collected from 11 lower limb muscles using bipolar surface electrodes (Myon aktos). These muscles were: biceps femoris (BF), semitendinosus (ST), vastus lateralis (VL) □ medialis (VM), rectus femoris (RF), gluteus maximus (GMA) □ medialis (GMED), tibialis anterior (TA), gastrocnemius lateralis (GL) □ medialis (GM) and soleus (SO). EMG signals were normalized to each subject's maximum activations during a high vertical jump.

Recorded data were processed (inverse kinematics and inverse dynamics) using OpenSim 4.1 based on three different musculoskeletal models: *Hamner* [2], *Rajagopal* [3], and *Lai-Arnold* [4], and scaled to each subject's dimensions. Muscle redundancy was solved by minimizing squared muscle activations using direct collocation [5]. Predicted and recorded muscle excitations were compared qualitatively.

**Results and Discussion**

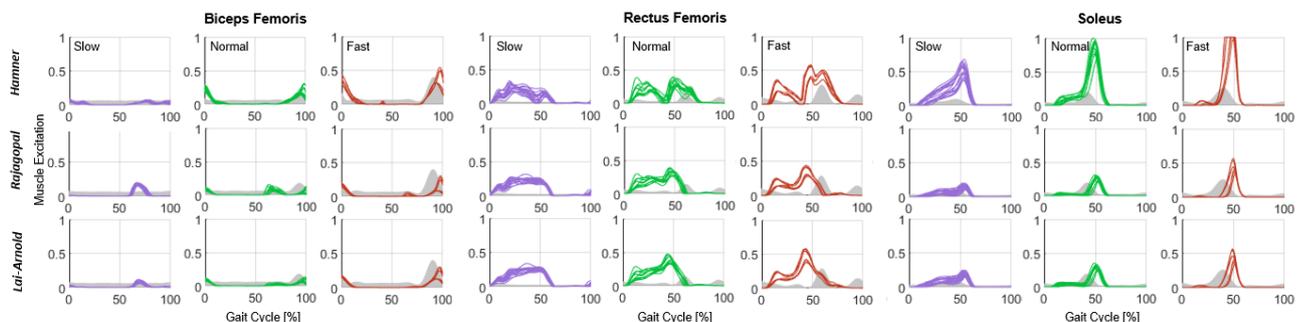

All models captured main trends of muscle excitation time series in VA, VL, GM, GL, SO, and TA as observed in EMGs in that their magnitudes increased with walking speed. They, however, predicted delayed SO excitation (Figure 1) and did not reliably predict RF excitation at midstance. *Rajagopal* and *Lai-Arnold* tended to underestimate BF and ST excitation in late swing. *Hamner* tends to overestimate SO, GMA □ and GMED in stance □ its plantarflexor muscle parameters, specifically maximum isometric force, seem less suitable for simulations of high walking speeds than the other models. Limitations in surface EMG recording and data processing may have contributed to the observable discrepancies in measured and predicted muscle excitation.

**Conclusions**

Estimated changes in predicted muscle excitations with increasing walking speed in VA, VL, GM, GL, SO, and TA are similar between models. Predicted BF, ST, RF, GMA □, and GMED vary among the different models and do not agree with measured EMG as closely, even with the modifications of *Rajagopal* and *Lai-Arnold*. Among the models, *Lai-Arnold* better predicts muscle excitations for walking than *Rajagopal* and seems more suitable for higher speeds than *Hamner*.

**Summary**

Soft tissue balancing is one of the most important factors for a successful knee arthroplasty however, there is no consensus for the most appropriate surgical technique. This *in-vitro* study aimed to assess to what extent a novel Patella-in-Place tensioner balancing (PIP) technique restores the biomechanical behavior of the native knee. Our findings showed that the PIP technique seemed to restore knee joint kinematics and collateral ligament strains better in passive than in dynamic conditions, i.e. squatting. Care must be taken when translating intraoperative assessments of knee balance during passive flexion to loaded conditions.

**Introduction**

Although soft tissue balancing is vital for successful total knee arthroplasty (TKA), there is no consensus for the most appropriate technique towards an optimally balanced TKA and the associated restoration of native joint function [1]. We aimed to use a cadaveric knee simulator to assess the biomechanical impact of a novel Patella-in-Place tensioner balancing (PIP) technique, which aims to restore native collateral ligament behavior without any ligament release.

**Methods**

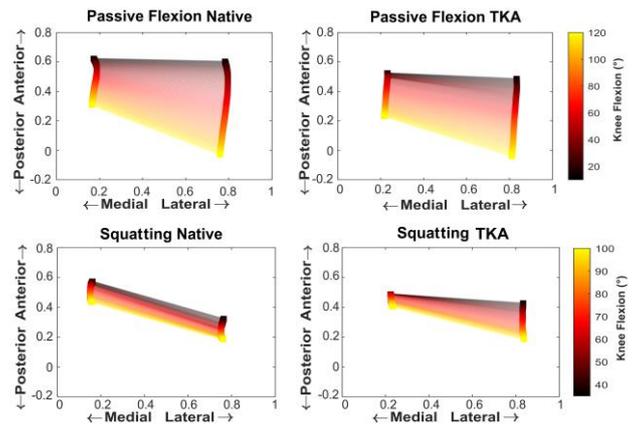

Eight fresh-frozen legs were dissected and the soft tissue around the knee was removed, while preserving the joint capsule, ligaments and tendons. The native specimens were mounted on a validated physiological knee simulator [2] and subjected to passive flexion (10°-120°) and squatting motions (35°-100°) the latter with actively controlled quadriceps tendons. Specimens then underwent a single-radius cruciate-retaining TKA (Stryker Triathlon, MI, USA) using the PIP surgical technique, followed by the same tests. Extensometers (MTS, Minnesota, USA) were affixed to the superficial collateral ligaments to measure strain, while a motion capture system (Icon, Oxford, UK) was used to obtain tibiofemoral kinematics. Tibiofemoral kinematics and collateral ligament strains were compared between pre- and post-operative conditions using a linear mixed model (p<0.05).

**Results and Discussion**

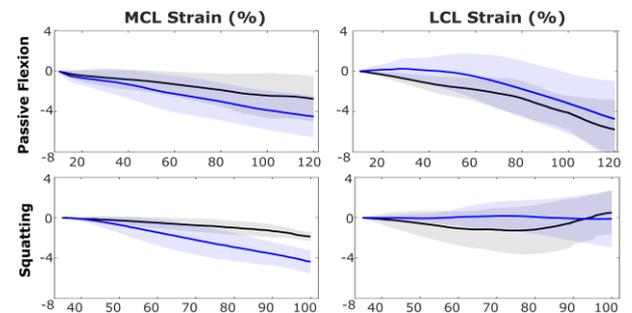

As compared to the native condition, post-operative tibiofemoral kinematics revealed similar medial and lateral translations during passive flexion (Fig.1). Moreover, strain behaviors for medial and lateral collateral ligaments were statistically different only in deep flexion and mid-flexion, respectively (Fig.2). For squatting, the post-operative condition exhibited a more pronounced medial pivot configuration. Conversely, the post-operative medial

collateral ligament strain significantly differed from the native condition from mid-flexion onwards, while the lateral collateral ligament strain differed in mid-flexion.

Increased post-operative MCL strain (Fig.2) could be attributed to greater tibial internal rotation resulting in increased lateral translations following TKA during squatting.

**Figure 1:** Mean femoral rollback patterns (normalized to tibial plateau geometry) across eight specimens in the native condition (left) and following TKA (right) throughout the range of flexion during passive flexion (top) and squatting (bottom).

**Figure 2:** Collateral ligament strains (mean±SD across eight specimens) in the native (black) and post-operative (blue) conditions during passive flexion (top) and squatting (bottom).

**Conclusions**

The PIP technique seemed to restore joint kinematics and strains better in passive condition as compared to squatting. Care must be taken when translating intraoperative assessments of knee balance during passive flexion to loaded conditions.

### Summary

Severe joint injuries frequently involve cartilage defects which propagate after mechanical loading. The propagation of these tears may contribute to the development of post-traumatic osteoarthritis (PTOA). Predictive tools would provide insights into crack growth in injured tissue. Here, we developed a numerical model to estimate crack propagation under dynamic loading. Computational predictions were compared to experiments reported in the literature. Our numerical estimations corresponded well with the experimental results suggesting that our approach may help in developing better tools for predicting crack propagation in soft tissue after injury.

### Introduction

Traumatic joint injuries often involve cartilage tears which contribute to the development of PTOA. This degenerative disease includes a decrease in the mechanical properties, volume, and thickness of the tissue. After the injury, the size of the cartilage defects increases due to the limited tissue healing capacity. Previous experimental investigations have studied crack growth and fracture toughness to understand their role during cartilage degeneration [1]. However, there are no numerical predictive models on crack growth in cartilage under dynamic loading. Thus, we aimed to develop a model capable of simulating crack propagation under tensile cyclic loading. Numerical estimations were calibrated using previously reported experimental crack propagation results [1].

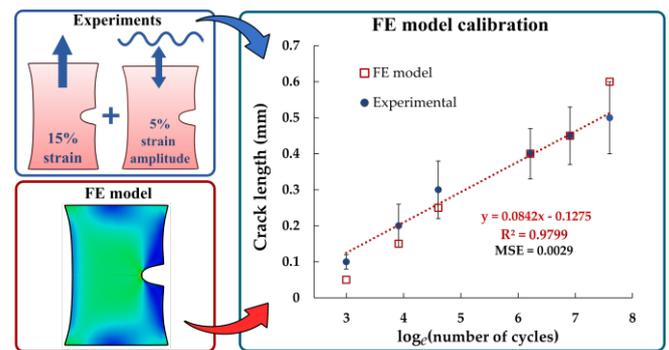

### Methods

**Numerical model:** A 2-D FE model was constructed in Abaqus (v2018) to predict crack growth. The specimen dimensions and loading protocol (Figure 1) were replicated from literature [1]. The cartilage specimen with dimensions of 10 x 10 mm, including a notch of 2.26 mm in the middle, was meshed with 7506 elements (CPE4P). **Cohesive damage model:** A cohesive element set (COH2D4) was used along a line ahead of the notch to represent the experimentally observed crack propagation direction. A traction-separation constitutive response was assumed to the cohesive element set. Damage initiation was modeled using a maximum nominal stress criterion ( $\sigma_f$ ). Moreover, a damage evolution law based on the fracture energy ( $G_f$ ) with a linear softening was adopted. **Boundary and loading conditions:** The loading protocol was simulated based on the experiments [1]. The bottom of the specimen was fixed, and a uniform tensile displacement was applied to the top nodes. Initially, 15% strain was applied to the model in tension and held for 5s. This was followed by a 5% sinusoidal loading amplitude (1

Hz) imposed for 2,000 cycles. **Model calibration:** Articular cartilage was modeled as a poro-hyper-viscoelastic material. Poro-hyperelastic properties were adopted from the literature [2,3], but the damage initiation stress  $\sigma_f$ , fracture energy  $G_f$ , and viscoelastic Prony-parameters were calibrated by fitting the simulated progression (crack length) to the experimental data [1] using an iterative optimization approach (Matlab).

### Results and Discussion

Our numerical predictions corresponded well with the reported experimental crack growth under tensile dynamic loading showing greater crack length with an increasing number of loading cycles (MSE=0.0029). The fitted values for the  $\sigma_f$  (4.72 MPa) and  $G_f$  (1.1 N/mm) were within the range reported in previous studies [4,5]. However, more experiments and different loading frequencies are required to fully validate our computational approach.

**Figure 1:** A FE model was developed to estimate crack propagation under dynamic loading. The sample dimensions and loading conditions were adopted from a previous study [1]. Our model was able to reproduce the crack growth observed in the experiments.

### Conclusions

Our numerical predictions corresponded well with the experimental results. This cohesive crack model provides a novel platform for predicting tear propagation in injured tissue.

### Summary

In two experiments separated by 2-7 days, we compared sCOMP concentrations before and after the same 30-min walking stress test. sCOMP concentrations showed good to excellent repeatability between the two measurements.

### Introduction

Articular cartilage blood marker concentrations and load-induced marker kinetics were proposed to serve as surrogate parameter for articular cartilage metabolism and its response to load [1]. One of these markers is serum cartilage oligomeric matrix protein (sCOMP), a cartilage constituent that is involved in collagen fibril organization [2] and serum concentrations may represent cartilage turnover or degeneration [3]. The purpose of this study was to determine the repeatability of load-induced changes of sCOMP concentration after 30-minutes treadmill walking.

### Methods

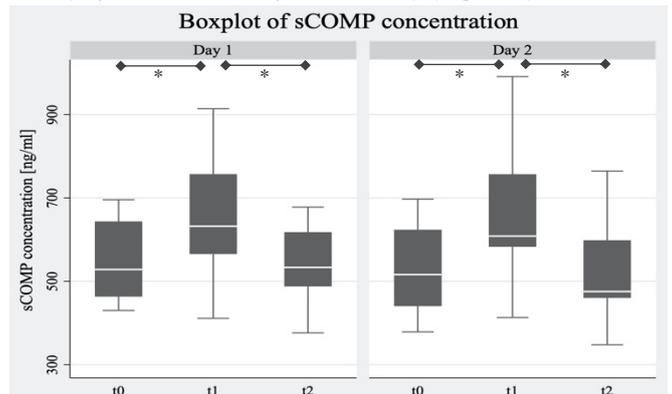

Ten healthy subjects (5 male, 5 female; median [interquartile range], age 27 [26–29] years; body mass: 62.5 [58.5–79.7] kg; height: 1.70 [1.63–1.76] m; body mass index: 22.2 [21.8–23.5] kg/m<sup>2</sup>) completed the same walking stress test in two measurements within 6 [4-7] days. On each day, venous blood samples were collected after 60-min of rest before (t<sub>0</sub>), immediately after (t<sub>1</sub>) and 30-min after (t<sub>2</sub>) a 30-min treadmill walking stress. Samples were aliquoted and frozen to -80°C until analysis. sCOMP concentrations were assessed using a commercial enzyme-linked immunosorbent assay (BioVendor, Modrice, CZ). Steps were counted with a hip-worn accelerometer (GTX3+ ActiGraph, Pensacola, USA). Because of the small sample size, non-parametric tests (sign tests) were used to detect significant differences in the number of steps during the test and absolute sCOMP concentrations between test days and between time points of the stress test. We computed intraclass correlation coefficients (ICCs) to determine the repeatability of sCOMP concentrations between test days across all and for each time point.

### Results and Discussion

A priori self-selected walking speed was 1.38 [1.31-1.39] m/s. The number of steps taken during the 30-min walk did not differ between day 1 and day 2 (day 1: 3336 [3261-3465] steps; day 2: 3328 [3298-3516] steps; P=0.754).

sCOMP concentrations at t<sub>0</sub>, t<sub>1</sub> and t<sub>2</sub> were 528.4 [463.3-643.5], 632.2 [565.6-757.1] and 533.4 [487.8-617.7] ng/ml on day 1 and 516.2 [440.5-623.7], 608.3 [582.8-757.0] and 475.4

[460.3-598.2] ng/ml on day 2. Concentrations did not differ between measurements (t<sub>0</sub>: P=0.344; t<sub>1</sub>: P=0.754; t<sub>2</sub>: P=0.344). The ICC for sCOMP across all time points was 0.869. The ICCs for each time point were 0.706, 0.864, and 0.910 for t<sub>0</sub>, t<sub>1</sub> and t<sub>2</sub>, respectively. sCOMP increased from t<sub>0</sub> to t<sub>1</sub> (day 1: P=0.022; day 2: P=0.002) and decreased from t<sub>1</sub> to t<sub>2</sub> (day 1: P=0.022; day 2: P=0.002) (Figure 1).

**Figure 1:** Boxplot of sCOMP concentration at timepoints t<sub>0</sub>, t<sub>1</sub>, and t<sub>2</sub> for the measurements on day 1 and day 2 (n=10). Significant differences are indicated as \* p<0.05.

### Conclusions

Serum concentrations of sCOMP appear to be consistent between days. Moreover, the overall load-induced increase of sCOMP after a walking stress test followed by a decrease is repeatable between days. While in most subjects the concentration kinetics in the sCOMP mechanoreponse appears to be remarkably consistent, some variability between measurements was observed in a few subjects. Because the two measurements were separated by only 7 days or less, physiological or metabolic variations are unlikely to cause such differences. The good to excellent day to day repeatability in load-induced blood marker kinetics in healthy subjects further support the feasibility of a well-controlled walking stress test to study the effects of biological variations and interventions on articular cartilage marker kinetics in response to ambulatory load.

### Summary

We have quantified the articular surface strain of human cadaveric supraspinatus tendon for varying simulated abduction angles and infraspinatus load using a custom positioning system mounted on an Instron load frame and opensource digital image correlation analysis (NCCorr).

### Introduction

Articular-sided partial rotator cuff tears are common and may be symptomatic or asymptomatic. [1] Classically, Nakajima et al. reported that the tendon's articular side is more vulnerable to tensile load than the bursal side, [2] which may be related to the random orientation of collagen fibers in this region. However, there is little evidence to determine which articular-sided tears are stable and which may progress. It has been shown in cadaveric studies that surface tendon strain is associated with tear progression and that the supraspinatus and infraspinatus tendons interact mechanically. [3] In this study, a single infraspinatus load was applied and the glenohumeral abduction angle was kept constant. Therefore, we aimed to assess 1) the effect of infraspinatus load and 2) glenohumeral abduction angle on the articular surface strain of the supraspinatus using a custom positioning system mounted on a material testing system and digital image correlation analysis.

### Methods

#### Specimen Preparation and Fixation

Two fresh-frozen healthy left cadaveric shoulders (one male, one female – mean age 57.5) were dissected of all tissue, leaving the supraspinatus and infraspinatus tendon and muscle units intact. No attempt was made to separate the interface between the tendons. The humeral head was resected to allow perpendicular line-of-sight to the tendon's articular surface at low abduction angles.

The specimens were potted in two-part epoxy (Smooth-Cast 300q and PMG Smooth-on Inc., Macungie, PA) and fixed in a custom positioning system mounted on an Instron load frame (8511, Norwood, MA). This system allows for changing the angle of the humerus relative to the loading axis of the Instron to simulate altered abduction angle. The articular surface of the supraspinatus was sprayed with hematoxylin stain to speckle the surface for image analysis. The supraspinatus was rigidly clamped to the Instron loading axis, and the infraspinatus was loaded along its physiological line of action via Krackow stitch and pulley system.

#### Data Acquisition

The supraspinatus was preloaded according to a previous study, namely 10 cycles from 10-50 N at 0.125mm/s. [3] It were then loaded to 200N for three cycles at 0.333m/s. The infraspinatus was statically loaded to 5, 10, 15, 20, and 25lbs,

while the humerus was oriented to simulate 90° of glenohumeral abduction. Then, the infraspinatus was loaded to 20lbs while the humerus was rotated to simulate 90°, 80°, 70°, and 60°. During loading, a CMOS microscope camera (PL-A662, Pixelink) was positioned to capture images of the tendon's articular surface at 2Hz.

#### Data Analysis

The articular surface strain on the supraspinatus tendon at 200N was estimated using an opensource digital image correlation package (NCCorr). [4] This analysis tracks the speckled surface between images to estimate the surface deformation, then calculates the strain associated with that deformation. The average supraspinatus surface strain at 200N for three cycles was calculated for each condition – abduction angle and infraspinatus load. One-way repeated measures ANOVA tests were conducted to compare the effect of abduction angle or infraspinatus load on articular supraspinatus surface strain.

### Results and Discussion

With this sample size, altering infraspinatus load or increasing glenohumeral abduction angle between 60° and 90° had no significant effect on the articular surface strain ( $P > 0.45$  and  $0.35$ , respectively).

#### Articular Supraspinatus Tendon Surface Strain

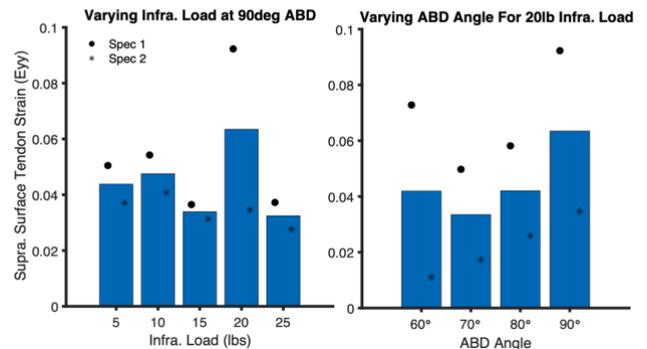

Figure 1: Articular Supraspinatus Tendon Surface Strain.

### Conclusions

The articular surface strain may not be affected by abduction angle or infraspinatus load, but additional specimens will help to elucidate this relationship.

### Summary

We investigated the effect of below-knee prosthesis alignment on metabolic cost in simulation. Metabolic cost was reduced when the prosthesis was abducted or externally rotated, though not significantly. Further research should investigate how joint reaction forces are affected by prosthesis alignment.

### Introduction

Metabolic energy expenditure and joint reaction forces are important gait variables when evaluating a prosthesis. Many studies have evaluated their relation to prosthesis stiffness (e.g. [1]), but little research has investigated how these variables are affected by prosthesis alignment. Prostheses fit depends on the experience of the prosthetist [2]. When a prosthesis is misaligned, the loading of the legs changes [2], which likely affects metabolic cost and joint loading.

Previous work has shown that a sagittal plane alignment change of a below-knee prosthesis increases metabolic cost [3], but no such study investigated transverse and frontal plane alignments changes. A predictive simulation study could provide insight into metabolic cost and joint loading without requiring a costly and time-consuming experiment. Therefore, we compared predictive gait simulations with different below-knee prosthesis alignments to investigate how an alignment change affects joint loading and metabolic cost.

### Methods

Predictive simulations were generated using the approach described in [4]. The below-knee prosthesis was modeled as a rotational ankle spring with a stiffness of 600 Nm/rad and a damping ratio of 15 Nms/rad [5]. The reference alignment was the original model alignment. The prosthesis alignment was then changed by introducing 5 and 10 degree offsets between the femur and the prosthesis in flexion, extension, abduction, adduction, and internal and external rotation.

Trajectory optimization problems were solved to simulate gait with all prosthesis alignments. Muscle stimulations were found to create a periodic gait trajectory while minimizing muscular effort and tracking normal gait data [6]. 50 virtual participants were drawn with a random mass, body mass index, isometric muscle force, optimal contractile element

length, and maximum shortening velocity. Tendon slack length was adjusted to not change the total muscle length.

### Results and Discussion

5 virtual participants were discarded since an unrealistic local optimum was found for at least one alignment. An ANOVA test found statistically significant differences ( $p < 0.0001$ ) in metabolic cost, calculated using Umberger's model [7], between alignments (table 1). A multiple comparisons test showed that only the 10-degree flexion alignment was significantly different from the reference. Similar to [3], metabolic cost increased with a sagittal alignment change. Metabolic cost was reduced 1% with a 10-degree abduction or external rotation alignment. Even such a small difference might be beneficial to persons with a transtibial amputation.

We also found that alignment changed joint moments and muscle activations. Therefore, joint reaction forces are likely altered as well. These changes were small for the external rotation, indicating that the energy expenditure reduction requires only small loading changes. Further analysis should identify any favorable changes in joint loading.

### Conclusions

We conclude that metabolic cost is not significantly altered by prosthesis alignment, though small reductions might be achieved. Kinetic results suggest that joint reaction forces are altered. Further analysis of joint reaction forces is required to completely understand the effect of prosthesis alignment.

## Summary

The selection of prosthetic componentry and their inherent mechanical function is critical for mobility in those with limb loss. Individuals with transfemoral amputation use both knee and ankle-foot components for mobility. The current study suggests that using a microprocessor-controlled knee with a hydraulically-articulating ankle-foot improves mobility, when compared to less functionally advanced components.

## Introduction

Individuals with unilateral transfemoral (UTF) amputation make use of both knee and ankle components for locomotion. Hydraulically-articulating ankle-foot components (HAD) have been shown to reduce trip risk [1] and increase mobility [2], whereas microprocessor-controlled knee (MPK) components reduce fall incidence [3]. Overcoming mobility and safety issues through prosthetic prescription can result in economic benefits to healthcare systems [4]. However, the benefits of combining HAD and MPK are not clear. Therefore, the aim was to investigate the effects of ankle-foot and knee component combinations on minimum toe clearance, gait stability and inverted pendulum model adherence in UTFs during level walking.

## Methods

Nine people with unilateral transfemoral amputation ( $52.8 \pm 9.7$  years,  $1.8 \pm 0.06$  m,  $83.3 \pm 13.0$  kg) walked at a self-selected speed along a 13m walkway in four prosthetic combinations using an MPK or non-MPK (NMPK) knee component, with either a HAD or rigid (RIG) ankle-foot component (all components manufactured by Bionica, Basinstoke, UK). The order of prosthetic combinations was randomised across participants. Reflective markers were attached to the whole body and kinematics were recorded using a 13-camera motion capture system (Qualisys A1, Gothenburg, SE). Gait stability, and safety were represented by the margins of stability and minimum toe clearance, respectively.

## Results and Discussion

Walking speed was highest in the MPKHAD combination, followed by the MPKRIG, NMPKHAD and the NMPKRIG combinations ( $F(3,24) = 4.50$ ,  $p < 0.01$ ,  $\eta_p^2 = 0.36$ ). Gait stability was higher in the intact vs. prosthetic limb,

particularly in MPK trials. Minimum toe clearance was higher in the prosthetic limb, particularly when using an NMPK.

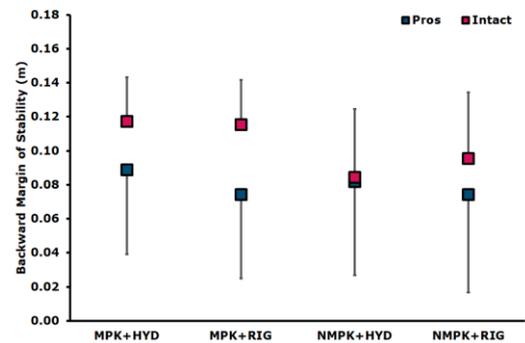

Figure 1. Backward Margin of Stability for all four prosthetic combinations and both the prosthetic and intact limbs.

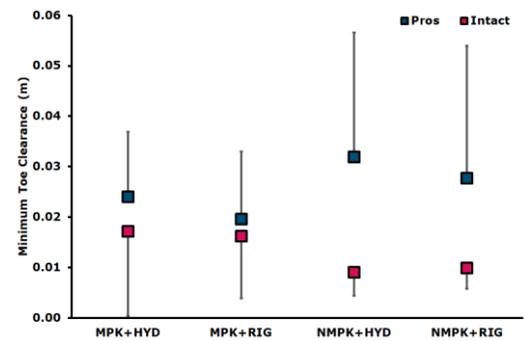

Figure 2. Minimum toe clearance for all four prosthetic combinations and both the prosthetic and intact limbs.

## Conclusions

Using a microprocessor-controlled knee combined with a hydraulically-articulating ankle-foot results in mobility benefits, when compared to non-microprocessor-controlled knee and rigid ankle-foot components.

### Summary

A major complication in total hip arthroplasty is cup loosening that may occur due to insufficient primary stability. The role of the cup design and the impaction process was analyzed within this study. Acetabular cups of different thickness were impacted in human acetabula. Cup deformation, cup seating and the lever out moment were evaluated. Thin-walled cups expressed higher primary stability. Excessive number of strikes may enhance the risk of cup loosening due to a release of cup deformation.

### Introduction

Insufficient primary stability of acetabular components is a complication resulting in early cup loosening. Available cup designs vary in thickness, which plays a role for the implantation process and primary stability. This study investigated the effect of cup design on the implantation process and the resulting primary stability.

### Methods

Two different cup designs (ca. 3 mm and 4 mm thickness, n=10 each, DePuy Synthes) were implanted in ten excised human pelvises (69 ± 3 years). Impaction was performed with constant energy (3.5 J, Kincise, DePuy Synthes) until no further cup seating was observed by a 3D digital image correlation system (Aramis 3D, GOM). Cup deformation was determined using strain gauges at the inner surface. Contact between bone and implant was analyzed with conducted laser scans. The lever out moment was used as a measure for primary stability.

### Results and Discussion

Thin-walled cups displayed higher strains ( $p = 0.006$ ) and a higher lever out resistance compared to thick-walled cups ( $p < 0.001$ ; Figure 1).

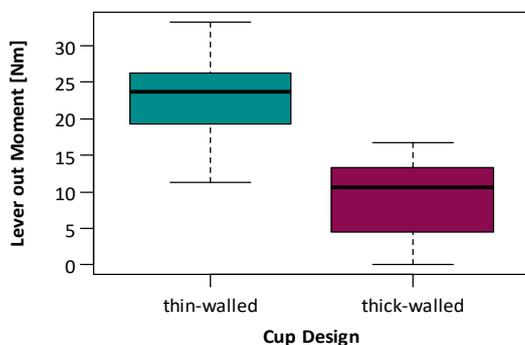

Figure 1: Higher lever-out moments for thin-walled cups.

Higher cup deformation, as well as low number of strikes, were associated with an increase in primary stability ( $p = 0.039$ ,  $R^2 = 0.24$ ). An increasing number of strikes resulted in strain release during the impaction progress ( $p = 0.016$ ,  $R^2 = 0.39$ ; Figure 2). The seating curves revealed a correlation between a high number of strikes and small seating steps at the end of the impaction ( $p = 0.002$ ,  $R^2 = 0.72$ ).

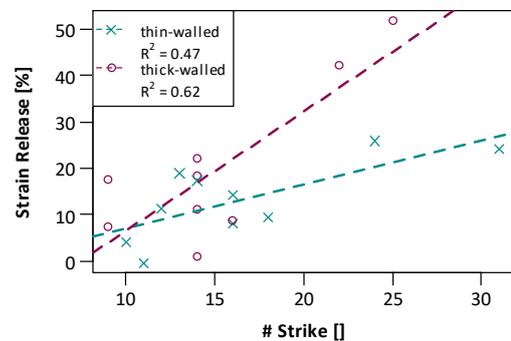

Figure 2: The strain release during cup impaction increased for high number of strikes.

Sufficient cup seating without over-impaction showed to be critical for initial cup fixation. Over-impaction is associated with bone damage and a negative influence on primary stability. Sufficient seating promotes cup deformation, as well as it restricts over-impaction due to further cup seating. For thin-walled cups, sufficient seating can be achieved with lower energy input, reducing the risk of bone damage.

### Conclusions

Thin-walled cups facilitate the prevention of impaction errors, which might promote early cup migration. Sufficient cup seating with low impaction energies reduces the risk of over-impaction and bone damage. Additional strikes should be avoided as soon as no further seating is observed. Excessive cup deformations have to be prevented since they can cause incomplete liner seating or excessive liner deformation, which might disturb the bearing tribology.

### Summary

Complications such as implant loosening and periprosthetic fractures (PPF) are often related to the surgical process in total hip arthroplasty (THA). This study investigates the variability within the surgical process between highly experienced surgeons. Variations were observed regarding stem positioning, sizing, press-fit and contact area. These even exist between experienced surgeons and may affect the PPF risk influenced by positioning and sizing.

### Introduction

Implant loosening and PPF are major complications in uncemented THA. Complications decrease with increasing experience and surgical volume [1]. Specific surgical parameters, indicative for these complications, have yet to be identified. The goal was to determine the extent of variability between highly experienced surgeons. Selected parameters were chosen (implant size, position, densification, press-fit and contact area) which bear the potential to determine differences in PPF risk.

### Methods

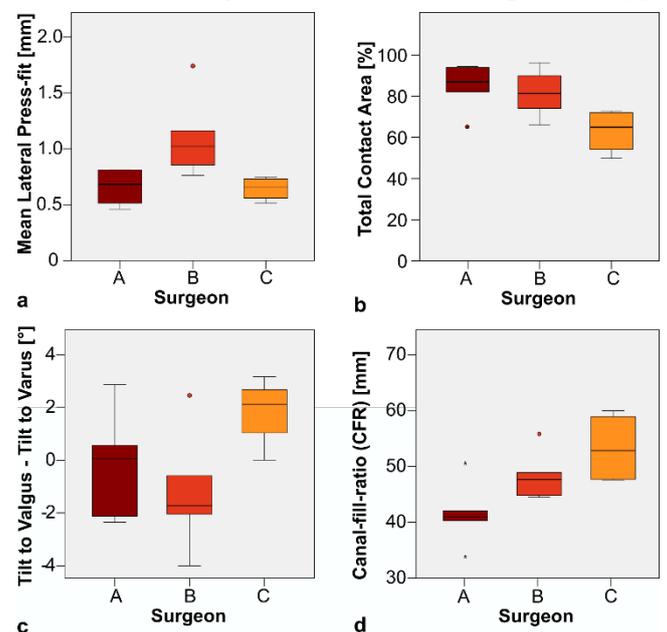

Primary hip stems (Corail, Depuy Synthes) were implanted in sixteen cadaveric femora ( $67 \pm 8$  years) by three experienced surgeons (surgeon A: n=6; surgeon B: n=6; surgeon C: n=4). All femora were  $\mu$ CT scanned and the BMD determined at three different time instances: native, with the reamed cavity, and after stem insertion. Stem tilt and canal-fill-ratio (CFR) were analyzed using the initial and implantation scans. Proximal densification at the bone-implant-interface was determined by computing the change in BMD between initial and cavity scans [2]. Press-fit and contact area were analyzed using a surface-to-surface comparison with the superimposed cavity and implantation scans.

### Results and Discussion

High variability between surgeons was observed regarding press-fit ( $p < 0.014$ , Figure 1a) and contact area ( $p < 0.011$ ). No differences between surgeons were observed for bone densification ( $p < 0.751$ , Figure 1b). Large variations were found in terms of implant sizing (CFR,  $p < 0.021$ , Figure 1d). A trend was observed regarding the stem tilt ( $p < 0.073$ , Figure 1c) and

A stem tilt towards varus might increase PPF risk as it increases bone stresses [3]. Larger implants increase the PPF risk, while smaller implants may reduce primary stability [4].

Bone densification appears to be influenced by the instruments rather than the surgeon [2]. The observed differences in contact area and press-fit may be linked to different stem impaction forces, which were not documented, as well as variations in BMD and technique. Including less experienced surgeons in the analysis may further increase the observed variability, partly explaining the relation between the number of THA surgeries and the risk for complications [1].

**Figure 1** a) Variability in the lateral press-fit. b) Variability in the bone implant contact area. c) Valgus-varus tilt of the stem in the femur. d) CFR as a measure for the chosen implant size.

### Conclusions

Variations exist even between experienced surgeons. Reported variations in implant position and size may have an impact on the PPF risk, as already shown in literature. Whether and to what extent other parameters affect PPFs is yet to be determined.

### Acknowledgments

DePuy Synthes financially supported the study.

## Are different foot models able to detect the same changes in kinematics due to foot orthoses □

### Summary

There has been significant progress in the field of multi-segment foot modelling over the past few decades. However, the ability of the different foot models to detect the same changes in kinematics due to foot orthoses has not been fully explored. This study used SnPM to determine if the same kinematic differences exist in the time series with and without foot orthoses using two previously reported foot models. Foot kinematics of thirty-two participants was recorded using the Oxford foot model and a 6DOF model. The rearfoot to tibial results show both models being in agreement in 86.4% of cases with both models being able to detect changes in 61% of the variables explored. However, the forefoot relative to the rearfoot showed agreement between the models in only about half of the cases, with an opposite effect seen 23% of the time.

### Introduction

There has been significant progress in the field of multi-segment foot modelling over the past few decades and enough evidence now exists to support the use of multi segment foot models in clinical populations, however to date there is little evidence on the use of such models to explore changes in kinematics when using foot orthoses within shoes [1]. Although the particular foot models have been used to explore the effect of foot orthoses on foot kinematics [2], the comparison of various foot models' ability to detect this effect remains unknown. Therefore, the aim of this study was to compare the ability of two commonly used foot models, the six-degrees-of-freedom CAST foot model (6DOF) and the Oxford Foot model (OFM), to detect changes in the rearfoot to tibial and forefoot to rearfoot kinematics during the stance phase of gait when using a foot orthosis.

### Methods

An eight camera □icon vantage □5 (Oxford Metrics, UK) motion capture system was used to collect three-dimensional kinematic gait data. Participants were fitted with uniform correctly sized rubber-soled shoes and walked at a self-selected speed under two different orthotic conditions □no foot orthosis and foot orthoses with a medial heel bar positioned under the sustentaculum tali. Retroreflective markers for lower limb model and both foot models were placed on the anatomical landmarks and shoes accordingly. A standard 14 mm marker was used instead of posterior calcaneus wand marker for the OFM. Seventeen walking trials were captured for each condition, order of which was randomized with both models applied simultaneously. Kinematic data were processed in □icon Nexus 2.10 and exported to C3D format. Gait events were identified manually based on linear

acceleration, velocity and visual inspection of the heel and toe marker trajectories. □oth the OFM and 6DOF were applied in □usual 3D (C-Motion, USA). Data were normalized to 100% of the stance phase. As the D'Agostino-Pearson K2 test failed to confirm time series data normality, a non-parametric version of vector field statistical analysis technique, statistical non-parametric mapping (SnPM) was used. The observed effects of the medial heel bar were compared between the two models, and the possible outcomes of □ the same effect, no effect for both models, a separate effect of either the 6DOF or OFM, or an opposite effect of the models.

### Results and Discussion

Thirty-two healthy participants (16 males) who were all right side dominant with a mean age, body weight and height of  $22.9 \pm 3.5$  years,  $67.9 \pm 10.4$  kg and  $173.7 \pm 10.3$  cm, respectively. The overall results across all planes and phases for rearfoot to tibia show both models being in agreement in 86.4% of the cases and both models being able to detect change over the other in approximately 7% of cases. Despite the different tracking markers and anatomical definition of the segments, which can explain differences in the values obtained from the two models, the ability to detect the same effect of medial heel bar remains high. In the forefoot to rearfoot kinematics agreement between the models was seen in about half of the cases, with the 6DOF being able to detect change over the OFM in 17% of cases, and the OFM being able to detect change over the 6DOF in 9% of cases. However, in almost a quarter of the cases the opposite effect was observed. The greater disagreement between the models in the forefoot to rearfoot kinematics can be explained by the different anatomical definitions of the tarsal-metatarsal segment and the different tracking markers used.

### Conclusions

According to our study results, when used to explore the effect of foot orthoses on rearfoot, both models perform in strong agreement. In forefoot the agreement drops to about 50% with 6DOF detecting around twice as much changes over the OFM. However, the study cannot answer the question, which model is correct.

## Summary

Inadequate fit, volume change of the limb and overheating of the limb are still the main problems limiting the use of prostheses. In this study, we compared different types of prosthetic liners using a newly developed generic 2D numerical prosthesis-liner-limb model, thus providing a tool to assess the suitability of each liner objectively. The better insight into the biomechanical behavior of the prosthesis-liner-limb system helps us to develop new materials and shapes suitable for prosthetic liners. The obtained results in terms of contact pressure serve as a comfort criterion - we want the lowest contact pressure over the largest area. On the other hand, we also want maximum stability with minimum relative displacement between components. By analyzing the contact pressure and relative displacement of different liners with the developed model, we compared the liners directly, thus finding the best solution for the given boundary condition.

## Introduction

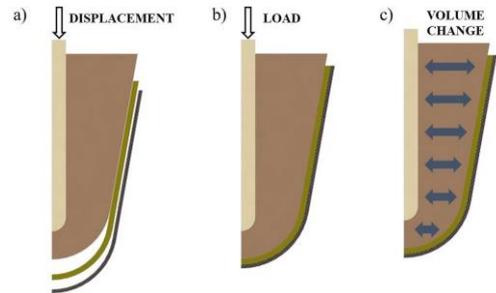

In recent years, total surface bearing (TSB) prostheses in combination with silicone liners have prevailed. The idea of such an implementation is to distribute the contact pressure over as large an area as possible and thus minimize it. The main problems with the use of TSB prostheses are: providing a good fit, the change in volume of the limb, and the increased temperature of the limb due to the low thermal conductivity of silicone liners. All of this can lead to discomfort that can develop into chronic pain and deep tissue injury [1]. With an improved liner-socket system, the duration of using the prosthesis can be extended, and the patient's mobility increased.

There are only a limited number of liners with generic properties that cover all subjects (commercial liners are not custom made for specific patient) [2]. Obtained results of contact pressure, displacements and strains can show us which liners are better in terms of comfort and stability and hence optimize the liner numerically.

## Methods

We utilized a previously developed generic axisymmetric 2D numerical model, which significantly reduces computation time, simplifies control over boundary conditions and still provides accurate results.

We used homogenous hyper-elastic material model for soft tissue, and liners [2,3], while a linear-elastic model was used for bone and prosthesis [2,4]. Material models were obtained from previous studies where the models were also validated. We defined three load cases that included all the critical moments during the use of the prosthesis (Figure 1).

**Figure 1:** Schematic representation of load cases: a) liner and socket donning; b) applying load; c) change in the soft tissue volume.

## Results and Discussion

The results obtained give us an insight into the behaviour inside the socket. The contact pressure at the tissue-liner and the liner-socket interface helps us to assess comfort, as minimizing and distributing it over a larger area protects the residual limb from damage and provides greater comfort.

The incompressibility of the silicone liner provides good overall pressure distribution. On the other hand, such a liner can be uncomfortable when the residual limb changes volume. In terms of adapting to the volume change, a liner with controlled compressibility could be the better option, but we must be careful not to compromise stability.

## Conclusions

The developed numerical model allows a relative comparison of different types of prosthetic liners, which serves us as an objective tool in the development of new liners and sockets. The results show that different liner properties are desirable for different load cases. To improve comfort while maintaining the patient's stability, the compressible liners with nonlinear behaviour should be investigated in the future.

### Summary

People with bilateral transfemoral amputation (TFA) have higher vertical and lower propulsive ground reaction forces (GRFs) during walking than people with bilateral through the knee (TKA) or transtibial amputation (TTA). People with bilateral TKA and TTA have similar GRFs, but people with bilateral TFA and TKA have different GRF peak forces during gait and should be separately considered in future work.

### Introduction

Bilateral lower limb amputation (LLA) results in altered gait kinematics and kinetics [1]. While GRFs in people with unilateral amputations are well documented, there are limited data for bilateral amputation at all LLA levels. While less common than unilateral amputation, bilateral amputation is prevalent in blast injury survivors. In addition, TKA and TFA are often grouped together in biomechanical studies of people with amputations, and potential differences between these groups remain unclear. Thus, we evaluated peak GRFs of bilateral TTA, TKA, and TFA and an able-bodied group.

### Methods

Ten people with bilateral, traumatic lower-limb amputations and nine able-bodied controls (34yo, 84kg, 182cm, all males) walked at self-selected speed on a level walkway containing two embedded force plates (Kistler Instrumente AG, 1000 Hz). Participants with amputations included five bilateral TFA (34yo, 76kg, 165cm, all males), three bilateral TKA (32yo, 94kg, 178cm, all males) and two bilateral TTA (46yo, 100kg, 187cm, all males). All participants walked across the walkway at least five times with both feet hitting consecutive force plates. Vertical and A/P peak GRFs were normalized by body weight and compared across the different levels of amputation and to the control group. Peak forces and average walking speed were evaluated across groups with an ANOVA ( $\alpha=0.05$ ). When significant main effects were found, pairwise comparisons using a Tukey's HSD test ( $\alpha=0.05$ ) were done.

### Results and Discussion

People with bilateral TFA had higher peak vertical and braking but lower propulsive GRFs compared to those with

bilateral TKA and TTA while having a slower walking speed than TTA (Table 1). These results suggest that sagittal plane GRFs of TFA were more vertically directed than A/P directed, supporting body weight. Greater peak vertical GRFs in TFA compared to controls, even when they were walking at a much slower speed, may have implications for long term joint health in this group. Bilateral LLA at all amputation levels lack the function of the ankle plantarflexors, which explains the lower propulsive peak compared to able-bodied controls for people with TFA and TTA. The higher vertical peak GRFs and lower propulsive forces during gait in TFA compared to TKA suggest that TKA should not be grouped with TFA and requires further study of biomechanical outcomes. Further, TKA had similar GRF peak values to TTA, but further study is needed with a greater sample size. GRFs for all levels were consistent with prior studies. Specifically, GRF peak values for bilateral TTA were similar to prior work [1]. Vertical and braking GRF peak values for bilateral TFA are larger than prior results in people with unilateral TFA, but propulsive peak values were similar [2]. Further, while there are limited data about TKA, GRF peak values were similar to the values reported for a single unilateral TKA [3].

### Conclusions

These results suggest that bilateral TKA and TFA should not be grouped together for biomechanical studies and that bilateral TKA may be considered an alternative to TFA when TTA is not feasible. TFA had higher vertical peak forces and lower propulsive peak forces than other LLA levels.

<sup>1</sup>Department of Rehabilitation and Prevention Engineering, Institute of Applied Medical Engineering, RWTH Aachen University, Aachen, Germany

### Summary

Low Back Pain (LBP) patients are facing a higher risk of injury through missing guidance and control in an out-patient environment. IMU sensors were used to detect movements and record accelerations along the back during exercise performance. 30 healthy subjects performed three different exercises: Prone-Rocking, Bird-Dog and Rowing according to two conditions: clinically prescribed exercise (CPE) and mimicking a typical compensatory movement (TCM). The order of these conditions and exercises was randomised.

From the processed IMU signals a set of N parameters was utilized to train a classifier to distinguish CPE from TCM. The method developed was shown to be effective for the exercises investigated. The results showed that the classification achieves an accuracy of up to 98%.

### Introduction

Low Back Pain (LBP) is prevalent in western society and a common reason for a medical consultation [1, 2]. The exercises typically prescribed in the rehabilitation of LBP are designed to optimize muscle activation and coordination, reduce pain, and improve patients' quality of life. Unfortunately, 70% of patients do not rigorously perform the prescribed exercises [3]. This reduces the effectiveness of rehabilitation and increases the risk of secondary injury. Thus, methods to monitor the execution of rehabilitation exercises outside of clinical or rehabilitation environments are needed to minimize secondary injury.

### Methods

Thirty healthy subjects (15 males/15 females) without a history of back pain participated in this study. The subjects' ages ranged from 18 to 35 years with an average age of 27.4 ± 2.5 years. Three IMU sensors were used to detect movements of the back and to record accelerations. Volunteers were asked to perform three exercises according to two conditions: clinically prescribed exercise (CPE) and mimicking a typical compensatory movement (TCM). The three exercises were Prone-Rocking, Rowing and Bird-Dog, where the latter needed to be performed on each side of the body. In each case a subject executed 3 sets of 6 repetitions

for every exercise. The order of the conditions i.e. CPE and TCM and exercises was randomised.

To minimize any errors introduced through outliers, the data points of six repetitions (set) were averaged per sample point. In this manner pre-processed accelerometer readings from the 3 sensors were used to calculate a series of features based on nine signals (x-, y- and z-axis per sensor). Through feature selection processes a set of N features was selected for each exercise based on their ability to discriminate between CPE and TCM. The best set of features per exercise was used to train a simple binary decision tree to classify exercise performance.

### Results and Discussion

The method of feature selection and decision tree training introduced provides a classification accuracy of up to 98.9% for Prone-Rocking using only one feature (**Table 1**). However, it has to be mentioned that the results for Rowing indicate that there might be limitations to the system which may require an adjustment of the sensor set.

### Conclusions

By analyzing the main axes of movement in the three selected exercises, it can be concluded, that the method developed can be applied to all exercises that include movements of spine and head with slight adjustments of the sensor positions.

### Summary

Outdoor, real-life handcycling requires both propulsion and steering. On the other hand, during indoor testing or training, a fixed ergometer is used, which has no steering requirements. The effects of steering on the metabolic strain were investigated for both asynchronous and synchronous straightforward handcycling. Handcycling technique was studied by means of the propulsion and steering torque as a cause for a change in metabolic strain. For synchronous handcycling, metabolic strain or handcycling technique did not change, regardless of the steering requirements. For asynchronous handcycling, however, an increased metabolic strain is found when steering is required. In order to cancel out unwanted steering movements, participants need to change their handcycling technique, as could be shown by the propulsion and steering torque. For testing or training handcyclists, who have a synchronous set-up in real-life, a synchronous ergometer set-up is advised.

### Introduction

During outdoor handcycling the front wheel axis is to rotate freely around the steer axis. This results in a combined requirement of propulsion and steering. The handcycle cranks are mostly mounted synchronously (parallel). Arm cycle ergometers, on the other hand, are often fixed to the wall or floor and cranks are mostly mounted asynchronously (anti-phase). The aim of the study is to evaluate the biophysical effects of combining propulsion and steering requirements in both asynchronous and synchronous submaximal handcycle ergometry.

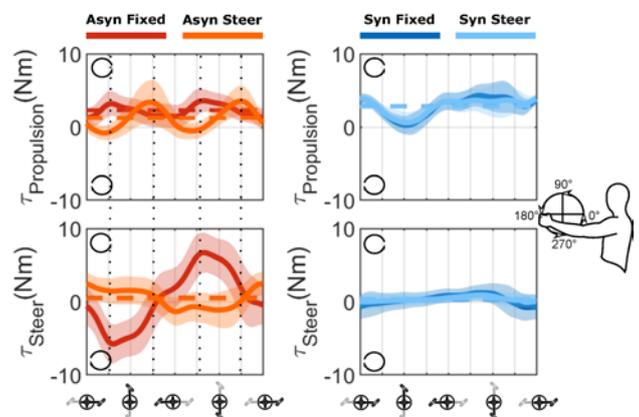

### Methods

Sixteen able-bodied male novices volunteered in this experiment. The set-up consisted of an instrumented handcycle ergometer that allows 'natural' steering, which could be fixed at the steering axis [1]. Four submaximal steady-state exercise conditions were evaluated: asynchronous versus synchronous and fixed versus steering. All participants practiced 3x4 minutes in each of the four conditions in a counterbalanced order, with 2 minutes rest in between. Finally, they handcycled (4 minutes) in each of the four conditions, with 10 minutes rest in between, while metabolic outcomes, ergometer kinematics and kinetics were recorded using bilateral instrumented handlebars with 3D

force sensors and optical encoders. Before statistical analyses, the data of one participant was removed, as this data was found to be recorded wrongly.

### Results and Discussion

Steering requirements have an effect on several metabolic outcomes, including mechanical efficiency ( $P = .003$ ,  $r = -.55$ ), due to an increase in strain during asynchronous handcycling. In the Asyn Fixed condition, the force produced at the handlebars causes a peak propulsion torque simultaneously with a peak steering torque (Figure 1). As the steer axis is fixed, no steering movements are created. To avoid the high peaks in steering torque, the propulsion torque pattern is different in the Asyn Steer condition. Hence, participants have another handcycling technique whenever steering is required. In the synchronous handcycling conditions, almost no steering torque is produced, so that the same technique can be used in the fixed and steer condition.

**Figure 1:** Bilateral propulsion and steering torque profile (mean cycle,  $n=570$  (15 participants\*38 cycles per participant)).

### Conclusions

To test or train handcyclists, who have a synchronous crank mode in their daily handcycle, a synchronous crank set-up of the ergometer is advised, as exercise performance in terms of metabolic strain and torque production is independent of steering requirements in that mode.

## Implications of a familiarization phase with a robot-assisted rehabilitation system on motor performance during simulated daily activities

Sybele E. Williams<sup>1</sup>, Catherine Disselhorst-Klug<sup>1</sup>

<sup>1</sup>Department of Rehabilitation and Prevention Engineering, Institute of Applied Medical Engineering – Helmholtz Institute, RWTH Aachen University, Aachen, Germany.  
Email: williams@ame.rwth-aachen.de

### Summary

The aim of this initial study was to test whether a familiarization phase with an end-effector robot-assisted rehabilitation system could ensure that patients performed more physiological movements during rehabilitation. 2 simulated daily activities, involving the upper limb were investigated under 2 conditions: (i) unconstrained arm movement and (ii) with a passive robot-arm coupled to the test subject's forearm. 23 healthy subjects were assessed during 2 test sessions, at least a week apart. The familiarization phase was included only in the first test session. Analysis of kinematic data recorded, showed differences in movement performance under both conditions. The familiarization phase did not reduce differences within a test session. However, a training effect seemed to reduce performance differences at the second test session.

### Introduction

End-effector robotic rehabilitation systems support early intervention using high intensity, task-oriented exercises. It was reported that healthy subjects showed increased muscular activation while performing robot-assisted movement tests [1]. This has implications for the use of robot-assisted rehabilitation systems since poor motor learning may negatively affect rehabilitation goals. This study investigated the introduction of a familiarization phase to an end-effector robot-assisted rehabilitation system during selected movement tests in order to assess the effect of such familiarization and changes in movement performance..

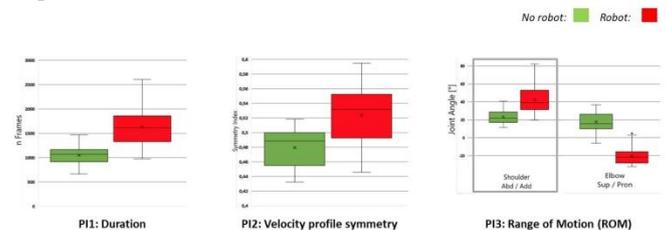

### Methods

23 healthy subjects (10 males, 13 females, avg. age: 25 ± 2.70 yrs.) were measured during two test sessions, at least 1 week apart. The measurement protocol had 3 phases: (i) simulated daily activities with unconstrained arm, (ii) a familiarization phase with robot, and (iii) simulated daily activities with robot. The 'robot' condition infers that the subject's forearm is coupled to the passive robotic arm. Two versions of the test protocol were used, a complete protocol with all 3 phases and a second, which omitted phase (ii). During testing, each subject sat in a standardized position before the robotic arm LBR Med (KUKA), which was mounted on a special table. Data was recorded using a 3D motion analysis system (Vicon). Two movement tasks were investigated Cup to Box and Cup to Mouth (CBCM) and Sorting Elements (SE). The familiarization phase involved a 'reach-to-touch' test. Joint angles in the elbow and shoulder were determined using a suitable biomechanical model [2]. Three performance indices (PI) were used to compare

movements: PI1: duration, PI2: velocity profile symmetry, and PI3: range of motion (ROM).

### Results and Discussion

Results are presented for the sequence Cup to Mouth of the movement task CBCM. This comprised 2 main movement sequences: S1 - lift cup up to mouth from table, S2 – return cup to table.

**Figure 1:** Comparison of performance indices for 2 conditions (robot/no robot).

The duration of the movement (PI1) was significantly longer in the robot condition ( $F(1)=84,942$ ,  $p<0.01$ ). This could be caused by the mass inertia and braking effect of the robotic arm. Acceleration time during S1 was slightly longer than the deceleration during S2 in the robot condition. The difference in elbow supination/ pronation was significant ( $F(1)=188,79$ ,  $p<0.01$ ). Greater abduction in the shoulder joint was also significant in the condition 'robot' ( $F(1)=62,438$ ,  $p<0.01$ ). In the 'robot' condition the ROM was negative, which suggests that subjects performed a pronation while lifting the cup.

### Conclusions

While the introduction of a familiarization phase did not reduce differences in movement performance within a test session, differences were smaller at the second test session. This may be due to a training effect of the initial test session.

### Summary and Introduction

From 2012, the program called “functional analysis and individual training for children with muscular hypotonia” (F-A-I-T-H-kids) has been delivered by the Swiss physiotherapist Jens Hentschel in an interdisciplinary cooperation with speech and myofunctional therapists [1]. Children affected by muscular hypotonia have often been sent from speech or myofunctional therapists to physiotherapy. Muscular hypotonia is usually described as a symptom of underlying neurological diseases, but not yet as an independent and classified pathology. In cases where no cause of a hypotonia can be detected and the etiology remain unclear; the authors of this paper coined the term «Constitutional Muscular Hypotonia». The aim of this study is to examine the clinical efficacy of the F-A-I-T-H-kids method with children diagnosed of constitutional muscular hypotonia. Furthermore, the authors intend to call attention for this issue as well as the interdisciplinary correlation.

### Methods

- P:** Children with constitutional muscular hypotonia and myofunctional deficits
- I:** 18 physiotherapy units of 30 minutes within the F-A-I-T-H-kids method supplied by weekly home training
- C:** Every child represents its own control object, no comparison between the participants
- O:** Parameters for symmetry and trunk force such as y-balance test, plank test and trunk-symmetry test according to Hentschel, myofunctional tests such as palatogram and spring scale test, health questionnaire, adherence of home training

**Study design:** Prospective quality control trial with surveys before and after the interventional time, three probands have been tested

**Data evaluation:** Due to the small number of participants the results have not been statistical evaluated

**Ethics:** This study has been registered by Business Administration System for Ethics Committees (BASEC), it has not been defined as ethically obligated

### Results and Discussion

All the participants showed a statistical improvement in the myofunctional tests. A few of them were detected as clinically relevant. In the Y-balance test, only one participant achieved improvement, though not clinically relevant. In the trunk-symmetry test according to Hentschel, all participants improved considerably. The result of the plank test showed a

clinically unimportant improvement of two participants and a slight worsening of the third.

Due to the Covid-19 pandemic, the authors were only able to recruit five participants for the clinical trial. Out of this group, two participants did not complete the entire intervention period. The small number of participants as well as the partially inconsistent results measured by the authors hinder an accurate answer to the scientific question. In general, a positive trend for the efficacy of the F-A-I-T-H-kids method can be shown. Resulting from these, only a few minimal clinical important differences (MCID) were achieved. The interpretation of the results was difficult due to the lack of evidence for quality criteria in myofunctional tests. The chosen metrical assessments have only been examined fragmented in the sighted literature. Therefore, the authors created the described trunk-symmetry test according to Hentschel. This test shows potential in its further development of objectivity and accuracy.

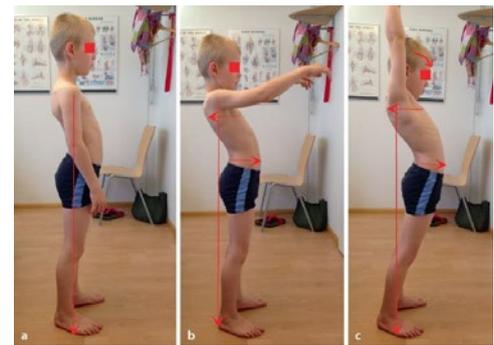

Figure 1: A boy with constitutional muscular hypotonia showing its typical pattern during movement of the arms straight in front of him. a) Hanging arms, the perpendicular goes through the middle of the feet; b) Arms in 100 degree of shoulder flexion, the perpendicular through the shoulder raises behind the heels c) Arms in maximal shoulder flexion, a maximal ventral translation of the pelvis as well as a cervical spine flexion can be observed [1].

### Conclusions

There is a wide variance according the results of this study, which are partially contradictory and can be traced back to the small sample size. Although the results show a positive tendency, the authors cannot make a definitive conclusion about the efficacy of the F-A-I-T-H-kids method. Therefore, the authors recommend the verification of the effectiveness of the F-A-I-T-H-kids method in further studies as well as the evaluation of the applied quality criteria.

### Summary

In recent years forefoot strike running style has been idolized as a superior running technique since most of the elite east African distance runners with world class performance use it. However, most of the elite marathon runners use rearfoot strike [1]. Therefore, we investigated if there is any difference in muscle function between fore and rearfoot strike running. In this study we demonstrate that muscle activation level is unaffected by the foot strike style in competitive Caucasian runners.

### Introduction

Forefoot strike and rear foot strike pattern has a distinctive kinematic difference regarding the degree of ankle and knee joint rotation [2] which can affect the muscle-tendon interaction [3]. We think that the higher knee rotation during rearfoot strike compared to forefoot running can decrease the efficiency of the gastrocnemii muscles [3], but soleus muscle can compensate it with higher activation level. Therefore, the aim of this study was to investigate the difference within the ankle plantar flexor muscle function/activation between forefoot and rearfoot strike running during different running speeds.

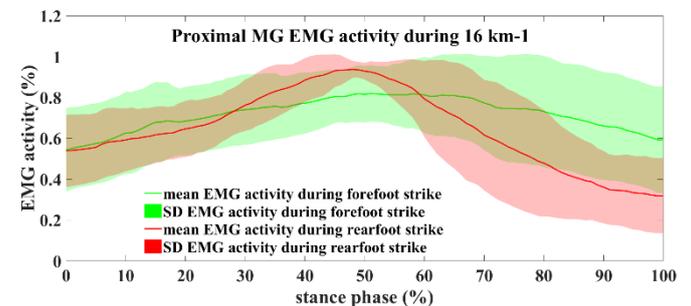

### Methods

Fourteen male and female competitive distance runners volunteered for this study. The participants ran on a motorized treadmill at three running speeds: 12, 14 and 16 km<sup>-1</sup> with rearfoot strike and with forefoot strike pattern. During running we measured lower leg kinematics and the electromyographical activity (EMG) of ankle plantar flexor muscles simultaneously. In the case of medial gastrocnemius, we mounted electrodes on the proximal, middle and distal region of the muscle. To test statistically the difference between joint angular displacement and EMG amplitudes we used SPM analysis in Matlab.

### Results and Discussion

As expected, we found that there is a statistical difference between foot strikes in ankle joint rotation during early stance phase. In opposed to previous findings we did not detect relevant difference in knee joint rotation between rear and forefoot strike running at any speed. We expected to detect significant difference in EMG activity of the proximal region of the medial gastrocnemius due to the assumed difference in

knee joint rotation. However, there was no difference in knee joint rotation and as a consequence we did not find statistical difference in EMG activity (Figure 1.) of the investigated muscles between different foot strike patterns irrespectively of running speeds. The difference in initial foot strike ankle angle between rear and forefoot strike also suggests an increased muscle-tendon unit lengthening during forefoot strike running, and also a different Achilles tendon moment arm length, since the moment arm length is angle dependent [4].

**Figure 1:** Difference in EMG activity of the medial gastrocnemius proximal region during forefoot and rearfoot strike running at 16 km<sup>-1</sup> speed.

Therefore, it can be assumed that a longer Achilles tendon moment arm at initial foot strike during forefoot strike running can result in similar EMG activity to that of rearfoot strike running. We did not measure the resting or dynamic length of Achilles tendon moment arm length therefore this assumption needs to be investigated in future studies.

### Conclusions

In summary we did not find any difference in EMG activity of the plantar flexor muscles between forefoot strike and rearfoot strike running in opposed to previous reports and despite of the difference in ankle joint rotation between the two conditions. We can assume that for competitive distance runners changing the foot strike pattern has not associated with short term beneficial effects on the neuromuscular activation level.

### Summary

We investigated whether local dynamic stability (LDS) is affected by the intensity domain in which running is performed. Ten trained male runners completed four running trials to task failure at speeds below (95%), equal to (100%), and above (105 and 115%) critical velocity (CV). The local dynamic stability (LDS) of the sacral marker was calculated using the Lyapunov exponent (LyE). Our results showed LDS during running reduced throughout running trials performed in the severe intensity domain. Alterations to sacral dynamics suggest that peripheral fatigue mechanisms may be predominantly responsible for changes in LDS.

### Introduction

Gait stability can be quantified by measures of LDS quantified using LyE [1]. The LyE computes the ability of the motor system to attenuate small perturbations and can be affected by mechanical and sensory inputs [2]. Further to mechanical and sensory mechanisms, metabolites such as H<sup>+</sup> and lactate are thought to affect gait stability, exerting inhibitory effects on  $\alpha$ -motoneurons by activating fatigue-sensitive muscle afferents [3].

The critical velocity (CV) demarks the heavy and severe intensity exercise domains. Above the CV, the severe intensity domain is characterised by an inexorable rise of metabolites including lactate and H<sup>+</sup> [4]. Below CV, in the heavy intensity domain, a metabolic steady state can be maintained. The influence of exercise intensity domains on LDS is poorly understood. Therefore, the purpose of this study was to examine changes to LDS in the heavy and severe intensity exercise domains.

### Methods

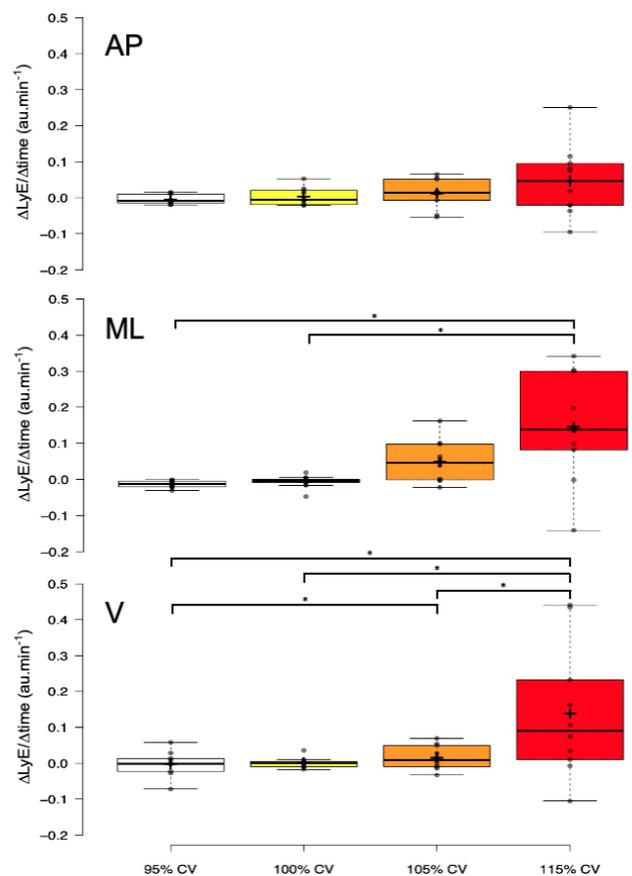

Ten trained males (age: 29.3 ± 10.1 years; mass: 72.1 ± 9.6 kg) provided written informed consent and completed the study. Four constant velocity runs to task failure were performed at velocities corresponding to 95%, 100%, 105%, and 115% of the estimated CV (CV<sub>95</sub>, CV<sub>100</sub>, CV<sub>105</sub>, and CV<sub>115</sub>) in a randomised order. Pulmonary gas exchange was measured breath-by-breath using a gas analyser (MetaLyzer 3, Cortex Biophysik, Leipzig, Germany). Kinematics of markers placed on the sacrum and right second metatarsal head were captured using a 14-camera high speed motion capture system sampling at 200 Hz (Motion Analysis Corp., Santa Rosa, CA). The sacral marker was used to approximate COM dynamics. Heel strikes of 80 consecutive strides were identified immediately after the initial 15 strides and prior to the final 5 strides in each trial. The sacrum marker velocity in the frontal, sagittal, and transverse planes of 80 strides was time-normalised to 8000 data points, corresponding to 100

data points within each stride. A time-delay of 10 was used based on the Average Mutual Information algorithm and a dimensionality of four was estimated using False Nearest Neighbour algorithm. Local dynamic stability of the sacral marker was assessed using the LyE estimation using the method defined by Rosenstein et al. [5]. Low values of LyE indicate greater stability and vice versa.

A one-way ANOVA was performed to test the effects of velocity on time to task failure (T<sub>lim</sub>), end pulmonary  $\dot{V}O_2$ , blood [La] responses and rate of change in LyE ( $\Delta LyE/\Delta time$ ) in the mediolateral (LyE<sub>ML</sub>), anteroposterior (LyE<sub>AP</sub>), and vertical (LyE<sub>V</sub>) directions.

### Results and Discussion

There was a significant effect of velocity on T<sub>lim</sub>, blood [La], and end pulmonary  $\dot{V}O_2$  ( $p < 0.001$ , Table 1). One-way ANOVA revealed the rate of increase of LyE<sub>ML</sub> in trials performed at CV<sub>115</sub> was greater than in trials performed at CV<sub>100</sub> ( $p < 0.001$ ) and CV<sub>95</sub> ( $p < 0.001$ , Figure 1).

**Figure 1:** Changes to LyE during trials performed below (95% CV), at (100% CV), and above (105% CV and 115% CV) critical velocity. Asterisks denote sig. dif. ( $p < 0.05$ )

Similarly, greater rate of increases in  $LyE_{\square}$  were evident at  $C_{\square 115}$  compared to all other conditions ( $p \square 0.05$ ). Significantly greater rate of change in  $LyE_{\square}$  was found during trials performed at  $C_{\square 105}$  when compared to  $C_{\square 95}$  ( $p = 0.039$ ).

Increased rates of  $LyE$  change were only demonstrated above CV, suggesting that stability is affected by metabolic rate. Exercise above the CV is associated greater levels of peripheral fatigue with a precipitous flux of metabolites and depletion of high-energy phosphates, and typically terminated when these reach a critical value [3]. It has been postulated that compromised stability after exercise is due to metabolites associated with exercise above CV, such as  $H^+$  ions and lactate [2]. However, inconsistent rates of change in  $LDS_{ML}$  at the end of trials in  $C_{\square 105}$  when compared to  $C_{\square 115}$  suggest that the metabolic environment is one variable of potentially many that affect LDS during running.

It is possible that during the current study, diminished LDS was evident due to limited degrees of freedom permitted by treadmill running. This may have limited the adaptability of running velocity and movement patterns when compared to overground running. Moreover, we cannot be entirely sure of

the levels of peripheral and central fatigue at task failure. However, given the low SEE of  $C_{\square}$  estimates and pulmonary responses in the current study, and the noted physiological responses in the severe intensity domain, it is reasonable to assume task failure coincided with considerable peripheral fatigue.

### Conclusions

Local dynamic stability of the sacral marker in ML and  $\square$  directions during running reduced at a greater rate in the severe intensity domain when compared to running at or below  $C_{\square}$ . These findings suggest that peripheral fatigue mechanisms may be predominantly responsible for changes in LDS of the centre of mass during treadmill running.

## The relationship between running speed and footfall sounds during overground running

Peter Dam<sup>1</sup>, Cristina Pircoveanu<sup>2</sup>, Anderson Souza Oliveira<sup>2</sup>

### Summary

The sound of footfalls has been suggested to be an effective measure of running impact properties. Therefore, present study aimed to investigate the relationship between running speed (RS) and footfall sound during overground running. Thirty-one recreational runners performed 3 x 3-minutes of overground running. Ground reaction force, RS, and sound of footfalls were assessed. The impact peak force, vertical loading rate, impact peak sound and late peak sound all increased as a function of RS. A correlation analysis showed that the sound properties are superior in describing RS than force parameters. The use of footfall sound showed to be an effective method of investigating running impact properties.

### Introduction

Running induces remarkable lower limbs loading, which has been quantified using peak vertical impact force (IPF) and vertical loading rate (LR) [1]. There is a close relationship between RS and vertical force parameters [2], and new evidence has proposed the use of footfall sounds to investigate running impact properties using single [3] and multi-directional recordings [4]. Since sounds of footfalls during running may be an alternative to investigate running impact properties, the aim of present study was to investigate the relationship between RS, vertical ground reaction force and sound properties of running footfalls recorded using multiple microphones and ground reaction forces.

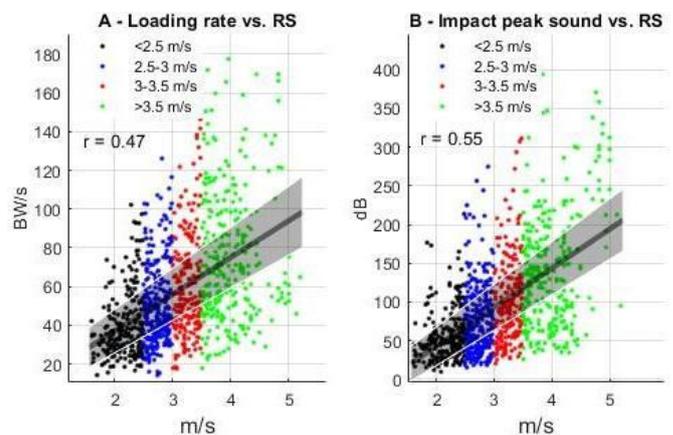

### Method

Thirty-one recreational runners performed 3 x 3-minutes overground running on a 20m obround running track containing a ground reaction force platform embedded at the middle of one of the straights. Participants were asked to run at different RS, varying from 2 m/s to 6 m/s. Vertical ground reaction force, head kinematics and surround sound waves from four microphones located equidistantly around the force platform [4] were recorded throughout the protocol. The IPF, LR, and peak impact sound (averaged across the four microphones) within the first 30% stance (SP) were calculated for each step on the force platform. Subsequently, RS was computed from head kinematics and steps were divided into four speed categories: <math>\leq 2.5</math>, 2.5-3, 3-3.5 and >3.5 m/s. A total of 1005 steps were analyzed (<math>\leq 2.5</math> m/s: 229 steps, 2.5-3 m/s: 296 steps, 3-3.5 m/s: 204, >3 m/s: 286 steps). Non-parametric Kruskal-Wallis tests with Bonferroni correction were used to investigate the effect of RS on the dependent variables. Moreover, Pearson correlations were computed between RS vs IPF, LR and SP. For all tests, the significance level was set to  $p \leq 0.05$ .

### Results and Discussion

The IPF, LR and SP values, all increased as a function of RS, statistically different from each other ( $p < 0.01$ ). Although this was expected for the force parameters [2],

our study revealed that sounds of footfalls are also sensitive in revealing speed-related changes in running impact properties. Moreover, weak, and moderate correlations were present between RS vs IPF ( $r = 0.36, p < 0.01$ ) and RS vs LR ( $r = 0.47, p < 0.01$ ). Interestingly, SP demonstrated the greatest (moderate) correlation with RS ( $r = 0.55, p < 0.01$ , Figure 1). These results suggest that early peak sounds captured from multiple directions were more related to RS than traditional force parameters (IPF and LR). A previous study using similar sound recording technique has demonstrated the relationship between the sound and force parameters are highly affected by the number and location of the microphones [4]. Therefore, multi-directional sound properties may be an alternative to investigate running impact properties.

**Figure 1:** Depicts the correlations between Loading rate (A) and the impact peak sound (B) with each speed category represented by a color and the Pearson correlation coefficient ( $r$ ).

### Conclusion

The use of multi-directional sound recordings demonstrated sensitivity to capture speed-related changes in running footfall sounds. Moreover, the early peak sounds of running stance presented greater relation to RS, reiterating the relevance of sound recordings to investigate running impact properties. Future research should aim to use multi-directional sound capturing from microphones attached to the shoe. This could potentially provide a robust and relevant method to investigate running impact properties in realistic conditions.

## Summary

The present study provides novel insights in the running style adaptations employed by high impact runners who completed a retraining outside the laboratory. Real-time music-based feedback on tibial shock was provided in a randomized controlled trial design. Gait analysis was conducted pre and post retraining. Runners allocated to the biofeedback condition succeeded in lowering their impact characteristics by 27-29% using two distinct strategies. (1) A more pronounced rearfoot strike or (2) switching to a non-rearfoot strike. This indicates that, at least two strategies are apparent to reduce tibial shock during over-ground running.

## Introduction

Real-time biofeedback on impact during gait-retraining proved to play a role in reducing running injuries, and altering biomechanical variables associated with it [1-3]. A full understanding of how runners achieve their goal directed over-ground gait-retraining is limited. Therefore we aimed to describe kinematic changes of high impact runners following a lower impact running retraining program.

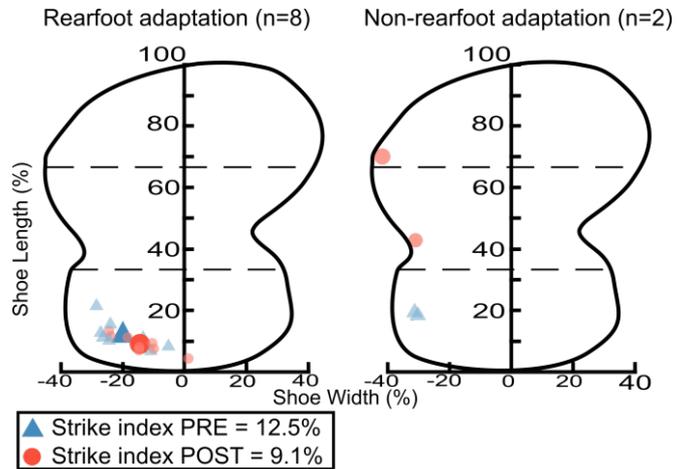

## Methods

Twenty high impact runners completed in a gait-retraining study consisting of six twenty-minute over-ground running sessions. Participants were assigned to a biofeedback (n=10) or a music-only (n=10) placebo condition. The biofeedback consisted of an amount of pink noise, distorting the tempo-synchronized music, based on the momentary tibial shock (the max positive acceleration (g) of the tibia during the first 50ms of stance) [3]. We asked subjects to run with music as pure as possible. Gait analysis took place over-ground in a lab pre and post intervention. Subjects ran at  $2.9 \pm 0.2 \text{ m}\cdot\text{s}^{-1}$  across a 30-m instrumented runway. The refined strike index of five footfalls was determined [4]. We also used vertical instantaneous loading rate of the vertical ground reaction force ( $\text{N}\cdot\text{s}^{-1}$ ) as a lab-based measure of impact. Statistics were done using a linear mixed-model in SPSS.

## Results and Discussion

The experimental group successfully reduced both the tibial shock ( $\Delta\bar{x}=-27\%$ ) and vertical instantaneous loading rate ( $\Delta\bar{x}=-29\%$ ) (Table 1), similar to a previous proof of concept study [3]. There were inter-individual strategies to achieve lower impact running. Two subjects opted for a non-rearfoot

strike pattern, while the remaining eight subjects were able to lower their impact while using a more pronounced rearfoot strike (Figure 1). Both strategies were earlier cross-sectionally characterized by a lower impact loading [4].

**Figure 1:** Initial points of contact on the shoe sole changed from pre (blue squares) to post (red dots) retraining. Individual and mean data are represented by respectively tiny and big markers. Mean data is shown for the rearfoot adaptation (left). The strike index of the music-only group remained unchanged (12%).

## Conclusions

An overground gait-retraining program with musical biofeedback on tibial shock successfully reduced impact loading. distinct adaptations were present as impact reduction was achieved by adopting either a non-rearfoot strike or a more pronounced rearfoot strike. Further research should seek if other running gait adaptations also contribute to the realized impact reduction.

### Summary (max. 150 words)

This study aimed to estimate mechanical power (MP) during level and inclined running. We equipped 34 participants with inertial measurement units (IMUs) on the feet, shank, sacrum, wrist, and head, to compare the accuracy of MP power estimated from each location. Participants ran on an instrumented treadmill, at speeds ranging from 8–14 km/h, and slopes from -20 – +20%. To estimate stepwise MP, we created two machine-learning models using 15 features based on gait temporal parameters, running speed, body mass, and statistical measures of IMU signals. Mechanical power, determined from the antero-posterior ground reaction forces, was used as reference for the leave-one-out cross-validation method. The lowest RMSE was  $11.1 \pm 4.8\%$  (shank) and  $20.9 \pm 14.2\%$  (head) for flat and inclined running respectively. These results show the promise of IMUs to estimate MP, even with the use of a single sensor.

### Introduction

Feedback of running mechanical power (MP) can be a promising tool for training and pacing strategies, but commercially available running power meters are not accurate enough [1]. Current analytical models focus either on the characterization of overall race performance [2] or on the power requirement while running on flat terrain [3]. An approach based on wearable inertial measurement units (IMUs) has shown promise, but requires data from 15 body segments [4]. Neither of these approaches are suitable for accurate real-time feedback of MP. To address this, we developed and validated two machine-learning (ML) models, for flat and inclined running, to estimate stepwise MP using one IMU on either feet, shank, sacrum, wrist, or head.

### Methods

We equipped 34 healthy participants with IMUs on the above-mentioned locations. The participants ran on an instrumented treadmill, at combinations of speeds ranging from 8–14 km/h, and slopes from -20 – +20%. Figure 1 presents the overall setup. For the ML model, we used data from 10 participants for feature selection and from 24 participants for training and testing using leave-one-subject-out cross-validation. We selected 15 features based on gait temporal parameters [5], running speed, body mass, and statistical measures of the filtered IMU signals to develop the model. The data was balanced using random oversampling [6] and the input features were scaled using robust z-score normalization [7]. Training was done using the LASSO method [8], with mechanical power estimated from the antero-posterior ground reaction forces (GRF) [9] as reference. To estimate stepwise MP using every sensor location, separate ML models were developed for flat and inclined running.

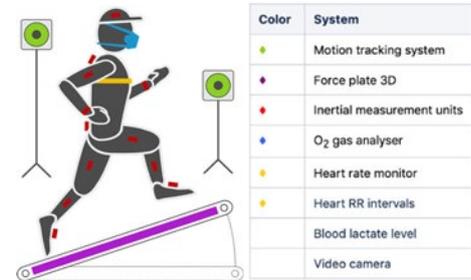

Figure 1: In-lab sensor setup for data collection of 34 healthy subjects

### Results and Discussion

Across individual sensor locations, the lowest RMSE (Table 1) was  $11.1 \pm 4.8\%$  and  $20.9 \pm 14.2\%$  for flat and inclined running respectively. Shank and head sensors provided the best results for flat and inclined running respectively, while the wrist sensors performed second best for both running modalities. The estimation accuracy showed similar order of magnitude across all locations. Unlike the ML model for flat running, the one for inclined running used vertical speed as feature and had a lower accuracy. These results were used as a starting point for the design of a sensor setup for conveniently providing real-time feedback based on MP. We demonstrated the utility of this work in a field study with 13 runners, with an IMU on the wrist used for estimating MP and providing real-time feedback.

Table 1: % RMS error (median  $\pm$  IQR) for different sensor locations

Location	Level running	Inclined running
Foot	$12.6 \pm 5.7$	$23.0 \pm 13.4$
Wrist	$12.2 \pm 6.2$	$21.7 \pm 12.7$
Sacrum	$14.2 \pm 6.2$	$25.3 \pm 15.2$
Head	$12.8 \pm 7.7$	$20.9 \pm 14.2$
Shank	$11.1 \pm 4.8$	$27.1 \pm 20.6$

### Conclusions

Our results show the promise of IMUs to estimate MP, even with when a single sensor is used. Estimation accuracy of the ML model can be improved further by combining features from sensors on different body segments.

## Runners don't bounce - power economy in springless legged locomotion

Scott L. Tucker<sup>1</sup>, Natalie Harold<sup>2</sup>, Sarah R. Chang<sup>2</sup>, David Boone<sup>2</sup>

<sup>1</sup>FastEquation Inc. Portland OR, USA

<sup>2</sup>Orthocare Innovations LLC Edmonds WA, USA

Email: [Scott.Tucker@vimazi.com](mailto:Scott.Tucker@vimazi.com)

### Summary

The discovery of impact impulses from discrete plantar structures led to a plantigrade running theory that models vertical and horizontal ground reaction forces (GRF) from 2D center of mass (CoM) motions. The accuracy of the theory's predictions results from treating tendon elasticity and compliant tissues not as springs, but as mechanical resistors. When applied to legged locomotion with a flight phase (i.e. running), mass-spring-damper (MSD) predictions conflict with observations and the laws of motion. Specifically, the frequency of impact force and the direction of CoM motion are incompatible with bounce. By applying the theoretical framework of plantigrade running to the computation of power and running economy, we demonstrate that the most economical locomotion system results from the elimination of springs.

### Introduction

MSD models of GRF profiles for horizontal human running assume tendons function with spring-like properties [1]. Fundamental to this concept is the conversion of kinetic energy into spring potential energy and the return of some portion of the spring energy in the form of work done on the mass. Assuming some frictional losses, the solution to this equation is damped harmonic motion with a predictable frequency and amplitude. Given the boundary conditions for legged locomotion (striding) at human velocities (<10 m/s) in a gravitational field where the point of impact (foot) is anterior to the CoM, there are no real solutions that incorporate damped harmonic motion.

The theoretical framework for Plantigrade Running (PR), based entirely on measurable parameters and  $F=ma$ , describes running dynamics as the superposition of a high frequency gravitational impact force at landing and a low frequency muscular propulsion force to create liftoff. The framework predicts the force amplitudes, periods, and sequential timing for each plantar region (calcaneal, tarsal, metatarsal, phalangeal) according to velocity, stride length, and strike pattern, which sum to equal the overall GRF profile.

### Methods

The hypothesis that plantar force amplitudes and frequencies are a function of CoM energetics was tested in a controlled barefoot experiment including 270 trials using a Matscan system (Tekscan Inc.) operating at 476 Hz. All individuals provided written informed consent for the IRB approved study. The healthy participants ran according to taped stride length markers, a metronome, and prescribed strike pattern on a level 60 m indoor runway. The dense grid of force sensors allowed precise delineation of the plantar regions, their respective vGRF profiles, and timing of touchdown for each region (Fig. 1).

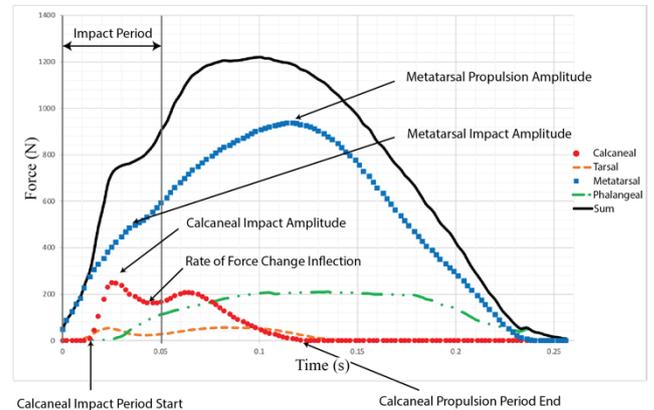

Fig. 1. Plantar regional vGRF trials example with forefoot strike

### Results and discussion

Impulse amplitudes and periods were clearly discernable for each plantar region (impact:  $p=0.006$   $r^2=0.999$  and propulsion  $p=0.005$   $r^2=0.999$ ) in 100% of the trials and support rejecting the null hypothesis. Foot strike pattern was quantified by defining the parameter FT as the time differential between calcaneal contact and metatarsal contact. Changes in FT correlate with the relative distribution of impact force between calcaneal and metatarsal regions, but do not change total impact force [2]. FT does not correlate with propulsion forces. Together these data support the theory and physical model that the gravitational kinetic energy dissipates during the period of impact. The result is consistent with the observation that horizontal and vertical CoM momentum are not reversed during impact, thereby excluding the possibility of damped harmonic motion.

### Conclusion

External power, the work to move the CoM vertically and achieve liftoff velocity over time, decreases with increasing cadence, due to the shorter stride lengths and lower trajectory heights during the flight phase [3]. Spring activity during the propulsion phase would increase energy loss, and therefore, increase external power consumption due to frictional losses. Total running economy at any given speed will be determined by the cadence-driven external power and the cadence-driven muscular (internal) power consumption.

# The physiological and biomechanical adaptations to acute fatigue on running economy and pelvic-thorax coordination in sub-elite runners

Craig Hicks, Robert A. Needham, Nachiappan Chockalingam

Centre for Biomechanics and Rehabilitation Staffordshire University, Stoke-on-Trent, UK.

Email: Ch56@staff.staffs.ac.uk

## Summary

This study investigated the effect of fatigue on running economy and pelvic-thorax coordination. Ten sub-elite runners performed two 10-minute runs at their ventilatory threshold. Between each 10-minute run participants performed a localised eccentric fatigue protocol. A significant difference in  $\dot{V}O_2$  uptake was found between pre-post fatigue runs. Similar pelvic-thorax coordination patterns were noted in all three planes between the pre-post fatigue runs. However, an increase in thorax forward lean in the sagittal plane was noted across the entire gait cycle in the post-fatigue run that could have impacted on running economy.

## Introduction

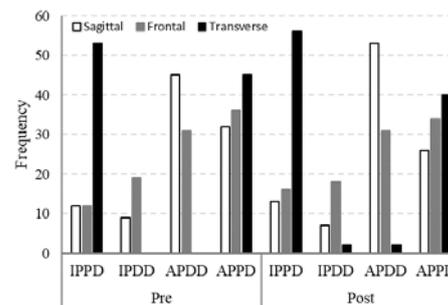

Quantifying the coordination between the thorax and pelvis during running may have implications with performance and injury risk. For example, pelvic-thorax coordination during running may detail desired movement strategies that inform on the position and control of the centre of mass (COM) [1]. In addition, trunk and pelvis posture is thought to be one of the several factors that may influence running economy (RE) [2]. However, there is limited research on the relationship between RE and trunk kinematics, although research has shown that running when fatigued can increase trunk flexion [3]. This study investigated the effect of fatigue on running economy and pelvic-thorax coordination.

## Methodology

Ten sub-elite male distance runners (age,  $33.8 \pm 13.9$  years, height,  $178.5 \pm 11.4$  cm and mass,  $76 \pm 12.3$  kg) took part in two laboratory visits. A maximal  $\dot{V}O_2$  max test was conducted using breath by breath analysis (Metalyzer 3B, cortex Leipzig Germany). to gain participants ventilatory threshold. Seven days later, participants performed two 10-minute runs on a treadmill (model t9700HRT, vision fitness) at their individual ventilatory threshold. Between each 10-minute run participants performed a localised eccentric muscle fatigue protocol consisting of 100 box jumps off a 40cm box with 20 seconds recovery between each jump. Marker coordinate data was captured at 200 Hz using a 17-camera motion capture system (VICON, Oxford, UK). Thorax and pelvis segment angles were processed in Visual3D (C-motion Inc, MD, USA). Vector coding was used

to quantify pelvic-thorax coordination [4].  $\dot{V}O_2$  uptake was analysed during the final minute of each 10-minute run.

## Results & discussion

**Figure 1:** Average frequency count on pelvic-thorax coordination during running across the gait cycle in the sagittal, frontal and transverse plane. (IPDD – inphase proximal dominance / (IPDD – inphase distal dominance / (APDD – antiphase distal dominance / (APPD – antiphase proximal dominance).

In the current study, 3D pelvic-thorax coordination patterns during the pre-fatigue run confirmed the results of a previous study [1]. Coordination patterns during the post-fatigue run did not differ to the pre-fatigue run. However, there was a significant increase ( $p < 0.07$ ) in  $\dot{V}O_2$  uptake during the final minute of the post-fatigue run ( $39.9 \pm 6.2$  ml/min/kg) compared to the final minute of the pre-fatigue run ( $38.4 \pm 4.3$  ml/min/kg). While not highlighted from vector coding analysis, sagittal plane kinematic waveforms highlighted an increase in thorax flexion across the entire gait cycle during the final minute of post-fatigue run. This postural adaptation following induced fatigue is in line with a previous study [3].

## Conclusion

This study highlighted that an increase in thorax forward lean as a result of being in a fatigued state may impact on running economy due to an increased  $\dot{V}O_2$  uptake.

## Effect of the wear of city shoes on the variables characterizing the foot / ground interaction

Éliot Polomé<sup>1,2</sup>, Nicolas Théveniau<sup>1</sup>, Cédric Vigier<sup>1</sup>, Raphaël Dumas<sup>2</sup>, Thomas Robert<sup>2</sup>

<sup>1</sup>CTC, Comité Professionnel de Développement Économique Cuir Chaussure Maroquinerie, Lyon, France

<sup>2</sup>Université Lyon, Université Gustave Eiffel, LEMC UMR 519406, F69622, Lyon, France

Email: [epolome@ctcgroupe.com](mailto:epolome@ctcgroupe.com)

### Summary

This study examined the effect of the wear of city shoes on different variables characterizing the foot / ground interaction during gait analysis and during physical tests. Gait analysis variables did not change while physical tests revealed significant decreased with wear of the shoe.

### Introduction

During locomotion, the shoes deteriorate over the multiple steps a person has taken. Wear occurs both on the sole and on the upper (loss and fatigue of material, formation of holes, etc.). However, there is little information on the rate of deterioration as the number of steps increases, nor on its impact on the gait characteristics. Information only exists regarding the rate of deterioration over increasing mileage for running shoes [1, 2, 3]. Therefore, this study examined the effect of the wear of city shoes on gait.

### Methods

Six healthy men (age  $36.8 \pm 7.8$  years, height  $1.78 \pm 0.03$  m, body mass  $74.9 \pm 6.1$  kg) received a new pair of city shoes (Stan Smith, Adidas, DE) which they were required to wear during their working day for a period of 60 days. Step counts were determined using an ONWALK 900 pedometer (Newfeel, Decathlon, FR).

The participants carried out three series (initial test, 30-day test and 60-day test) of gait analysis on a dual-belt instrumented treadmill (Ortec, Columbus, OH, USA) with two imposed speeds (3 and 5 km/h). Acquisition frequency was set at 2000 Hz. Before each acquisition, two physical tests were carried out on the shoe in order to evaluate the effect of the wear on the sole and the upper: generating homogeneous shock at the base of the sole to assess the transfer coefficient of the sole and flexing the shoe in the forefoot with an angle of 45 degrees to assess the longitudinal flexibility in flexion.

Data processing was carried out using MATLAB software. Data from the treadmill was filtered (Butterworth low-pass 4th order, cut-off frequency of 50 Hz). The heel-strike and toe-off events were detected using the vertical ground reaction forces (vGRF), with a threshold set at 5% of the body weight. The following variables were observed: number of steps from the pedometer, initial peak vertical ground reaction force (IPF), loading rate of the vertical force from touchdown to the first peak vertical force (FLR), breaking peak anteroposterior ground reaction force (bPPF), propulsive peak anteroposterior ground reaction force (pPPF) from the treadmill and transfer coefficient of the sole (TCS) and longitudinal flexibility in flexion (LFF) from the

physical tests. ANOVA with repeated measures was employed to assess wear effect,  $\alpha$  was set at 0.05.

### Results and Discussion

After 60 days, participants have performed  $379\,161 \pm 110\,000$  steps, corresponding to  $6\,319 \pm 1\,835$  steps per day of use. Table 1 shows that gait analysis variables did not change between initial and 60-day tests. Conversely the physical tests revealed significant decreased in TCS and LFF between initial and 30-day tests. No further change was observed between 30-day and 60-day tests. As expected, gait kinetic variables were dependent on velocity.

**Table 1:** Gait analysis and physical variables during walking for initial, 30-day and 60-day tests. Mean (SD) data of each variables. \*Significant difference between 3 and 5 km/h. \*\* Significant difference between initial and 30-day / 60-day tests.

Thirty days and about 200 000 steps were sufficient to demonstrate wear of the shoes (degradation of their mechanical properties). Although the physical measures did not evolve during the second month, tests will be performed to assess further changes. The changes in the shoe revealed by the physical tests did not affect the foot / ground interactions, possibly due to participant adaptations [4] - that we plan to further investigate - or lack of sensitivity of these kinetic variables due to the fact that walking is a less dynamic activity than running.

### Conclusions

While ground reaction forces during gait remains unaltered, physical tests allow to characterize some alteration of the materials of a shoe after one month of wearing.

### Summary

Understanding lower extremity leg joint functions (JFs) is essential for the design of technical devices to assist locomotion. In running, footwear is the interface between the foot and the ground, modulating the distribution of mechanical work across joints [1]. However, little is known about how footwear can redistribute joint work and thus change the JFs. Here we analyzed the JFs for running in different footwear conditions by using the joint functional indices (JFIs). We found that the JFs were significantly affected by the type of footwear. The strut index of the ankle and knee increased in more minimal footwear. We found an inverse relationship between footwear minimalism and the spring index. We suggest that the type of footwear used should be considered when designing passive or active e.g. biomechatronic systems.

### Introduction

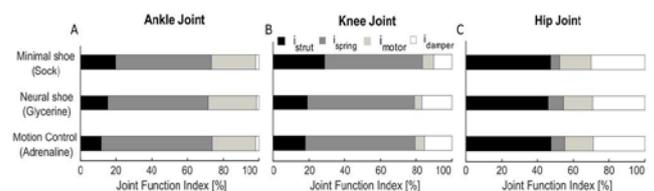

The JFIs describe the lower extremity JFs based on mechanical joint work as spring, damper, motor, and strut elements [2]. It has been shown that the JFs of the lower extremities adapts to various task demands. However, the influence of footwear on the JFs in running has not been studied yet. Therefore, the purpose of the study was to quantify if the JFIs are affected by the type of footwear used.

### Methods

We determined lower extremity sagittal plane joint biomechanics (n=103) with a motion capture system and a force plate during overground running (3.5 m/s). Participants ran with three types of shoes (minimal, Sock; neutral, Brooks Glycerine; support, Brooks Adrenaline). We calculated the JFIs for the stance phase of running [2]. Friedman's test and effect sizes (Kendall's W) for each JFIs were determined to quantify the influence of footwear on the JFs.

### Results and Discussion

We found the strongest footwear effects at the ankle and the knee joint (Tab.1). The strut index of the ankle and knee joint was higher in the minimal compared to the cushioned footwear conditions (Fig.1). In contrast, the spring index of the ankle and knee joint was higher in more cushioned footwear. We observed a significantly higher damping index for the minimal compared to the cushioned shoe condition. We further observed a high footwear effect for the damping index of the knee joint induced by the minimal shoe. Differences in JFs might be caused by changes in the footfall pattern and the associated load and work redistribution while running in a more minimal shoe.

**Figure 1:** Lower extremity JFIs for the three footwear conditions.

### Conclusions

Footwear can affect the JFs in running. Therefore, footwear should be considered when evaluating training interventions and designing, e.g. biomechatronic systems for the assistance of human locomotion. In this context, further studies might also explore the relationship between JFIs and injury risk.

## The effect of running shoes' milage on lower limb muscle actiCity

□□ abenicht<sup>1</sup> □ S. Kratzenstein<sup>1,2</sup>

<sup>1</sup> Institute of Sport Science, Kiel University, Germany □ <sup>2</sup> CAU Motion Lab, Kiel University, Germany,

### Summary

Previous studies showed that the mechanical properties of running shoes change with increasing milage, which requires an adaptation of muscle responses to continuously changing load to protect the musculoskeletal system from injuries. Furthermore, the runner must decide when the original shoe properties are worn out. An autonomous quantification of biomechanical key parameters could provide an individual assessment of increasing pathological impacts. This study quantifies the muscle activity as a direct motor response to ground impacts and aims to investigate changes in the integrated EMG (iEMG) within 500km of running. The activity of four lower limb muscles was quantified every 100km and compared to iEMG while running un-worn reference shoes. The results revealed no systematic, intra-individual changes in the muscle response. It remains unclear whether the iEMG was not suitable to identify changes in activity patterns or the range of usage did not lead to effective changes of the mechanical properties.

### Introduction

The mechanical properties of running shoes change with increased usage [1]. Here, most studies analysed ground reaction forces to quantify the physiological response to these changes. Only very few studies quantified changes in muscle activity [2]. Recommendations for a shoe substitution range from 300-1000km, depending on i.e. runners' weight and shoe type. An autonomous analysis, which identifies physiological thresholds could enable runners to individually identify the time when the original mechanical properties are worn-out. In this study, we quantify the iEMG during ground contact of four lower limb muscles and evaluate changes considering the runner's feedback on shoe comfort.

### Method

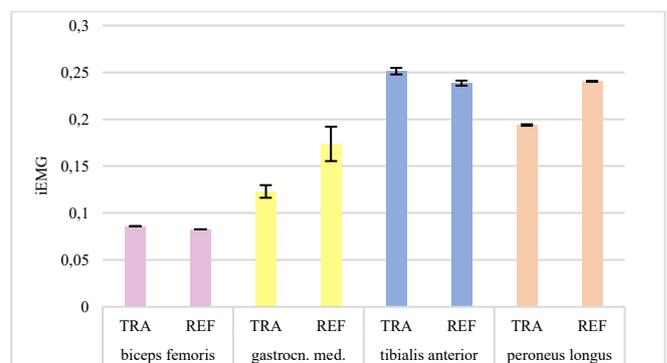

Eight recreational runners participated in this study. Each runner was considered as single case study, since the heterogeneity of the cohort included age, gender, performance level, and shoe type. All runners were equipped with two identical new pairs of running shoes, whereas one pair was kept un-worn as the reference shoe (REF), while the other pair (TRA) was worn for at least 500km within the regular training. The muscle activity of the left biceps femoris (□F), gastrocnemius med. (GM), peroneus longus (PL), and the tibialis ant. (TA) was measured every 100km during 3 x 8min (warm-up, TRA shoe, REF shoe) treadmill runs at a sub-maximal velocity. The order of REF and TRA was randomized with 4min rest between the sessions.

EMG electrodes placement and signal processing were conducted according to SENIAM recommendations [3]. The EMG (myon320, prophysics, 1000Hz) data collection

included at least 25 ground contacts. iEMG was calculated for each cycle. Student t-test was applied to test for intra-individual differences between the shoes.

### Results and Discussion

The average differences ( $n \geq 25$  ground contacts) in iEMG over all athletes, here focussing on the final difference from REF after 500km, range from  $0.02 \pm 0.004$  (□F),  $-0.01 \pm 0.002$  (TA),  $0.02 \pm 0.003$  (PL), and  $-0.01 \pm 0.003$  (GM). All differences are significant ( $p \leq 0.05$ ). Figure 1 shows exemplary results for a male runner ( $m \approx 78\text{kg}$ ) after 500km.

**Figure 1** □ Averaged iEMG ( $n \geq 25$  ground contacts) of one runner after running 500km

The results show individual characteristics and changes of the iEMG. It remains unclear whether the iEMG is not suitable to identify smaller changes due to its already high variation within each trial or the milage of 500km did not lead to effective changes in the shoe's mechanical properties, although this would contradict the runner's feedback about decreasing comfort. Furthermore, it should be considered that the large number of involved muscles leads to a high number of degrees of freedom to response to the load change, which cannot be recorded in a single measurement.

### Conclusion

This study showed the sensibility and the individuality of muscle activity. Although there are differences in the muscle activity while running in the TRA or the REF, these differences are not consistent. An EMG analysis alone seems not to provide a reliable indicator of the need to change the running shoes.

## Predictive neuromuscular simulation of the sit-to-walk movement

van der Kruk, Eline<sup>1</sup> & Geijtenbeek, Thomas.<sup>1</sup>

<sup>1</sup>Biomechanical Engineering, Delft University of Technology, Delft, the Netherlands

Email: [e.vanderkruk@tudelft.nl](mailto:e.vanderkruk@tudelft.nl)

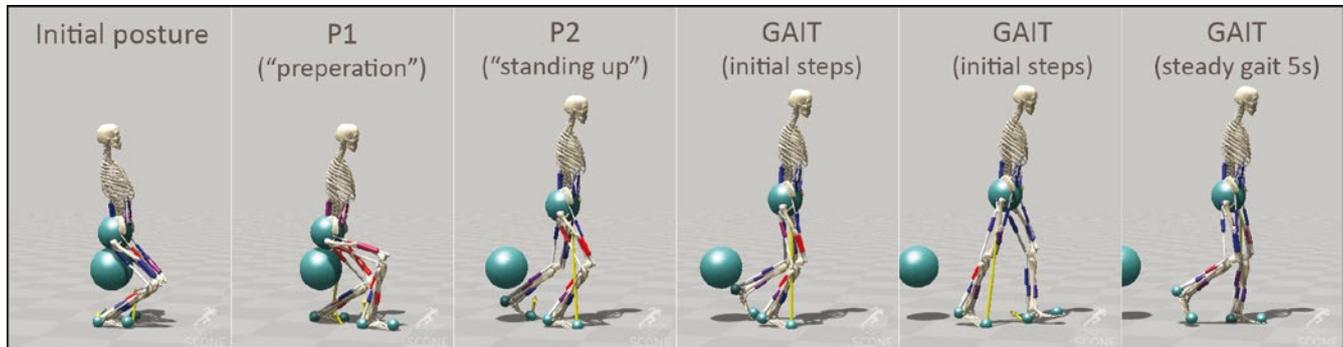

Figure 1: Images from the predictive sit-to-walk simulation using CMA-ES optimization of three controllers (GAIT, P1, P2) in SCONE.

### Summary

Progression of neuromuscular decline often leads to incorrect or insufficient compensation strategies, both through altered muscle recruitment and changes in movement trajectories. Predictive neuromuscular simulations are an effective tool for discovering those strategies, enabling clinicians to design treatments that are both more effective and efficient for prolonging the mobility of the patient. In this study we have developed a predictive neuromuscular model that can simulate the sit-to-walk movement using SCONE.

### Introduction

The treatment of age-related mobility impairments is increasingly relevant in our ageing societies. These impairments typically do not arise at the onset of age-related physical decline, due to the redundancy of the human movement system. Functional redundancy is the redundancy in the muscle architecture of the human body; the result of functional redundancy is compensation. Most state-of-the-art musculoskeletal studies (inverse/forward) however do not account for compensation: they use prescribed movements (kinematics) to study decline of variables. Predictive models that generate kinematics *de novo* have the potential to simulate the capacity versus compensation relationship, since they can generate new movement trajectories. The aim of this study is to develop a predictive neuromuscular model that can simulate the sit-to-walk movement, an important daily life activity.

### Methods

The musculoskeletal model is based on an OpenSim [1] model representing a male adult with height of 1.80m and a mass of 75kg. The model has 10 DOF (2D model) and is actuated by 22 Hill-type muscle-tendon units. Contact force between the feet and the ground and between the buttocks and the chair were modelled with Hunt-Crossley force spheres (two at the foot, one at the pelvis, one at the chair). Our sit-to-walk controller consists of a gait controller (GAIT) based on [2] and a two-phase stand-up controller (P1, P2) based on proprioceptive feedback from muscle

length feedback (L), tendon force feedback (F), and constant excitation (C). The delayed feedback pathways were both monosynaptic and antagonistic. The controller was developed and optimized in SCONE [3] using a shooting-based optimization method. The 152 free parameters were optimized to minimize the gross cost of transport, at a prescribed minimum gait velocity, while avoiding falling, ligament injury, and excessive head motion. We ran multiple parallel optimizations with the same initial guess and used the best set as start for the next set of optimizations. Final results were compared to recorded kinematics (Vicon), ground reaction forces, and EMG from young (18-35 year) and older (>65 year) adults (N=50) [4], in which participants were asked to stand up and walk to a table, at self-selected (5x) and fast speed (5x).

### Results and Discussion

The predictive 2D lower limb model was able to simulate a sit-to-walk movement that matches real-world kinematic recordings. The experimental study showed that >80% of the older adults used their arms to push off while standing up in a daily life setting. To allow for realistic compensation, we are working on a 3D upper- and lower limb model.

### Conclusions

With its current limitations the developed model was not able to simulate all daily life compensation strategies in sit-to-walk, but the model does simulate the sit-to-walk movement well for some strategies.

### Summary

We developed a simulation workflow to estimate rotator-cuff muscle strains and to explore 3D shoulder movements that minimize strain in rotator-cuff muscle tendons. Our findings reveal that the shoulder can be mobilized within a large workspace of low strain, which could be adopted during physical therapy to safely increase the range-of-motion of the shoulders of patients with rotator-cuff injuries.

### Introduction

Shoulder injuries are common with rotator-cuff tears alone occurring at a rate of 50% among individuals over 60 [1]. With rehabilitation, it often takes a year for patients to recover normal range-of-motion (RoM) and strength. Immobilization after surgery and limited RoM during rehabilitation, particularly in the early stages, limit the risks of reinjury, but also delay recovery. Reinjury is associated with strains in torn or sutured tendons of rotator-cuff muscles. Our aim is to find rehabilitation movements with increased RoM while limiting reinjury risk during the recovery from a rotator-cuff injury.

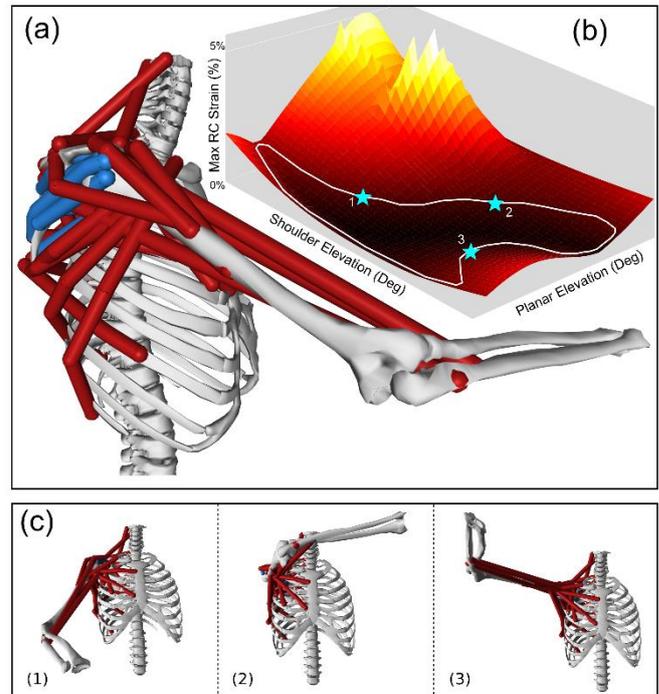

### Methods

We employed a musculoskeletal model of the shoulder [2] (Fig. 1(a)) to explore the passive movements of the glenohumeral joint while estimating the tendon strains in the affected rotator-cuff muscle(s). Muscle strains were computed by solving for muscle forces necessary to hold the shoulder in a given position using static optimization to resolve individual muscle activations and forces in OpenSim [3]. An entire workspace of tendon strains was computed for each rotator-cuff muscle for glenohumeral joint positions that span its RoM. From this workspace, low strain trajectories and subspaces were visualized and identified. The musculoskeletal model was then used to visualize shoulder motions along low strain paths. A strain of 1% was used to highlight regions of low reinjury risk. These regions were compared to the passive RoM of physical therapy movements prescribed post-surgery [4].

### Results and Discussion

Large regions of low rotator-cuff strain were found in the movement space of the shoulder as were regions of high strain (Fig. 1). Strains were particularly sensitive to internal and external rotation of the glenohumeral joint. Identified regions of low rotator-cuff strain were typically larger than those prescribed during physical therapy.

The strain spaces from our musculoskeletal model indicate that shoulder movements can be planned in such a way that they minimize strain and limit the risk of reinjury. □y estimating strains that cannot be perceived by the therapist, the model could provide therapists with visual and/or vibrotactile feedback of strains to keep motions safe during physical therapy when applying shoulder movements in real-time.

**Figure 1:** (a) OpenSim shoulder model used to estimate strains in specific rotator-cuff muscle tendons. (b) 3D surface plot showing the max strain experienced by any tendon of the rotator-cuff muscles at every pose (specified by glenohumeral joint angles) in the reachable workspace. The weight of the arm is assumed to be supported in such a way that the shoulder is moved passively (with minimal muscle activation related to gravity compensation). In white is an example trajectory (movement) that traverses a large range-of-motion at low rotator-cuff tendon strain. (c) Sample of the shoulder model in selected poses (1), (2) and (3) along the low-strain trajectory. Note, two degrees of freedom are shown for visualization, however our strain maps include axial rotation for full motion of the glenohumeral joint.

### Conclusions

Our musculoskeletal simulations reveal a large range of shoulder movements that pose minimal risk of rotator-cuff reinjury. We hope this work will enlighten and encourage physical therapists to explore these movements during the rehabilitation of rotator-cuff injuries and limit losses in RoM and thereby speedup the recovery of their patients.

## Summary

Patients with symptomatic lumbar spinal stenosis have higher paravertebral and hip abductor muscle activation at the beginning of a 30min walking test compared to healthy controls that further increases at the end of the test in the longissimus thoracis muscle.

## Introduction

Patients with symptomatic lumbar spinal stenosis (sLSS) suffer from pain and functional limitations such as a limited walking distance [1] or altered pelvic acceleration compared to healthy people [2]. After onset of claudication symptoms, increased postural sway [3] and increased forward flexion of the trunk [4] have been reported. Paravertebral muscle activation and forward trunk flexion during walking decreased after decompression surgery, [4]. The aim of this study was to compare muscle activation patterns of hip abductor and paravertebral muscles and joint kinematics during walking between patients with sLSS and healthy persons and to investigate whether these patterns change during a 30min walking test.

## Methods

Twenty patients (12 female, 8 male; age, 70.4±8.5 years; body mass index (BMI), 26.8±4.0 kg/m<sup>2</sup>, Oswestry Disability Score (ODI), 28.9±13.1) with sLSS scheduled for decompression surgery and 19 healthy subjects (11 female, 8 male; age, 63.0±10.1 years; BMI, 24.1±3.4 kg/m<sup>2</sup>; ODI, 1.2±2.2) performed a 30min walking test along a 200m corridor with continuous measurement of surface electromyography and 3D accelerations (myon, Switzerland) of the gluteus medius, multifidus and longissimus thoracis muscles. Every 3 min, sagittal kinematics of the ankle, knee and hip joint were recorded with seven inertial sensors (RehaGait, Hasomed, Germany). In case of onset of symptoms that caused patients to pause, the test was ended prematurely. Accelerometer signals of the longissimus sensor were used to determine the heel strikes of 20 consecutive steps at the beginning and end of the walking test [5]. EMG envelopes were calculated using

a moving average filter (window size, 100 ms) and normalized to the peak activity at the beginning of the walking test. Differences in muscle activation patterns and joint kinematics between patients and controls (independent sample t test) and between beginning and end of the walking test (paired t tests) were determined using statistical parametric mapping ([www.spm1d.org](http://www.spm1d.org); P<0.05).

## Results and Discussion

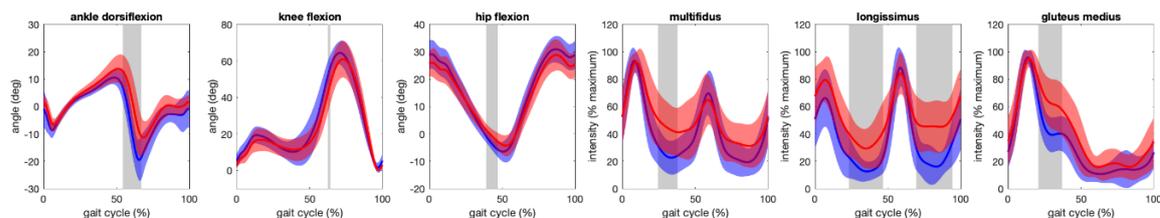

The patients walked slower (1.00±0.19 vs. 1.26±0.10 m/s, P<0.001) and for a shorter time (22.8±10.7 vs 30min; P=0.006) compared to healthy controls. Patients had less ankle plantarflexion (54-67% gait cycle (gc), P=0.002) and less hip extension (39-47%gc, P=0.029), as well as higher muscle activation of the multifidus (25-38%gc, P<0.001), longissimus (24-47%gc, P<0.001 and 70-94%gc, P<0.001) and gluteus medius (21-37%gc, P<0.001) than controls (Figure 1). In patients, right longissimus muscle activity was higher at the end of the test compared to the beginning (+16%, 0-5%gc and 97-100%gc, P=0.016 and P=0.035).

## Conclusions

The more continuous and for longissimus even increasing muscle activity during the walking test may be related to the reported greater lumbar flexion in patients with LSS [4]. The slower walking speed and slightly altered kinematics might be caused by nerve dysfunction due to increasing epidural pressure [6] and indicate other adaptations in the gait patterns to relieve pain during walking. Whether these altered muscle activation patterns and kinematics during walking can be influenced by surgery and following rehabilitation still needs to be investigated.

## Altered timing in trunk rotation with the ToneFit Reha compared to Nordic Walking in people with low back pain

Eveline S. Graf, Carole A. Pauli, Bettina Sommer

Institute of Physiotherapy, School of Health Professions, Zurich University of Applied Sciences, Winterthur, Switzerland

Email: [eveline.graf@zhaw.ch](mailto:eveline.graf@zhaw.ch)

### Summary

This study compared the trunk rotation during walking with the ToneFit Reha (TFR), a product with push-pull resistance handles, and Nordic Walking. The TFR resulted in a delayed reversal of trunk rotation towards the end of the second double support phase. This change in timing allowed to manage the challenged balance when walking with the TFR.

### Introduction

Physical activity is widely used for the treatment of low back pain (LBP) [1]. Nordic Walking (NW) has been used as an exercise to increase the benefits of walking in such population resulting in increased core stability [2].

The ToneFit Reha (TFR) is a newly developed product, worn around the waist (Figure 1). It mimics normal walking but with added push-pull handles with adjustable resistance. The TFR is intended for rehabilitation, allowing individual settings for each person and each side of the body. The aim of this study was to determine the effect of walking with the TFR on trunk rotation compared to NW.

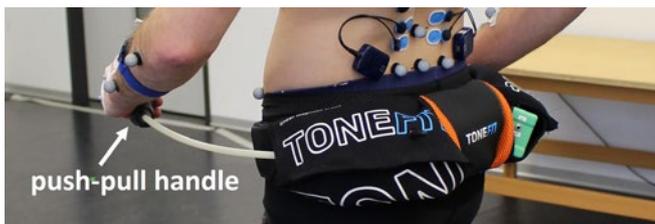

Figure 1: ToneFit Reha.

### Methods

Ten participants with LBP (age  $42.1 \pm 5.4$  years, mass  $71.4 \pm 8.0$  kg, height  $172.1 \pm 5.2$  cm) were recruited. After signing informed consent, retro-reflective markers were added to the spine [3] and arm and a familiarization period for each condition was allowed. Each participant performed ten trials with NW followed by the TFR at the same speed.

Marker trajectories were recorded using 12 Vicon cameras (240 Hz, Vicon Vantage, Vicon Motion Systems Ltd, UK). Trunk rotation angles, shoulder flexion angles as well as durations of double and single support phases were averaged over the left and right side and of all trials per participant for statistical analysis. A paired t-test with Bonferroni adjustment resulting in a significance level of 0.01 was used to determine statistically significant differences between conditions.

### Results and Discussion

While the peak contralateral trunk rotation angle did not differ between TFR and NW, the peak occurred later during

TFR. Further, the first double support phase was significantly longer while the second single support phase was significantly shorter for TFR (Figure 2). The timing of the peak shoulder flexion (indicating the reversal of the arm movement) did not differ between TFR (43% of gait cycle) and NW (45% of gait cycle).

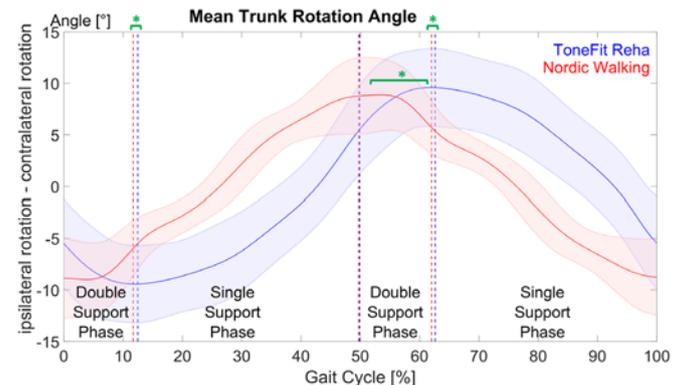

Figure 2: Mean trunk rotation angle [in degrees] during gait cycle [in percent], blue = ToneFit Reha, red = Nordic Walking, green: sign. difference ( $p < 0.01$ ).

During TFR, the push-pull movement with the handles needed to be counterbalanced by the trunk. Changing the direction of the trunk rotation while simultaneously generating enough force to stabilize against the applied force at the handles, is a challenging task. It is concluded that this challenge was met by delaying the directional change of the trunk rotation towards the end of the second double support phase. The increased base of support during this phase provides more stability to the body. Also, due to this delay, the leading arm was closer to the body when the change of trunk rotation occurred. Therefore, the lever arm was smaller resulting in less force needed in the trunk to keep the upper body stable.

### Conclusions

The TFR caused significant changes in the timing of the trunk rotation to manage the increased challenges due to instability. If this added challenge in stability and the chosen strategy is beneficial for rehabilitation, will need to be determined in future research.

## 3D Characterisation of Isolated Disc Specimens Subject to Cyclic Loading

Shahid Sayward, A.W. Miles, P.S. Keogh, S. Gheduzzi

Department of Mechanical Engineering, University of Bath, Bath, United Kingdom

Email: [sh2616@bath.ac.uk](mailto:sh2616@bath.ac.uk)

### Summary

Defining the viscoelastic behaviour of spinal specimens is critical to understanding the biomechanics of the healthy, damaged and surgically modified spine. A method using MATLAB SimScape to tune a non-linear Kelvin element to spinal load-displacement curves is proposed to fully characterise behaviour. The model matches experimental dissipated energy with a mean difference of 4% and allows full characterisation of the intervertebral disc behaviour.

### Introduction

Back pain affects around 80% of the population and research in the field has been prominent since the mid 1900s [1]. The most widespread technique for analysing spinal test data uses linear least squares regression to calculate gradients of load-displacement curves from specimens subject to cyclic loading [1, 2]. It is favoured for simplicity but relies on assumptions which neglect viscoelastic characteristics.

Loaded cyclically, spinal specimens exhibit a time-dependent response in an S-shaped hysteresis loop [3]. This response can be approximated using a polynomial or double sigmoid function but these approaches give non-unique solutions defined by parameters without useful physical representation. A computational method for tuning non-linear viscoelastic models to spinal load-displacement data has been developed to fully characterize behaviour using spring and damper elements. This method expands on that introduced by Panjabi (1991) [4]. The model comprising a non-linear Kelvin element (Figure 1 left) is implemented.

### Methods

Three thoracic porcine functional spinal units were obtained and dissected into isolated disc (ISD) specimens. During testing, specimens were wrapped in moist tissue and plastic wrap to prevent dehydration. A 500N preload was applied for a 30-minute equilibration period prior to 6-axis stiffness testing at a constant rate of 0.1 Hz (amplitudes in Figure 1).

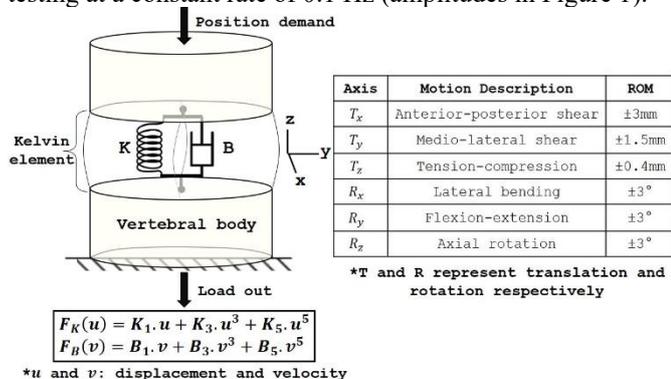

Figure 1: Viscoelastic model of disc and axis motion descriptions

The non-linear Kelvin model was implemented in MATLAB Simulink R2020b using the SimScape library. Solution coefficients were determined with an optimization cost function using sum of squared errors with a non-linear least squares optimization method and a Trust-Region-Reflective algorithm [5].

### Results and Discussion

Figure 2 shows an example of the fit obtained by the model for a single cycle in axial rotation.

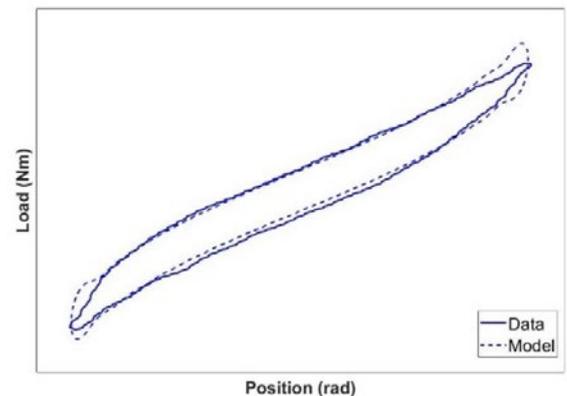

Figure 2: Viscoelastic model and fit obtained for axial rotation

The mean % difference between area enclosed by the model and experimental curves is below 4%, indicating the model's ability to represent dissipated energy.

At solution, the primary coefficients  $K_1$  and  $B_1$  showed average percentage deviations from mean less than 24%. However, for higher order coefficients, this repetition decays.

### Conclusions

The agreement between dissipated energy in the experiment and model data and repetition in primary coefficients shows good potential for use of this method. The method illustrates that non-linear viscoelastic models can be used to fully describe spinal ISD load-displacement curves. Further work

### Summary

The objective of this study is to find a strategy to estimate the acceleration of the center of mass (CoM) of the hockey player while doing a sprint task. The data are acquired directly on the field so the methodology used to calculate the acceleration must be usable without the instrumentation of a motion analysis laboratory. For that reason, we compared three different methods for calculating the acceleration of the centre of mass: the first considered the instantaneous acceleration of the anatomical point L5, the second considered the anthropometric formula of De Leva and the third considered the Winter's formula.

### Introduction

Field hockey is a competitive, high intensity sport game and one of the most popular team sports now played around the world. In this study we acquire data relative to a 10m sprint task, made by athletes of a female elite-hockey team, holding the hockey stick with one hand. The main purpose of this contribution is to analyze the Center of Mass (CoM) acceleration of the players while they are performing the hockey-specific task previously described. To this extent three approaches were adopted: 1. Track the anatomical point L5 2. Apply the anthropometric formula of De Leva [1] 3. Apply the Winter's formula [2] using plantar pressure data.

### Methods

Nine female athletes signed the informed consent and took part in the study (mean ± SD age: 21.56 ± 4.67 years, BMI: 22.01 ± 0.99 kg/m<sup>2</sup>). The players were acquired, directly on field, while performing a 10m sprint holding the hockey stick with one hand, by means of four synchronized GoPro Hero 3 cameras and a Novel Pedar plantar pressure system. For performing the video tracking, the application TrackOnField (SoF S.r.l.) was used, while to implement the three different approaches for calculating the CoM acceleration Matlab codes were developed. The following pipeline was used: 1. The 3D trajectory of the anatomical point L5 was extracted from the video sequences and its instantaneous acceleration was calculated. 2. To apply the anthropometric formula of De Leva [1], the anthropometric measure of the athletes was retrieved from the anatomical landmarks and the CoM trajectory calculated. 3. The center of pressure data (CoP) was extracted from the plantar pressure system and the Winter's [2] (1) formula was applied to calculate the CoM acceleration (CöM) as follows:

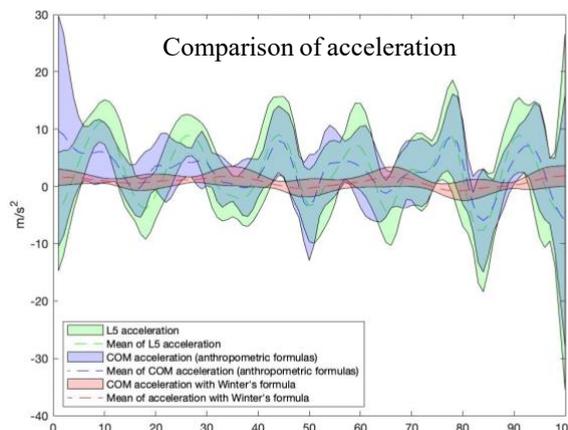

$$\text{CoP} - \text{CoM} = k \cdot \text{CöM} \quad (1)$$

where  $k$  is the ratio between the inertial moment of the human body and the product of the body force of the subject and the height of the CoM:

$$k = \frac{I}{W * h}$$

### Results and Discussion

The results showed a good agreement between the first two methods: the anthropometric approach and the trajectory of the anatomical point L5 (Fig.1). Meanwhile, CoM acceleration calculated using the Winter's formula was lower compared to the other two methods.

**Figure 1:** In the figure is reported the comparison across the acceleration extracted from L5, the anthropometric approach and the Winter's formula.

### Conclusions

This study showed that in dynamic conditions, CoM acceleration could be estimated using different approaches but, only in two of the considered cases this led to comparable results. For validation purposes this approach should be further applied in static condition with the aid of a force plate that could represent a gold standard.

## Summary

Trunk center of mass (COM) position at initial contact of a 90° cut was compared between soccer players who went on to ACL injury and those who did not. Measures of COM position were assessed at initial contact (IC) and peak knee abduction moment (PKAM) with no significant differences between injured and uninjured players. These findings suggest that trunk COM at IC and PKAM are not influencing risk of ACL injury when cutting.

## Introduction

Anterior cruciate ligament (ACL) injuries are a prevalent injury among women's soccer players, and many occur during cutting maneuvers without contact from another player [1,2]. High knee abduction moments have been identified as a lower extremity biomechanical risk factor for non-contact ACL injury [3]. Shifting the trunk laterally toward the stance foot has been shown to increase knee abduction moments by increasing the moment arm between the ground reaction force and knee joint [4]. Additionally, trunk lateral displacement after a sudden force has previously been used to identify athletes who go on to knee injury [5]. However, trunk displacement during a sport-specific task has not been studied prospectively before. Thus, the purpose of this study was to determine whether two methods of trunk COM position during a 90° cut differentiate between soccer players who went on to ACL injury and those who did not.

## Methods

Forty-one NCAA D1 and D2 women's soccer players completed preseason motion analysis of a 90° cut. Kinematic and kinetic data were recorded simultaneously using an 8 camera system and an embedded force plate. The trunk model used iliac crest and acromion markers to define the proximal and distal segments respectively, and a rigid cluster of tracking markers was placed on the trunk. The trunk was modelled as a cylinder and a universal segment depth of 0.12m was applied. Position of the trunk COM was also calculated at initial contact (IC) and peak knee abduction moment (PKAM) relative to proximal tibia (COM<sub>k</sub>) and relative to the foot (COM<sub>f</sub>). Position was normalized to leg length, and (-) position indicated the COM was medial to the knee. Throughout the season, each team's respective athletic trainer recorded injuries and four non-contact ACL injuries were reported at the conclusion. The right and left limb of the uninjured participants were averaged so that each uninjured participant contributed a single healthy limb and each injured participant contributed a single ACL injured limb to our statistical model [6]. Independent t-tests were used to determine whether COM position differed between players who

went onto ACL injury and those who did not. Alpha was set a priori at p<0.05.

## Results and Discussion

There were no significant differences between injured and uninjured participants at IC for COM<sub>i</sub> or COM<sub>f</sub> (Table 1). There were also no significant differences between injured and uninjured participants at PKAM for COM<sub>i</sub> or COM<sub>f</sub> (Table 1). Although uninjured players demonstrated a slightly more medial trunk COM position when measured relative to the foot, these results suggest trunk COM position does not differ between soccer players who go on to ACL injury and those who do not during a sport-specific task.

Variable, event	Mean±SD (m)		p-value	Effect Size
	Uninjured (N=37)	Injured (N=4)		
COM <sub>i</sub> , IC	-0.30±0.06	-0.30±0.1	0.95	D=0.03
COM <sub>f</sub> , IC	-0.26±0.06	-0.24±0.05	0.50	D=0.37
COM <sub>i</sub> , PKAM	-0.89±0.15	-0.84±0.05	0.51*	η <sup>2</sup> =0.01
COM <sub>f</sub> , PKAM	-0.80±0.08	-0.67±0.17	0.13*	η <sup>2</sup> =0.06

Table 1. Descriptive statistics for COM measures and results of independent t-tests at initial contact (IC) and peak knee abduction moment (PKAM) for soccer players completing a cutting task. \*Unequal variances between groups so Mann-Whitney U test utilized.

## Conclusions

These results suggest that trunk COM position at initial contact and at peak knee abduction moment may not be primary factors in lower extremity risk for ACL injury during cutting maneuvers. While larger frontal plane moments have been indicated to influence risk of non-contact ACL tears in the past, the present findings do not highlight any differences. The small number of injuries that occurred in our sample suggest further study may be warranted.

# SMARTPHONE-BASED DEMOCRATIZATION OF VERTICAL JUMP HEIGHT ESTIMATE

Guido Mascia<sup>1</sup>, Alessandro Valenti<sup>1</sup>, Valentina Camomilla<sup>1</sup>

<sup>1</sup>Interuniversity Centre of Bioengineering of the Human Neuromusculoskeletal System, University of Rome “Foro Italico”, Italy

Email: [g.mascia@studenti.uniroma4.it](mailto:g.mascia@studenti.uniroma4.it)

## Summary

A method for estimating vertical jump height directly from smartphone measures is presented, aiming to democratize this computation. Two multiple linear regressions, combining time-frequency and anthropometric quantities, were devised to correct for soft tissue wobbling. The height computed from force platforms measures was used as gold standard.

## Introduction

Vertical jump height ( $h$ ) is commonly used to analyze lower limb power generation both in clinical and sport context. Height is often computed through force platforms (FPs), although Inertial Measurement Units (IMUs) are becoming more and more popular, given their reduced cost and size. However, critical issues in  $h$  estimation with IMUs exist, mostly related to the inertial effects of wobbling masses, as part of a wider phenomenon known as soft tissue artefact (STA), also dependent on IMU location. Smartphones are devices within everyone’s reach whose internal IMUs can be exploited as a handy-but-bulky source of information. Hence, the aim of this study is to estimate accurate jump height from time-series measured with a smartphone. Reduction of STA-related errors is achieved by devising reliable multiple linear regression models (MLR) that embeds time-frequency and anthropometric quantities.

## Methods

Seventeen participants (11M, 6F; age:  $26.8 \pm 4.7$  years; height:  $1.7 \pm 0.1$  m; mass:  $72.0 \pm 13.6$  kg) were recruited. To each of them, biceps, triceps, subscapular, and superior-anterior iliac crest (B, T, S, and I, respectively) skinfold lengths were measured. They performed 3 countermovement (CMJ) and 3 squat (SJ) jumps on a FP, bringing the smartphone at the chest and maintaining the elbows at the waist height to limit the effects of arm swing. Smartphone measures were performed using the app Phyphox [1]. Smartphone IMU data were aligned to the world reference frame according to [2]. Variational Mode Decomposition (VMD) was applied to IMU acceleration signal to obtain three components, each centered around a central frequency [3]: the low-frequency ( $f_3$ ) component was associated with the jump; the mid- and high-frequency ( $f_1, f_2$ ) with the inertial effects due to wobbling masses. Moreover, the negative acceleration peak after the take-off instant (NP), the positive acceleration peak (PP) and their

ratio ( $R_{PN}$ ) were taken into account as associated with upward/downward arm swing and inertial effects. Take-off velocity method was used to compute  $h$  (FP),  $\hat{h}$  (IMU) and  $\hat{h}$  (MLR). Two MLRs were devised, one for CMJ ( $MLR_{CMJ}$ ), one for SJ ( $MLR_{SJ}$ ). Best-subset regression method with k-fold cross validation was used to select the best subset of variables to be included in each MLR. A scheme of the procedure is presented in Figure 1.

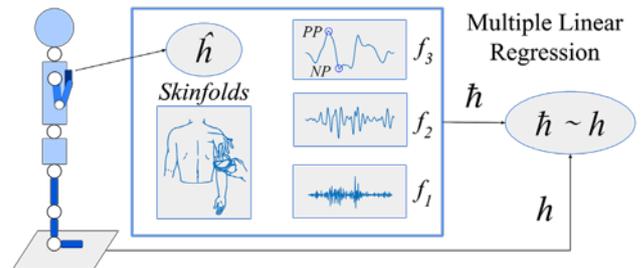

Figure 1: Schematic depiction of the procedure for  $\hat{h}$  estimation.

## Results and Discussion

Mean average errors with respect to  $h$  showed that  $\hat{h}$  was erroneous by  $6 \pm 5$  cm and  $5 \pm 4$  cm for CMJ and SJ, respectively. The  $\hat{h}$  estimated with  $MLR_{CMJ}$  showed an average error of  $2 \pm 1$  cm, while the one computed through  $MLR_{SJ}$  showed  $2 \pm 2$  cm average error.  $MLR_{CMJ}$  predictors explained the 83.8% ( $R^2 = .855$ ,  $F(5, 43) = 50.66$ ,  $p < 10^{-16}$ ) of  $h$  variation, while  $MLR_{SJ}$  explained the 75.9% ( $R^2 = .779$ ,  $F(4, 45) = 39.6$ ,  $p < 10^{-14}$ ). The coefficients and significance levels of these MLRs are shown in Table 1. MLRs obtained without considering skinfolds had no significant predictors and poorer performance (an average error: of  $3 \pm 2$  and  $2 \pm 2$  cm;  $R^2$ : .664 - .701, respectively for CMJ and SJ), and were not reported.

## Conclusions

A democratization attempt for  $h$  estimation was made. The use of an unaided smartphone for  $h$  estimation led to large errors either for CMJs or SJs. The two proposed MLRs largely reduced the error in  $h$  estimation for both tasks.

## Relationships between strength, jump and kinematic variables during resisted sled sprinting

<sup>1</sup>Department of Sport and Health Sciences, Athlone Institute of Technology, Athlone, Ireland

<sup>2</sup>SHE Research Group, Athlone Institute of Technology, Athlone, Ireland

Email: katja.magdalena.osterwald@gmail.com

### Summary

Resisted sprinting involves adding a load to the movement of sprinting, to improve specificity and is believed to increase strength specific to sprinting [1]. However the addition of load may negatively impact running mechanics. It is to assume that maximum strength influence this change in kinematics, however this is currently unknown. The main purpose of this research was to examine the relationships between change in kinematics and 1RM back squat (BS) and hip thrust (HT) strength measures. Further, the relationships were examined between several mechanical measures assessed (1RM), vertical jumps (CMJ, DJ), and the performances obtained by athletes in different sprint distances with different loading conditions.

### Introduction

Resisted sprint training increases the athlete's ability to produce horizontal and vertical forces during sprinting [2-4]. Multiple systematic reviews have demonstrated positive effects of resisted sprint training on sprint performance across multiple loading conditions. Petrakos et al. (2016) found that resisted sled sprinting is an effective method to improve sprint performance, specifically in the early acceleration phase [5]. Despite this not all findings are consistent, and this may be due to varying levels of strength [6]. It is unknown whether heavy loading is violating kinematic specificity for stronger athletes in the same manner as for weaker. This is interesting to know for coaches, as stronger athletes might be able to handle a higher overload without displaying changes in sprint kinematics.

### Methods

This study analyzed the relationship between levels strength and kinematic variables of field sport athletes and sprinters while towing a sled of varying resistances (10%, 20% and 30% decreases in maximum velocity) using a between-within repeated measures design. Thirty-three athletes completed 3 testing days. This included a familiarization day and two experimental days, which were separated by a minimum of 48 hours. Participants completed numerous 40 m sprints on an indoor running track at each of the above listed loading conditions as well as 1RM and vertical jumps. Sprints were recorded for examination on two different High-Speed Cameras. Kinematic analysis was undertaken with Dartfish Software (Fribourg, Switzerland). The tools incorporated into Dartfish high speed video analysis software facilitate the slowing down and magnification of video images to calculate joint angles. Joint (trunk, hip, knee and ankle angles) and segment angle (thigh, shank, foot) variables were calculated for the two first contacts of the right foot during the acceleration and one within maximum velocity phases of each

trial [7]. All angles were measured at toe-off (TO) and touch down (TD) [8].

### Results and Discussion

Significant negative correlations were found between strength measures and change in joint angles (hip, knee and trunk) for each loading condition. Further, significant negative correlations were found between maximum strength and unloaded sprint times ( $r=0.44-0.47$  for BS;  $r=0.71-0.72$  for HT). Significant negative correlations were found between jump height and sprint time. Controversy, no significant correlations were found between peak power and sprint time. Moreover, maximum strength measures and jump performance measures showed no correlations, except for BS and peak power of the CMJ ( $r=0.77$ ).

### Conclusions

The study indicates that stronger athletes might be able to handle a higher overload without displaying changes in sprint kinematics. This may have important implications in terms of training adaptations. Maximum strength measures may explain some of the responses of athletes during RSS and coaches should ensure athletes develop squat and HT strength.

# Training to be an Olympic ski jumper in less than four years – a joint level perspective on the early development of simulated ski jump take-off performance in young athletes participating in a talent transfer program

Paavo Partainen<sup>1</sup>, Pasi A Karjalainen<sup>1</sup>, Lauri Stenroth<sup>1</sup>

<sup>1</sup>Department of Applied Physics, University of Eastern Finland, Finland

Email: [lauri.stenroth@uef.fi](mailto:lauri.stenroth@uef.fi)

## Summary

We investigated the development of lower limb mechanics in simulated ski jump take-off in a group of novice ski jumpers aiming for the 2022 Winter Olympics with less than four years of ski jump training and compared the novice jumpers to a group of experienced jumpers. Surprisingly, only modest differences between the novice and experienced jumpers were found after the initial few months of ski jump training and the differences were further diminished during a 6-month follow-up.

## Introduction

China's talent transfer program aims for success in the 2022 Winter Olympics by recruiting young talented athletes from summer sports to winter sports. The program provides a unique opportunity to examine early sport discipline-specific development in talented athletes exposed to a new sport. The purpose of this study was to investigate how technical aspects and performance of simulated ski jump take-off (imitation jump) evolves during the initial stages of training and how they compare against experienced ski jumpers.

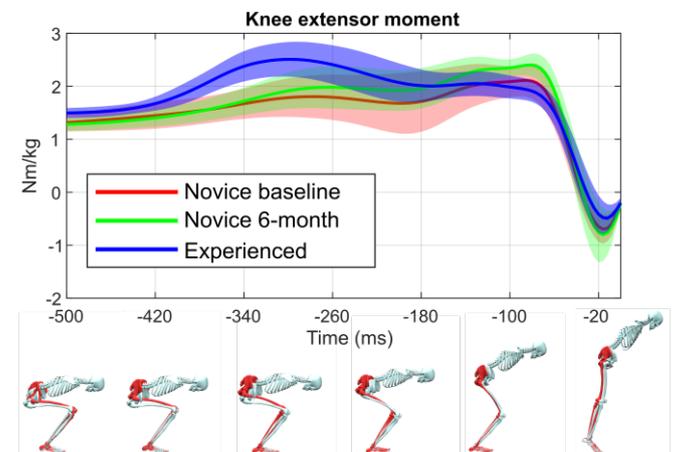

## Methods

Thirteen young Chinese males (age 15-18 y.) aiming for the ski jump competition at the 2022 Winter Olympics with less than four years of sport-specific training participated in the study. The athletes performed five maximal effort imitation jumps while ground reaction forces and lower body kinematics were recorded with two force plates (1000 Hz) and eight cameras (250 Hz). The athletes were first tested 2-3 months after entering the program (baseline) and a second time 6 months later. Nine experienced male ski jumpers from the Finnish national team (age 19-24 y.) served as a comparison group. Lower limb kinematics and joint moments were calculated in OpenSim [1]. Joint powers were calculated as the cross-product of the joint angular velocity and joint moment. Work done at each joint was calculated as the integral of the joint power with respect to time. Joint kinematics and kinetics were compared between the groups and test sessions using statistical parametric mapping and pelvis vertical velocity at take-off and contribution of each joint to the total joint work using t-tests.

## Results and Discussion

Pelvis vertical velocity at take-off increased by 6% ( $p=0.010$ ) during the 6 months in novices but did not differ from the experienced athletes at baseline ( $p=0.2103$ ) or at 6-month ( $p=0.8109$ ) time points. Knee extensor moment (Figure 1) and power were higher at the early push-off and

the hip joint was more flexed throughout the movement in the experienced jumpers. In the late push-off, novices generated higher ankle power. The differences between the groups were lowered during the 6 months but remained statistically significant. At baseline, the contribution of the knee joint work to the total joint work was larger ( $p=0.049$ ) and the ankle joint contribution was smaller ( $p=0.002$ ) in the experienced compared to the novices. After 6 months, ankle joint contribution was still lower in the experienced compared to the novice ( $p=0.010$ ). Greater between-jump variability was found in the novice jumpers in the knee joint angle, angle, moment, power, and work.

**Figure 1:** Knee extensor moment (mean and SD) during the push-off phase of the imitation jump from novice and experienced ski jumpers. Group average lower limb and torso kinematics is presented with the skeleton (red, novice-white, experienced). The torso is drawn only for the experienced group for clarity.

## Conclusions

Ski jump take-off performance, as measured by pelvis vertical velocity at take-off, did not differ between novice and experienced ski jumpers. However, the relative contribution of joint work across the lower limb joints differed and between-jump variability was greater in the novice compared to experienced ski jumpers. The results indicate that technical rather than physical performance aspects differentiate novices from experienced ski jumpers.

## Acknowledgments

The research was conducted in HUMEA laboratory of University of Eastern Finland ([www.uef.fi/humea](http://www.uef.fi/humea)) and supported by ERDF-projects A73200 and A73241.

## Validation of a monocular camera based method to obtain 3D kinematics in strength training

L. Noteboom<sup>1,2</sup>, M.J.M. Hoozemans<sup>1</sup>, H.E.J. Geeger<sup>1,2</sup>, F.C.T. van der Helm<sup>2</sup>

<sup>1</sup>Faculty of Behavioral and Movement Sciences, Vrije Universiteit Amsterdam, the Netherlands

<sup>2</sup>Department of Biomechanical Engineering, Delft University of Technology, the Netherlands

Email: l.noteboom@vu.nl

### Summary

Camera-based motion capture has the potential to take kinematic analysis out of the lab and into the field in sports science. In the present study, the kinematic accuracy of a new deep-learning based method, requiring only one simple camera, is evaluated during strength training tasks.

### Introduction

Both the state-of-the-art optoelectronic measurement system (OMS), as well as the marker-less motion capture alternative, the Microsoft Kinect, are dealing with restrictions in set-up time, capture volume and light sensitivity, which limits their applicability outside a controlled environment [1]. Recent developments in the field of deep-learning present marker-less motion capture methods, requiring only one simple camera, and therewith yielding the potential of bringing movement analysis into the field [2]. The aim of the present study is to validate the 3D kinematics obtained from this method during strength training exercises.

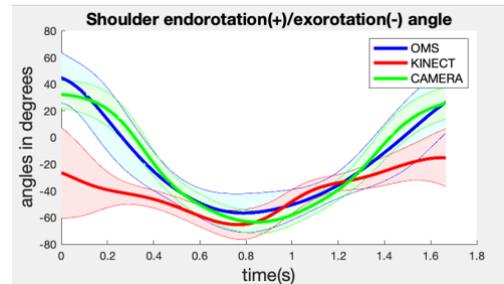

### Methods

Five male subjects each performed fifteen repetitions of two upper-body strength exercises: the lateral fly (LF) and the biceps curl (BC). Motions were simultaneously recorded by three systems: OMS (gold standard), Microsoft Kinect and a normal camera. Two different upper-body biomechanical models were created: one for the OMS in accordance with ISB recommendations [3], and one for the marker-less systems, adjusted for the different input coordinate set. Euler angles were calculated for the shoulder [3] during the LF, and the elbow flexion angle was calculated during the BC. Statistical analysis included RMSD and Pearson's correlation ( $r$ ) of joint angle time series, and an ICC agreement for peak joint angles between Camera and OMS and between Kinect and OMS.

### Results and Discussion

Results are summarized in table 1. For the Kinect, compared to OMS, mean correlations ranged from weak to excellent (0.21-0.989), with mean RMSD's ranging from 5 to 13 degrees. For the camera, compared to OMS, mean correlations

ranged from moderate to excellent (0.47-0.996), with mean RMSD's ranging from 4 to 8 degrees. Thus, the camera seemed to capture these movement cycles with reasonable accuracy, and seemed to outperform the Kinect, especially in tracking the shoulder endo-/exorotation rotation angle, as shown in Fig.1, and the shoulder elevation plane angle. However, when absolute peak values were considered, the low ICC's of the camera for all angles indicated an unacceptable agreement (ICC), which appeared to be due to both systematic errors and inconsistencies between trials and individuals. Considering the agreement on peak values, the Kinect appeared to be advantageous, although still unacceptable in most cases.

**Figure 1:** Shoulder endo-/exorotation angle during LF, captured by OMS (blue), Kinect (red) and camera (green), presented as mean  $\pm$  1SD (shaded) over all trials and all subjects.

### Conclusions

The deep-learning based camera method seems a promising tool to capture 3D kinematics within a sports environment, indicated by reasonable correlations and RMSD's when compared to the gold standard and Kinect. However, for capturing single (peak) values the camera method needs to be improved in future research before this method can be applied in the sports practice.

## A deterministic model of the Bottom turn Technique

Micael De Sousa<sup>1</sup>, Miguel Moreira<sup>1</sup>, António P. Veloso<sup>1</sup>, Vera Moniz-Pereira<sup>1</sup>

<sup>1</sup> Universidade de Lisboa, Faculdade de Motricidade Humana, CIPER, LBMF, Lisboa, Portugal

Email: micaelf.sousa@gmail.com

### Summary

The aim of this study was to determine the critical features of the surf Bottom-Turn (BT) manoeuvre. To accomplish this goal, a deterministic model was built. A panel constituted by biomechanists and surf coaches critically analysed the model and the derived critical features. The consensus version is now being analysed by the top National coaches so that a qualitative tool, aiming at assessing the BT technique, can be developed.

### Introduction

Surf is a sport where the main manoeuvres are performed on the top of the waves. The most common trajectory, after standing up, is going down in the wave and turn to the side of the wave that will break to go up again. This manoeuvre, named Bottom-Turn (BT), is, therefore, fundamental to the ride of the surfer and one of the first to be taught.

In order to assess the BT technique, surf coaches use a qualitative approach, supported on direct or video observation., as collecting quantitative data in the sea is very difficult [4].

One important step of the qualitative approach is the development of the deterministic model. This process starts with the establishment of the main objective(s) of the task, and then progresses by identifying and judging the relationship between the result and each factor that produces the result [2], allowing a more systematic approach, and less subjected to past experience bias, determination of the critical features [6].

The purpose of this study was to establish a deterministic model and to determine the critical features of the BT technique.

### Methods

MS and VMP developed the first version of the model and table of critical features based on the work done by Hay and Reid (1982) and other studies using the same approach. All doubts and disagreements were noted. Then two experts, one in biomechanics (APV) and other in surf (MM), were invited to analyse and discuss the model and the critical components. Based on all comments a consensus version was created.

### Results and Discussion

The main goal of a surfer is to obtain the highest score possible. Although the BT alone is not punctuated, the fact that it will affect the score of the following manoeuvre led us to establish the judges' score as the main goal, as it is the case of other sports like gymnastics and diving [2]. The next box is the trajectory shape, which is the global criterion commonly used by the judges to distinguish a good from a

bad BT. Further, because the main goal of the BT is to place the surfer at the pocket of the wave [5] (trajectory precision) with postural control (the surfer should be able to maintain balance throughout the manoeuvre) and velocity (the surfer should arrive at the pocket of the wave with the highest possible velocity), the flowing boxes of the model include trajectory precision, postural control and velocity

Following the example of other theoretical model obtained for the Change of Direction of 90° and 180° [3] one of the factors responsible from a good precision, is the head orientation that allows the surfer to see the wave breaking and should lead the movement. The precision is further determined by the trunk rotation and body leaning into the curve that follows.

The postural control be accomplished by using a large base of support, lowering the COM [1] and leaning into the curve.

The velocity of a surfer Centre Gravity at the top of the wave, will be influenced by the velocity at the take-off and the change in velocity generated by the surfer. The first is influenced by height of the wave, the inclination of the wave and wave speed. The second, is influenced by the impulse that the surfer produces.

Both the postural control and the change in velocity are dependent on trunk and lower limb flexion-extension patterns throughout the movement.

### Conclusions

A theoretical model of the BT technique was built based on Hays' framework [2]. The critical features derived from the model include: the head orientation, knee flexion/extension angle, the use of the rail (body leaning), hand positioning during body leaning, trunk rotation, and BT duration and trajectory shape. The motion was then divided in temporal phases and a table of critical components was created accordingly. We are now interviewing the top National Coaches to integrate their views and learn about their acceptance regarding the model and critical features established.

## Lateral Heel Release Reduces ACL strain in Simulated Backward Twisting Falls

Ryo Ueno<sup>1,2</sup>, Dieter Heinrich<sup>1</sup>, Kurt Schindelwig<sup>1</sup>, Nathaniel A. Gates<sup>2</sup>, Nathan D. Schilaty<sup>2</sup>, Werner Nachbauer<sup>1</sup>

<sup>2</sup> Department of Orthopedic Surgery, Mayo Clinic, Rochester, Minnesota, USA

Email: ryo.ueno@uibk.ac.at

### Summary

Anterior cruciate ligament (ACL) strain was estimated via a finite element (FE) knee model during various conditions of simulated backward twisting fall with and without a lateral heel release. Lateral heel release reduced ACL strain by 6-91% relative to simulations conducted with lateral toe release.

### Introduction

Bindings with lateral heel release mechanism have been developed to reduce ACL injury risk in backward twisting falls, which is one of the most frequent ACL injury mechanisms in skiing [1]. However, their efficacy in the reduction of ACL loading remains unclear. The purpose of this study was to simulate the effect of lateral heel release on ACL strain during backward twisting fall simulated with a FE model.

### Methods

An experimental binding release test was performed with a lateral toe release binding and a lateral heel release binding. Lateral forces were applied on the ski tail and increased until the binding released under various pre-applied normal forces (0, 0.5 and 1 body weight (BW) of 70 kg person) and load application location (25, 35 and 45 cm behind from the center of binding). Recorded release forces were applied quickly within 60 ms on a previously developed and validated specimen-specific FE knee model [2]. Inertial properties of boot-ski-binding system were added to the model. The knee angle was set at 25° and the femur was fixed. A minimal quadriceps-hamstring force of 120 N was constantly applied. The kinetic and kinematic parameters, including knee flexion angle, hip internal rotation, load application time and quadriceps-hamstrings force were changed from the highest and lowest ACL strain condition to cover more variations of backward twisting falls. The estimated ACL strain and knee kinematics up to binding release were compared between lateral toe and lateral heel release.

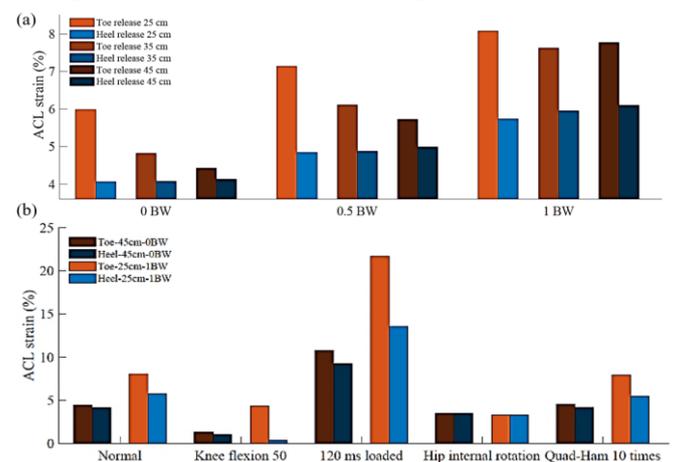

### Results and Discussion

The lateral heel release decreased ACL strain by 6-32 % relative to lateral toe release (Fig. 1-a). The highest ACL strain of 8.1 % from a lateral toe release binding decreased to 5.7 % with a lateral heel release binding. For lateral heel release, the peak ACL strain of 6.1 % was derived from 45cm-1BW trial. The largest change in kinematics due to the lateral heel release was always found in the knee abduction angle that ranged between 11-40 % decrease relative to lateral toe release.

By changing the parameters for the base conditions (45cm-0BW as lowest and 25cm-1BW as highest ACL strain trials),

the lateral heel release decreased ACL strain by 31-91% relative to lateral toe release except for the condition with hip internal rotation (Fig. 1-b). Longer loading time of 120 ms increased ACL strain 123-168% relative to base conditions. This derived peak ACL strain of 21.7% within all simulations with lateral toe release and was decreased to 13.6% with lateral heel release.

The binding with lateral heel release includes two pivot points. It can release whenever medio-lateral force was applied on ski tip or tail [3]. The pivot is on toe for heel release whereas it is on heel for toe release. Thus, lateral heel release will be triggered with smaller lateral force due to a longer moment arm when lateral force is applied on ski tail, relative to lateral toe release. This resulted in lower knee abduction angle and ACL strain, and would decrease ACL injury risk during variations of backward twisting fall.

**Figure 1:** Comparisons of peak ACL strain between lateral toe release binding (red) and lateral heel release binding (blue).

### Conclusions

Lateral heel release might reduce ACL injury risk as it decreased ACL strain during various conditions of simulated backward twisting fall compared to lateral toe release.

Email: t.rietveld@umcg.nl

## Summary

The purpose of this study was to describe and explore an inertial measurement unit-based method to analyse drag forces and external power loss in wheelchair tennis, using standardised coast down and 10m sprint tests. Drag forces and power output were explored among different wheelchair-athlete combinations and playing conditions (tyre pressure, court surface). Eight wheelchair tennis players participated in this study. Three inertial measurement units (IMUs) were placed on the frame and axes of the wheels of their wheelchair. All players completed coast-down trials and 10m sprints with different tyre pressures on hardcourt surface. One athlete completed additional tests on a clay and grass tennis-court. A higher tyre pressure led to lower drag forces during coast-down tests on hardcourt surface. The current prediction of power output was successfully implemented during coast-down testing, unfortunately the power prediction during 10m sprints were difficult to accomplish.

## Introduction

Wheelchair tennis is part of all grand slam tournaments like Wimbledon & Roland Garros. Unfortunately, there is a lack of wheelchair tennis specific knowledge. One of the key areas identified by wheelchair tennis players is the interaction between tyre pressure and surface competed on. The purpose of this study was to describe and explore an inertial measurement unit-based method to analyse drag forces and external power loss in wheelchair tennis, using standardised coast down and 10m sprint tests. Drag forces and power output were explored among different wheelchair-athlete combinations and playing conditions (tyre pressure, court surface).

## Methods

Eight highly trained wheelchair tennis players participated in this study. Three inertial measurement units (IMUs) were placed on the frame and axes of the wheels of their wheelchair. All players completed a set of three standardised coast-down trials and two 10m sprints with different tyre pressures on hardcourt surface. One athlete completed additional tests on a clay and grass tennis-court.

## Results and Discussion

Coast-down based drag forces of 4.8-7.2N and an external power loss of 9.6-14.4W at a theoretical speed of 2 m/s were measured on hardcourt surface. A higher tyre pressure led to lower drag forces during coast-down tests on hardcourt surface ( $F_r(4) = 10.7$ ,  $p = 0.03$ ) (Fig 1). For the single athlete an external power loss of 10.4, 15.6 and 49.4W respectively for the hardcourt, clay and grass. The current prediction of power output was successfully implemented during coast-down testing, unfortunately the power prediction during 10m sprints were difficult to accomplish.

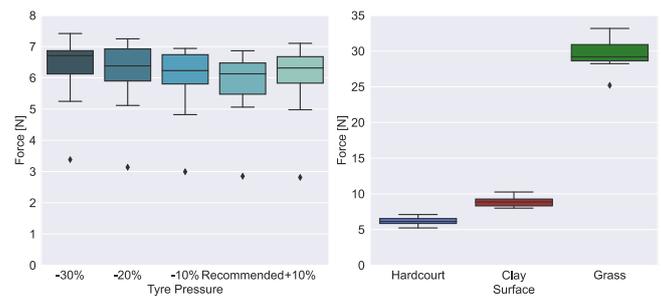

Figure 1: Differences in tyre pressures (left) and surfaces (right)

## Conclusions

This research showed the added value of coast-down testing in wheelchair tennis, by the prediction of drag forces and power loss. The usefulness and sensitivity of these measures was illustrated by the negative effect of reduced tyre pressure on the necessary power output for the group of athletes. Albeit measured in only one person, court type is a more important factor to consider, with clay showing almost 1.5 times higher drag forces compared to hardcourt, while grass showed even five times higher drag forces compared to hardcourt.

## Acknowledgments

The authors would like to thank the UK Lawn Tennis Association for the provided courts, players and financial resources, in particular special thanks to Alex Cockram. Also big thanks to all players for their participation.

# Biomechanical alterations as potential risk factors for ACL re-injury in soccer: a systematic review

Sanchez-Alvarado A

Clinical Exercise Science, University of Potsdam, Potsdam, Germany

Email: [sanchezalvarado@uni-potsdam.de](mailto:sanchezalvarado@uni-potsdam.de)

## Summary

ACL injuries in soccer threaten the athlete's career as high reinjury rates remain. To ensure a safe return to sport, a comprehensive understanding of potential biomechanical risk factors being present after reconstruction is required. Therefore, this systematic review aimed to identify biomechanical alterations as potential risk factors for ACL re-injuries in soccer players. A literature search was conducted in PubMed and Web of Science databases. Article rating was based on NIH quality assessment tools, according to study type. Out of 185 unique articles, 9 met the inclusion criteria, which was restricted to case-control or prospective study designs (rated between 6-9 for the 8 case-control articles, and 8 for the prospective study). Although the occurrence of several biomechanical alterations was identified, their predictive value for ACL re-injury is limited as only one prospective study was included, and therefore, their clinical relevance remains unclear.

## Introduction

A high rate of Anterior Cruciate Ligament re-injury in athletes has been reported in the literature [1,2]. Biomechanical alterations have been identified in soccer player following the initial ACL injury, however, their clinical relevance and predictive value for future ACL injuries remains in discussion [3,4]. Therefore, this systematic review aimed to identify potential biomechanical alterations associated with an ACL re-injury as risk factors in soccer players.

## Methods

This systematic review followed the PRISMA guidelines, and the literature search was conducted in PubMed and Web of Science databases until December 2020. The inclusion criteria were defined as: (1) investigations of ACL re-injuries in soccer with functional, kinematic, and kinetic outcomes, (2) case-control (CC) or prospective study (PS) designs, and (3) English language only. Study quality was rated by the NIH quality assessment tools (NIQA), based on study type (both out of 12 total points). The alterations were divided into differences between ACLR and controls (CAC), and intra-individual ACLR differences (IAD).

## Results and Discussion

Nine out of 185 unique articles met the inclusion criteria. There were 8 CC studies (NIQA: 6-9), and 1 PS (NIQA: 8). Table 1 displays the summarized significant mean differences found between groups (CAC) and intra-individuals (IAD).

The highest significant differences in soccer players with ACLR compared to controls, respectively, (3 CC, NIQA: 7-9)

revealed increased asymmetries in jump height (24.1±13.7% vs 10.5±7.8%), and Reactive Strength Index asymmetries (27.9±14.5% vs 13.1±9.9%) during 10 seconds vertical hops (10SVH) tests and higher variability couplings angles (mean difference 23.3° vs 16.2°) in a side-cutting maneuver (SCM). Five CC showed increased landing errors, lower jump distances, lower hip abduction, and external rotation, lower ankle inversion, and higher knee extension angles during jump-based assessments.

Other reported assessments were countermovement jump (CMJ), single-leg drop vertical jump (SLDVJ), isokinetic testing at 60°/s and 300°/s (IK60, IK300), and leg-press tests.

Table 1: Summary of highest significant differences

Category	Study type	Significant differences (mean difference)
BAC	CC	<ul style="list-style-type: none"> <li>↑ jump height asymm. (13.6%) @10SVH</li> <li>↑ RSI asymm. (14.8%) @10SVH</li> <li>↑ joints variability (7.05°) @SCM</li> <li>↑ LESS in a fatigued state (3 err.) @CMJ</li> <li>↓ gastrocnemius EMG (≈10%) unplan.</li> </ul>
IAD	CC	<ul style="list-style-type: none"> <li>↓ jump height (3.2 cm) inv. leg @10SVH</li> <li>↓ RSI (0.11 m/s) inv. leg @10SVH</li> <li>↓ RSI (0.16 m/s) inv. leg @SLDVJ</li> <li>↓ peak torque (48%) inv. leg @IK60</li> <li>↓ peak torque (27%) inv. leg @IK300</li> <li>↓ hip flex. angle (21.28°) unplan.</li> <li>↓ knee flex. angle (22.67°) unplan.</li> <li>↓ hip ext. moment (0.57 Nm/kg) unplan.</li> <li>↓ peak pressure (115.17 KPa) unplan.</li> </ul>
	PS	<ul style="list-style-type: none"> <li>↓ RFD (&gt;20%) @6 mo. vs preinjury</li> </ul>

Intra-individual comparisons in ACLR athletes displayed main differences between involved (inv.) and uninvolved legs, and unplanned (unplan.) and planned landing, during jump-based and isokinetic testing. Finally, one prospective investigation found an increased risk of re-injuries by reduced rates of force development (mean difference ≈20%) during isometric leg-press tests after 6 months of ACLR.

## Conclusions

Despite the occurrence of several biomechanical alterations, their predictive value is limited as only one prospective study was included. Without further longitudinal investigations the clinical relevance of found alterations remains unclear.

## The Simulation of Kayak Paddle Blade Based on Individual Stroke Technique Characteristics

Andrey Pomerantsev

Institute of Physical Education and Sports, Lipetsk State Pedagogical P. Semenov-Tyan-Shansky University, Lipetsk, Russia

Email: [a.pomerantsev.1981@gmail.com](mailto:a.pomerantsev.1981@gmail.com)

### Summary

Spatial reconstruction of the real stroke underwater trajectory allowed identifying the individual characteristics of the kayaking technique. Simulation of hydrodynamics forces based on genuine blade geometry and real stroke trajectory let to see the shortcomings of existing paddles. Besides that the proposed approach allowed to simulate the most appropriate paddle for a particular athlete considering his technique features.

### Introduction

Sports technique of each athlete is unique [1]. The aim of the study was to model the paddle that takes into consideration the individual biomechanics characteristics of the technique.

### Methods

Two high-speed video cameras Fastec InLine (1000 fps) were used to fix the coordinates of markers placed on surface part of the paddle. Using this data 3D underwater stroke trajectory was reconstructed (Figure 1).

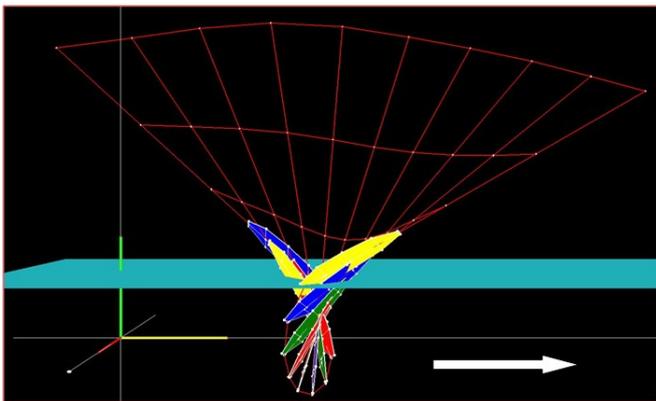

Figure 1: Spatial reconstruction of the stroke trajectory

The next step was virtual reconstruction of the genuine blade geometry and its integration with real stroke trajectory. Pressure at each point of the blade was calculated using computer simulations. Pressure depended on hydrodynamic characteristics incoming water flow and the orientation of the blade in space [2]. We determined the combinations hydrodynamics forces (drag and lift) for all parts of the blade as well as the spatial superposition of forces and its projection on the course of the kayak [3]. After that we started to change paddle blade form. During numerous iterations with various blade parameters (spatial petals orientation, petals area) optimal geometry of the paddle was found. The

hypothetical paddle will maximally appropriate for specific athlete with unique technique.

### Results and Discussion

The study revealed that different blade areas have different efficiency in performing the stroke. The maximum efficiency is registered on the distal section of the blade. This paddle part provides the greatest propulsive effect on the boat during entire stroke. The proximal blade section produces a braking effect colliding with incoming flow of water by outer side of the paddle.

The calculated blade is still theoretical (Figure 2). When creating a physical model it may be difficult to provide strength for a multiblade paddle. Another scientific dilemma is that the new paddle will change the hydrodynamic forces. It means that the kayaking technique will change and the athlete will not be able to repeat the same trajectory.

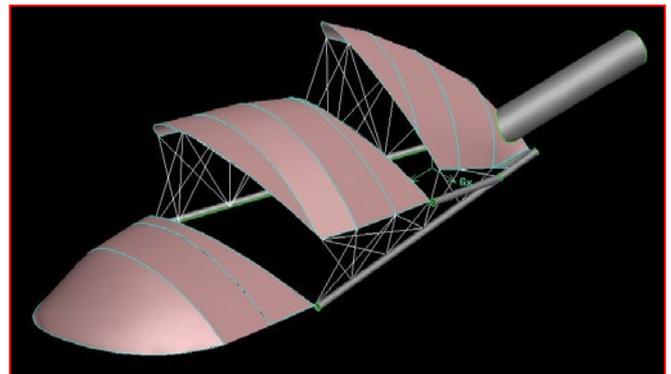

Figure 2: Multiblade paddle

### Conclusions

A new approach to design of paddle blade based on the spatial reconstruction of the stroke. It contains a huge potential for improving sports paddles taking into consideration the individual features of the sport technique.

### Acknowledgments

The author is grateful to a member of the Russian national canoe team Kirill Luchkin for his participation in the study.

## Toe flexor strength in elite female gymnasts compared to toe flexor strength trained men

Philipp Goldmann<sup>1,2</sup>, M. Sedler<sup>1,2</sup>

<sup>1</sup>Institute of Biomechanics and Orthopaedics, German Sport University Cologne, Germany

<sup>2</sup>German Research Centre of Elite Sport, German Sport University Cologne, Germany

Email: goldmann@dshs-koeln.de

### Summary

The strength of toe flexor muscles (TF) seems to create a good prerequisite for jump performance. Since gymnastics is a typical jumping and landing sport, we expected increased TF strength in elite gymnasts. The analysis showed that elite female gymnasts' TF revealed 80% to 86% higher strength compared to male sport students, and the same strength level compared to TF strength-trained men. TF in elite gymnastics seem to be highly loaded and have to be of particular interest for training and performance enhancement.

### Introduction

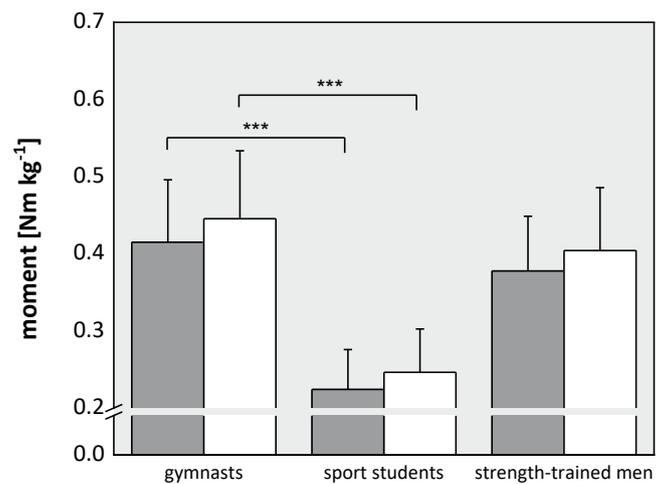

There is some evidence that intrinsic foot muscles propel the body forward during locomotion [1]. Nearly 80% of intrinsic foot muscles consists of toe flexor muscles (TF) [2] proceeding from the heel to the distal phalanges of the toes. TF strength capacity has the potential to enhance jump performance [3]. Since the ability to jump is a performance-limiting factor in gymnastics, we hypothesized that elite female gymnasts' TF strength is higher than in male sport students, but similar to TF strength-trained men.

### Methods

28 female gymnasts ( $15 \pm 2$  y,  $47 \pm 9$  kg,  $1.56 \pm 0.09$  m) of the German national team and a basic control group of sport students ( $n = 28$ ,  $25 \pm 3$  y,  $77 \pm 8$  kg,  $1.83 \pm 0.06$  m) performed three maximum voluntary isometric contractions (MVC) of TF for each foot. TF strength was determined by measuring the moment about the transverse axis of a custom-made dynamometer in 25 degrees toe dorsiflexion. The external moments of force about the axis represented the moments of force produced by the TF [3]. The best of three trials was used for further analysis. Peak moments were determined as the mean value of a 2 s time window of the plateau region. Data were compared to a previous study with the same dynamometer, where a TF strength training group (15 men,  $24 \pm 4$  y,  $77 \pm 9$  kg,  $1.85 \pm 0.07$  m) performed a heavy resistance TF strength training with 90% of MVC for 7 weeks [3]. Statistics: Kolmogorov-Smirnov, unpaired t-test.

### Results and Discussion

TF strength significantly differed ( $p < 0.001$ ) between elite female gymnasts (left:  $0.41 \pm 0.08$  Nm kg<sup>-1</sup>, right:  $0.45 \pm 0.09$  Nm kg<sup>-1</sup>) and male sport students (left:  $0.22 \pm 0.05$  Nm kg<sup>-1</sup>, right:  $0.25 \pm 0.06$  Nm kg<sup>-1</sup>). There were no significant differences ( $p > 0.05$ ) between the TF strength of elite female gymnasts and the male strength training group after 7 weeks of TF strength training (left:  $0.38 \pm 0.07$  Nm kg<sup>-1</sup>,  $p = 0.07$ , right:  $0.40 \pm 0.08$  Nm kg<sup>-1</sup>,  $p = 0.07$ ).

**Figure 1:** Moments about the dynamometer's axis normalized to body mass caused by TF contraction for the left (grey) and right (white) foot ( $p < 0.001$ )

Adolescent female gymnasts showed 80% to 86% higher TF strength than male sport students, but nearly the same strength level as adult men after 7 weeks heavy resistance TF strength training [3].

### Conclusions

TF in elite gymnastics seem to be highly loaded and have to be of particular interest for training and performance enhancement.

## The applied analysis of kayaking ergometer with different drag resistance in kayak training: a plot study

Jiaxiang Yan<sup>1,3</sup>, Zhiqiang Liang<sup>2</sup>, Jianshe Li<sup>1,3</sup>

<sup>1</sup> Faculty of Sports Science, Ningbo University, Ningbo, China

<sup>2</sup> School of Kinesiology, Shanghai University of Sport, China

<sup>3</sup> Research Academy of Grand Health, Ningbo University, Ningbo China

Email: jiaxiang0016@163.com

### Summary

The purpose of this study was to evaluate the effect of two different kayaking ergometers (wind resistance, KWR; electronic resistance, KER) on training. Six elite male kayakers executed three trainings of 200m, 500m and 1000m on-water (TW) and two kayak ergometers. The significance testing was used to analyze the difference between KWR and KER on TW, the coefficient of variation (CV) was used to analyze the working stability of the two ergometers. The results showed that no significant difference was found between the TW and the two ergometers performance on 200m. In 500m and 1000m, the two kayak ergometers showed poorer sport performance than the TW. In addition, the results also show that both kayak ergometers have good stability. Therefore, KWR and KER can be used by athletes as a training device. But an athlete's TW performance could not be predicted by KWR and KER.

### Introduction

Most kayakers rely on ergometers for training, especially in winter seasons [1,2]. The KWR calculate power via a mathematical relationship with the angular velocity of the flywheel. About KER, on the other hand, does not use the same approach [3]. Therefore, the purpose of this study was to analyze of kayaking ergometer with different drag resistance in kayak training.

### Methods

Six elite male kayakers volunteered to participate in the study (age: 17±1 years; Height: 182±4.45cm; Weight: 75.5±5.47kg; Training years: 4.67±0.47 years).

The test was conducted on six separate days, it was performed on TW and two kayak ergometers respectively, in randomised order. Three different distances of 200m, 500m and 1000m were tested. Before the each test, the athletes had a 15-minute warm-up followed by a 2-minute rest. Participants were asked to perform at the highest level throughout the test on TW and on two ergometers.

The participants' performance on TW was collected by the testers, and the measured data on the display of the ergometers was downloaded. Shapiro-Wilk's Test was used to test the normal distribution of the data. Since the data were normally distributed, the independent samples T-test was used to test the significance of the TW and two ergometers performance. CV was used to analyze the stability of KWR and KER in test. Data were analyzed using SPSS 19.0 statistical software, and the significance level was set at  $P < 0.05$ .

### Results and Discussion

In the 200m race, the difference between the two kayak ergometers and the TW performance was not found ( $P > 0.05$ ) (Table 1). In 500m and 1000m sports, the two kayak ergometers showed slower athletic performance than TW ( $P < 0.05$ ). Kayakers increase thoracolumbar extension and wider lateral bending range of motion during on water kayaking [4], over a long period of kayaking, these differences are magnified. The CV has good consistency when less than 10% [5]. Two kayak ergometers possess a stable CV (2.77 - 9.8 %) (Table 2).

### Conclusions

These findings show that both kinds of kayak ergometers have good stability in operation. They can be used by athletes as a kind of land training device. But, an athlete's TW performance could not be predicted by KWR and KER.

## Joint moments have greater impact on vertical jump height than joint angular velocities

### Summary

The differences in joint moments and joint angular velocities between good and poor performers of the countermovement jump (CMJ) were investigated ex-post-facto. Good performers showed sig. higher joint moments and joint angular velocities at the hip, knee, and ankle joint than poor performers (except for hip angular velocity). Since the effect sizes were greater in favor of joint moments, the authors suggest that it is more crucial to provoke high joint moments in athletic training rather than high angular velocities to improve the performance of ballistic movements such as the vertical jump.

### Introduction

The ability to maximally accelerate one's body from rest or after a preceding countermovement is a critical limitation in athletic performance (e.g. vertical jumping). To accelerate the body's COM during a vertical jump, the hip, knee, and ankle joint must generate a high mechanical power. Since joint mechanical power is the product of joint moment and joint angular velocity, a given power output can be achieved by different relative contributions of those two components. Good performers of the vertical jump show higher mechanical power at the hip, knee, and ankle joint than poor performers [1]. Moreover, it is valuable knowledge for athletic coaches if there are differences in the joint moments and joint angular velocities between good and poor performers.

### Methods

An ex-post-facto-experiment has been applied to the database of the German Research Centre of Elite Sport Cologne, which encompasses vertical jump performance diagnostics of young athletes in North-Rhine-Westphalia (10 infrared cameras, 120 Hz, VICON Motion Systems, Oxford, UK; 2 force plates, 1080 Hz, Kistler Winterthur, Suisse; inverse two-dimensional model Alaska Dynamicus, Alaska, Chemnitz, Germany). For the analysis, the database was sorted by countermovement jump height resulting in a group of *good* (0.35 - 0.40 m jump height, n = 52, male, 17.4 ± 3.5 yrs., 70.2 ± 12 kg) and a group of *poor* (0.20 - 0.25 m jump height, n = 52, male, 14.4 ± 1.4 yrs., 60.0 ± 11.7 kg) performers. The group differences in the time series of hip, knee, and ankle joint moments and angular velocities were investigated by using statistical parametric mapping.

### Results and Discussion

During the negative phase of the CMJ there is no difference in the angular velocities between *poor* and *good*, whereas during the positive phase, the *good* group shows sig. greater peak angular velocities at the knee (105.1 ± 12.3°/s, p = 0.001) and ankle joint (99.4 ± 14.9°/s, p = 0.01) than the *poor* group (93.3 ± 13.6°/s, 87.3 ± 17.6°/s). Regarding the external joint flexion moments, a sig. difference between the two groups was found for all joints. The joint moments of the *good* group were sig. higher at the hip (1.9 ± 0.4 Nm/kg vs. 1.4 ± 0.3 Nm/kg, p = 0.001), knee (1.1 ± 0.2 Nm/kg vs. 0.9 ± 0.2 Nm/kg, p = 0.001) and ankle joint (1.5 ± 0.2 Nm/kg vs. 1.2 ± 0.1 Nm/kg, p = 0.001) than those of the *poor* group. Additionally, the effect sizes of the differences in joint moments were larger than the effect sizes of the differences in angular velocities (hip: d = 1.7 (0.3), knee: d = 1.0 (0.8), ankle: d = 2.1 (0.7)), which indicates that the ability to generate higher joint moments might be more crucial in the performance of vertically directed ballistic movements than joint angular velocities.

**Table 1:** Peak joint moments and angular velocities at the hip, knee and ankle joint during maximal CMJ (\* sig. difference to low).

	Joint Moment [Nm/kg]		Angular Velocity [°/s]	
	<i>poor</i>	<i>good</i>	<i>poor</i>	<i>good</i>
<b>Hip</b>	1.4 ± 0.3	1.9 ± 0.4***	44.7 ± 8.8	47.3 ± 7.5
<b>Knee</b>	0.9 ± 0.2	1.1 ± 0.2***	93.3 ± 13.6	105.1 ± 12.3***
<b>Ankle</b>	1.2 ± 0.1	1.5 ± 0.2***	87.3 ± 17.6	99.4 ± 14.9**

The difference in hip moments was present for the longest time during the jump phase (58-94 %), which confirms the importance of this joint also found by [2]. Interestingly, the higher hip moments did not lead to a significant increase in hip angular velocity, which implies a proximal to distal energy transfer through biarticular muscles [3].

### Conclusions

These findings suggest that athletic training should focus on provoking high joint moments rather than high angular velocities to improve vertical jump height.

<sup>1</sup>CAU Motion Lab, Kiel University, Germany, <sup>2</sup>Institute of Sport Science, Kiel University, Germany

<sup>3</sup>DLRG Rescue Sports, Team Germany

Email: stefan.kratzenstein@email.uni-kiel.de

### Summary

The systematic optimization of movement strategies in board paddling requires the identification of relevant kinematical parameters. In rescue sports, these parameters only exist as trainer's experiences and individual case observations, which need to be validated considering the competition-specific profile. In this pilot study, the movements of 16 athletes of Team Germany are recorded during a 5-minute all-out ergometer test to (1) validate existing movement guidelines, (2) evaluate the use of a new paddle ergometer, and (3) derive specific questions for further analysis. The analysis of the shoulder, hip, and knee joint movements resulted in significant correlating movement patterns. Only two athletes differed from the group by a significantly more upright upper body posture. The results emphasized the need to include performance parameters to conclude the effectiveness of the movement pattern. Specific questions about the role of movement specialization and the transferability of lab results to open water conditions were derived.

### Introduction

Board paddling is a discipline of beach competitions in rescue sports. The lack of a description of the basic paddling movement restrains the evaluation of techniques that deal with external environmental conditions (e.g. waves) and for coping with tactical manoeuvres on water. The athlete's motor competence is considered to be an intentional variation of a basic movement pattern to solve the situational task. Thus, this study aimed to analyse the kinematics of board paddling under standardized conditions to systematically derive further questions regarding the more complex situation on the water during races.

### Methods

16 elite athletes from Team Germany (8 males, age 22±3 years) were analysed. It was assumed that the movement patterns of this cohort are highly automated. Nevertheless, the athletes had no experience of paddling on the ergometer, which was developed exclusively for this study. The ergometer (WEKA Sport, Powerbox, AUT, Fig.1) had independent parallel ropes with flat hand paddles. The maximum braking power was 60kg per rope.

The 3D motion analysis included the analysis of the right shoulder, hip, and knee joints in the sagittal plane and was conducted with an inertial measurement unit system (Noraxon, myo-motion, US). The warm-up was followed by a calibration of the sensors and a 5-minute all-out test, which corresponded to a competition-specific load protocol. 30s time segments were recorded in the 1st, 3rd, and final minute.

An ANOVA was conducted to prove the data for differences between athletes and between time points.

### Results and Discussion

Significantly correlating movement patterns and no differences between kinematic parameters were found for all joint angles within the entire cohort. The only exceptions were found for two athletes who paddled with an elevated centre of mass position. Further studies are required to investigate if this posture is intended to allow dynamic reactivity and is therefore a result of the athletes' specialization in a heavy swell.

In addition, all athletes reported that ergometer paddling differs significantly from paddling on the water in terms of intensity, volume, and body posture. The following investigations need to compare the ergometer directly with paddling on water to evaluate the transferability of the analysis output of standardized ergometer analyses to training practice.

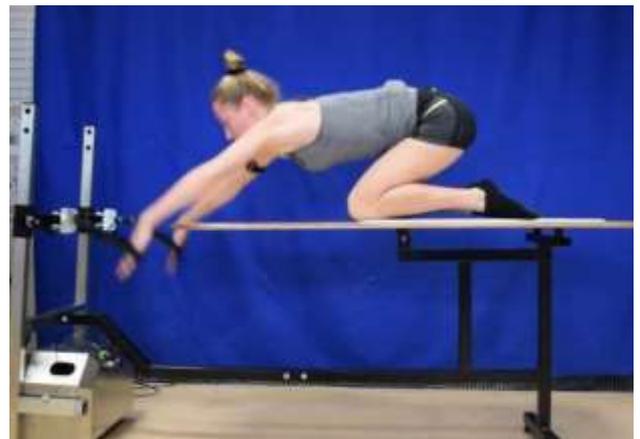

Figure 1: Athlete in catch position on the board paddle ergometer.

### Conclusions

In this study, we quantified the basic movement of elite athletes. Further questions were systematically derived from the results, which are fundamental for subsequent projects, which aim to identify the individuality of the athletes and to develop standardized movement and performance analysis.

### Acknowledgments

We acknowledge the support of Jana Emken during the data collection and the reliable cooperation with Team Germany and the DLRG.

# EFFECTS OF TAI CHI EXERCISE ON POSTURAL STABILITY AMONG THE ELDERLY DURING STAIR DESCENT UNDER DIFFERENT LEVELS OF ILLUMINATION

Yaya Pang<sup>1</sup>, Li Li<sup>2</sup>, Qipeng Song<sup>1</sup>

<sup>1</sup>College of Sports and Health, Shandong Sport University, Jinan, China

<sup>2</sup>Department of Health Sciences and Kinesiology, Georgia Southern University, Statesboro, 30460, USA

Corresponding author: Dr. Qipeng Song, songqipeng@sdpei.edu.cn

## Summary

The elderly prone to stair descent falls under low illumination. Tai Chi, a traditional Chinese conditioning exercise, has been proved to improve postural stability by altering movement pattern, gait, and proprioception. This study investigates whether Tai Chi exercise could improve postural stability during stair descent under high and low illumination. Three groups of elderly women who practice Tai Chi, brisk walking, and no exercise were included. They descended from a simulated staircase. Decreased horizontal velocity, center of mass (COM) sway, and increased foot clearance were observed among the Tai Chi group, compared with other groups. Compared with under high illumination, Tai Chi participants decreased horizontal velocity, loading rate, braking impulse, and increased inclination angle COM sway, center of pressure displacement under low illumination. Tai Chi participants were more sensitive to the difference in illumination and took corresponding strategies to stabilize their bodies during stair descent.

## Introduction

Recent reports have identified that stair gait falls account for 26% of all self-reported falls [1] and have become the leading cause of accidental death for the elderly [3]. Stair descent imposes significant challenges to movement control in people of all ages [2], but especially to the elderly due to the functional decline in many of their physiologic systems. Tai Chi is a traditional Chinese conditioning exercise. It has been proved that Tai Chi could improve postural stability in the elderly by altering their movement pattern, gait, and proprioception [4,5]. A kind of exercise that could improve postural stability in the elderly during high-risk activities, such as stair descent under low illumination, remains unclear.

## Methods

Three groups of elderly women who practice Tai Chi (TC), brisk walking (BW), and no exercise (NE) were included. Each participant was asked to complete one testing session per day for a total of three testing sessions. In each session, the participants were asked to descend the staircase step over step under different illumination conditions. A simulated staircase with six steps was constructed for data collection in this study. Two force plates (KISTLER, 9287BA and 9281CA, Switzerland) were embedded in the third and fourth steps, to collect ground reaction force data at a sample rate of 1000 Hz. The stair descent test was recorded (100 Hz) by an eight-camera motion analysis system (Vicon, Oxford Metric, England). Descriptive analysis was conducted with the mean and

standard deviations for both kinematic and kinetic variables. Subgroup comparisons were assessed via respective 95% confidence intervals of mean difference. The confidence interval of mean difference values between groups was calculated by using the one-way ANOVA post hoc pairwise comparison with Bonferroni adjustment. The confidence interval of mean difference values between two illumination levels was calculated by using paired-sample t-test.

## Results and Discussion

Horizontal velocity was lower in TC group compared with BW group (95% CI: -125.09 to 3.46) and decreased under low illumination in TC (95% CI: 15.23-105.07) and BW groups (95% CI:54.22-99.78). TC group had a greater foot clearance than BW (95%CI: 24.96-45.41) and NE (95% CI: 3.39-38.93). There were no significant group differences for head and trunk inclination angles. Under low illumination, the TC group had a higher head inclination angle (95% CI: -8.03 to -1.32), whereas BW and NE groups had higher trunk inclination angles (95% CI: -4.38 to -0.99; -4.06 to -1.47, respectively). TC group had a smaller COM<sub>ml</sub> Sway than walking (95% CI: -19.32 to 0.31) and no exercise participants (95% CI: -23.97 to -3.59). All the three groups increased their COM<sub>ml</sub> Sway (95% CI: -15.26 to -5.87, -18.15 to -4.32, -11.08 to -2.19, respectively) under low illumination. TC group had a lower loading rate than the BW group (95% CI: -5.75 to -0.02). Under low illumination, TC group decreased their loading rate (95% CI: 0.86-4.34), braking impulse (95% CI: 0.001-0.005), and increased their COP<sub>ap</sub> (95% CI: -92.76 to -2.82) and COP<sub>ml</sub>(95% CI: -26.50 to -3.47). Under low illumination, BW group increased their COP<sub>ml</sub> (95% CI: -34.07 to -2.08).

## Conclusions

TC group adjusted their movement pattern to increase postural stability during stair descent. Furthermore, the TC group were more sensitive to the difference in illumination and took corresponding strategies to stabilize their bodies during stair descent.

## Effect of exercise on muscle oxygen saturation during the posterior 11 hours

A. Gandia-Soriano<sup>1</sup>, I. Catalá-Vilaplana<sup>2</sup>, M.T. Pellicer-Chenoll<sup>3</sup>, J.L. Bermejo-Ruiz<sup>3</sup>, A. Encarnación-Martínez<sup>2</sup>, J.I. Priego-Quesada<sup>1,2</sup>

<sup>3</sup>Dept of Physical Education and Sports, University of Valencia, Valencia, Spain

Email: j.ignacio.priego@uv.es

### Summary

The objective of this preliminary study was to assess the effect of exercise on muscle oxygen saturation (SmO<sub>2</sub>) in the posterior hours. Higher values of SmO<sub>2</sub> were obtained after exercise, with the peak value 5h after exercise.

### Introduction

The interest in measuring SmO<sub>2</sub> during exercise using near-infrared spectroscopy (NIRS) methods is increasing due to its non-invasive nature and price affordability [1]. SmO<sub>2</sub> measurement has been observed as a useful physiological indicator of athlete's exertion [1] or muscle oxygenation availability during exercise in different hypoxia scenarios [2].

However, there is a lack of knowledge about if SmO<sub>2</sub> values could be related with the fatigue level after exercise. Therefore, the objective of this preliminary study was to assess the effect of exercise on SmO<sub>2</sub> in the posterior hours.

### Methods

13 physically active participants volunteered to participate in the study (mean ± standard deviation: age 38 ±7 years, height 174.5 ±8.0 cm, body mass 74.5 ±9.6 kg and body fat percentage 16.7 ±6.2%). Participants signed the written consent form, and the study was approved by the University of Valencia ethics committee. From the 13 participants, 6 participated as control and 7 as experimental. SmO<sub>2</sub> of experimental participants were measured between 7:30 and 8:30 am (pre), then they performed exercise and were measured immediately after exercise (Post), 2 h, 5 h and 11 h after exercise (Post2, Post5, Post11). Exercise consisted in running 10 km at competition pace and performing 2 sets of 5 repetitions of 10m sprints. Controls did not perform exercise and were not measured in the Post moment (condition).

SmO<sub>2</sub> was measured using the NIRS instrument Humon. Humon was attached to the middle of the participant's quadriceps using a strap with a hook-and-loop fastener. Measurement was performed during 3 min and mean, minimum and maximum values of SmO<sub>2</sub> were obtained using a Garmin watch (model Fenix 5) and the Wko 5 application. Due to the low sample size, differences between control and experimental groups were assessed using Cohen's d Effect Size (ES).

### Results and Discussion

Similar results were obtained for mean, minimum and maximum values. Experimental and controls did not differ in the Pre measurement (ES=0.1), but after exercise, experimental groups presented always higher values (ES=0.6 in Post2, and ES=0.5 in Post11), with the higher differences in the Post5 (ES=2.5) (Figure 1).

### Conclusions

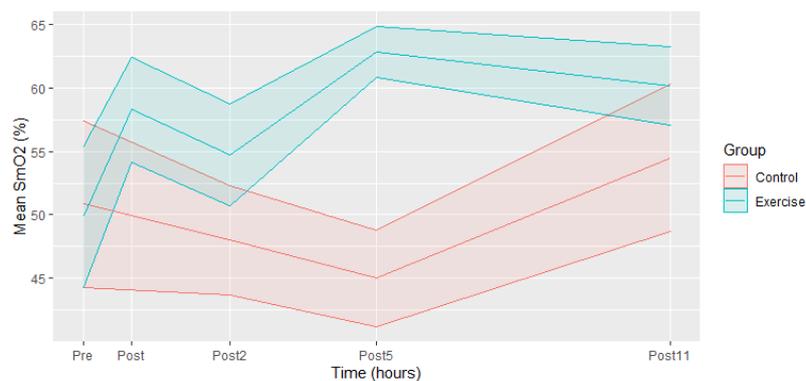

The preliminary results of this study suggests that SmO<sub>2</sub> data could be used as an indicator of the posterior physiological effect of exercise. Future studies should increase sample size and test the effect of different fatigues.

### Acknowledgments

# Mechanical work as a (key) determinant of metabolic cost in human locomotion: handcycling and handcycling-driven watercraft

Luca P. Ardigo<sup>1</sup>, Gabriela Fischer<sup>2</sup>

<sup>1</sup>Department of Neurosciences, Biomedicine and Movement Sciences, University of Verona, Italy

<sup>2</sup>Department of Physical Education, Federal University of Santa Catarina, Florianópolis, Brazil

Email: [luca.ardigo@univr.it](mailto:luca.ardigo@univr.it)

## Summary

It were reviewed recent findings on the mechanical determinants of metabolic cost during human locomotion, obtained by using a mechanical approach based on the König theorem (the “Fenn-Cavagna-Minetti” approach, FCM). Recent developments in analytical methods and of their applications allowed to better understand the mechanical-bioenergetic interaction in handcycling and handcycling-driven navigation. In spite of some investigations on biomechanics and bioenergetics variables other than total mechanical work, FCM was applied to the study of handcycling by Fisher [1] who, beyond the power against air resistance ( $W'_a$ ) and rolling resistance, ( $W'_r$ ) computed also the power needed to sustain the movements of the whole-body center of mass of the handbike-subject complex ( $W'_{bcom}$ ). Over the investigated speed range,  $W'_a$  and  $W'_r$  in addition to  $W'_{bcom}$  (substantial fraction of total external power) were observed to increase with effect on a *pendulum*-like energy recovery, too. FCM could be applied to studies on handcycling-driven navigation, as well.

## Introduction

Handcycling is a relatively new mode of paracycling available to athletes with disabilities. Over the years, investigated physical activity variables (besides performance time and distance travelled) have been related to handbike configuration, body segments and crank kinematics and submaximal or peak/*maximum* (crank) power output [1]. Researches have also investigated metabolic variables such as aerobic/anaerobic threshold, peak/*maximum* heart rate, oxygen consumption [1], lactate concentration, respiratory exchange *ratio*, rates of perceived exertion, locomotion (apparent) efficiency (total mechanical work/metabolic cost of transport [CoT] [1]) and muscular activation. It were reviewed recent findings on the mechanical determinants of CoT during handcycling and handcycling-driven navigation, obtained by using FCM [2,3].

## “Fenn-Cavagna-Minetti” approach in handcycling

The “Fenn-Cavagna-Minetti” approach was applied to the study of handcycling by Fisher [1] who, beyond  $W'_a$  and  $W'_r$ , computed also  $W'_{bcom}$ . Over the investigated speed range (2.8-8.5 m s<sup>-1</sup>),  $W'_a$  was observed to increases from 6 to 145 W,  $W'_r$  from 27 to 54 W (with lower values on macadam compared with tartan) and  $W'_{bcom}$  from 10 to 57 W (Figure 1). The latter is thus a substantial fraction total external power (~20%). In addition, in the study of Fisher [1], energy recovery was observed to range from 40 to 50% (and to decrease linearly with speed) suggesting some *pendulum*-

like energy-saving mechanism (Figure 2), and the mechanical internal power was observed to be almost negligible (5-7 W).

## Handwaterbike

A spin-off topic is represented by biomechanical and energetic assessment of synchronous arm cranking with human powered watercrafts (i.e. the handwaterbike) for people with disabilities [4]. The FCM could be used in this contest, as well as in future studies on handcycling, to provide researchers and disability field professionals with original and applicable findings.

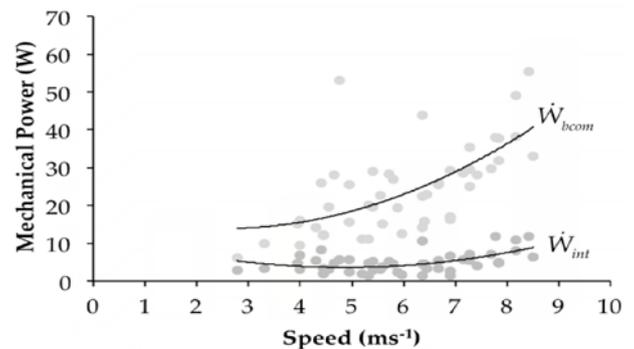

Figure 1:  $W'_{bcom}$  and  $W'_{int}$  over handcycling speed.

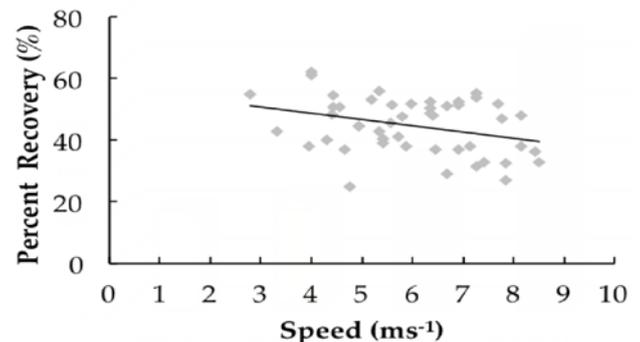

Figure 2: Energy recovery (Percent Recovery) over handcycling speed.

## Using In-Fibre Bragg Grating Sensors within the Periodontal Ligament Space of an Intact Swine Premolar: A Cross-Verification with a Representative Finite Element Model

\*Email: dromanyk@ualberta.ca

### Summary

The Periodontal Ligament (PDL) provides physical attachment between the tooth and surrounding alveolar bone. In-Fibre Bragg Grating sensors (FBG) have been used to measure repeatable strains from within the PDL space during displacement-controlled tests. Cross-verification was used to compare the FBG strains to physical strains within the PDL estimated from a linear elastic finite element (FE) model. Results suggest that the FBG can be used as a proxy for change in strain, as a change in FBG strain was linearly related to the corresponding change in FE strain.

### Introduction

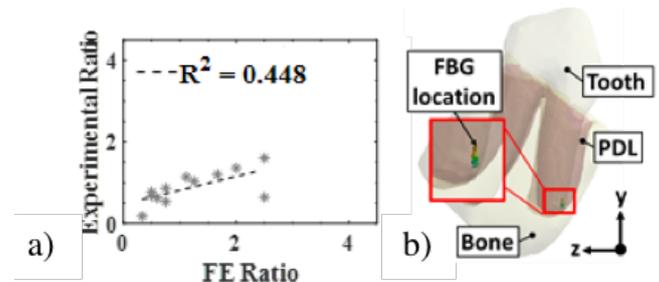

The PDL is a connective tissue that provides attachment between the tooth root and surrounding alveolar bone. The PDL mechanical properties are vital to understanding how the tooth-PDL-bone complex (TPBC) will respond to external loads, such as chewing or orthodontics [1]. The PDL is known to have a narrow and irregular width (0.06-0.25 mm in humans [2]) making the implementation of traditional strain sensors within an intact TPBC challenging [2,3]. FBGs are small (0.125 mm diameter), flexible, optical sensors that can be placed within the PDL space of an intact TPBC [2]. FBG strain measurements have been shown to be repeatable; however, the accuracy has not been studied. The objective of this work was to compare the FBG measured strains to those estimated through FE analysis to determine the suitability of FBG measurements in predicting PDL mechanics.

### Methods

Swine second premolars (n=14) were subjected to displacement-controlled tests with an FBG placed in the PDL space. Each premolar was subjected to two different quasi-static displacements. After preconditioning, 10 trials from each displacement were used and the mean peak strain measurements were calculated for each displacement. An experimental ratio was calculated for each mandible, dividing the mean strain from the first displacement by the second.

A representative FE geometry was created from Microcomputed Tomography ( $\mu$ CT) scans (SkyScan 1076; Bruker-MicroCT, Kontich, Belgium, at: 100 kV, 110  $\mu$ A, 17.2 micron resolution). A linear elastic FE model was created using ANSYS (ANSYS Academic Research Mechanical, Release 2020 R1, Canonsburg, PA, USA, total elements (SOLID187): 829,822). The tooth, bone, and PDL had a Young's Modulus of 20 GPa [5], 13 GPa [5], and 0.46 MPa, respectively. All materials had a Poisson's ratio of 0.30. FE strains were taken from the approximate location of the FBG (Figure 1), determined from  $\mu$ CT scans. An FE ratio was

calculated in the same manner as for the experimental ratio. A linear regression between the experimental and FE ratios was completed to determine the suitability of using FBG measures to predict change in strain.

**Figure 1:** a) Linear regression between experimental and FE ratios  
b) Representative FE model indicating FBG location

### Results and Discussion

The linear regression between experimental and FE strain ratios was statistically significant (p-value=0.017) and it was found that the FE ratio was capable of predicting 44.8% of the variation in the experimental ratio ( $R^2=0.448$ ) (Figure 1). The linear relationship implies that a change in FBG output measurements can be used to predict the change in physical strains within the PDL. This is significant as this sensing method would allow for measuring the change in strain within the PDL at various time points during temporal studies without having to sacrifice and dissect the PDL.

### Conclusions

FBG sensors can be used as a proxy for change in physical PDL strain over time. This preliminary relationship shows promise; however, more work must go into the effects of other external mechanical stimuli (e.g., effect of loading rate).

## Multi-scale constitutive model of human trabecular bone

Krzysztof Jankowski<sup>1</sup>, Marek Pawlikowski<sup>1</sup>

<sup>1</sup>Institute of Mechanics and Printing, Warsaw University of Technology, Warsaw, Poland

Email: krzysztof.jankowski.wip@pw.edu.pl

### Summary

The aim of this study was to formulate new multi-scale constitutive model of human trabecular bone. The model takes into account visco-elastic properties of human bone trabeculae, i.e. hysteresis loop, load rate dependency and stress relaxation. Calibration of visco-elastic constants was based on nanoindentation tests performed on trabeculae and relaxation test performed on whole sample. The constitutive model was formulated to implement it in finite element analyses. The validation presented in the study was based on the results from compression test and simulation of this test.

### Introduction

The constitutive model can be used to numerically model bone behavior and to predict all or some of the bone-related disorders, as well as to understand the relationship between bone and implants.

### Methods

The cuboid bone sample 9.8 x 9.6 x 9.6 mm was cut out from bone specimen resected from a femoral head of a 63-year-old patient during a hip replacement surgery. The 3D model of this sample was created from  $\mu$ CT images (Figure 1).

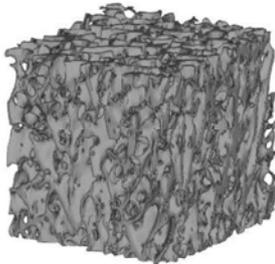

Figure 1: Model of a bone sample.

The micro-indentation tests were carried out on different trabeculae from the sample. A spherical diamond indenter tip was used. The tests were conducted until the maximal force values 300 mN, 500 mN and 700 mN were reached at the load and unload rates 500 mN/min and 1000 mN/min. A total of 18 tests were conducted. During relaxation test bone sample was compressed until strain value 0.01 was reached and then the change of the force was registered for 500 sec. Compression test was conducted on the cuboid bone sample with the same strain value. To model human bone behavior in micro- and macro-scale we proposed a non-linear visco-elastic constitutive model of general form:

$$\mathbf{S} = \int_0^t g(t-s) \frac{\partial \mathbf{S}^e}{\partial s} ds, \quad (1)$$

where:  $\mathbf{S}$  – second Piola-Kirchhoff stress tensor,  $\mathbf{S}^e$  – elastic second Piola-Kirchhoff stress tensor,  $g(t) = g_\infty + \sum_{i=1}^n g_i \cdot \exp(-t/\tau_i)$ ,  $g_i$  are characteristic amplitudes and  $\tau_i$  –

relaxation times. In this equation  $s$  represents the historical time, whereas  $t$  is the current time [1, 2]. The form of  $\mathbf{S}^e$  was derived from the Mooney-Rivlin strain energy density  $\Psi$ :

$$\Psi = c_{10}(I_1 - 3) + c_{01}(I_2 - 3), \quad (2)$$

where:  $c_{10}$ ,  $c_{01}$  are hyperelastic material constants,  $I_1$  and  $I_2$  – first and second strain invariants, respectively. The relaxation times  $\tau_i$  and the value of  $n$  were determined by fitting the curve described by (1) to the relaxation test in compression performed on bone sample. The elastic constants  $c_{10}$ ,  $c_{01}$  and the visco-elastic constants  $g_i$  were determined on the basis of micro-indentation tests using an indirect method based on finite element analyses [3] implementing the proposed constitutive model (1) into Abaqus<sup>®</sup> software by means of User-Supplied subroutine. Both the indentation and compression tests were simulated. To validate our constitutive model the results from simulation were compared to results from experiment.

### Results and Discussion

In Figure 2 the results of the constitutive model validation is graphically presented. The curve obtained from compression test is shown by means of squares and the FE analysis curve with a solid line. Reasonable accordance between the model and experiment is clearly visible.

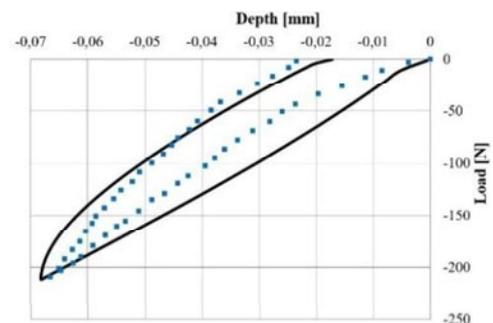

Figure 2: Validation of the constitutive model: experiment (squares) and FE simulation (solid line).

### Conclusions

The formulated multi-scale constitutive model for human trabecular bone proved to be capable to model visco-elastic properties of bone both in micro and macro scale. It can be utilized to simulate more accurately bone behavior and also to predict its reaction to various types of load conditions.

### Summary

This study aimed to assess the reliability and validity of a robotic manipulator to reproduce quasi-static humerus motions based on operator-induced humerus motions on cadaveric specimens. Reliability, quantified by the root mean square difference (RMSD) between a motion cycle and the related average across specimens, motions and cycles was  $0.28 \pm 0.13$  mm and  $0.15 \pm 0.08^\circ$  for humerus position and orientation, respectively. Validity, quantified by the RMSD between a cycle and the related operator-induced motion, was  $0.58 \pm 0.56$  mm and  $0.22 \pm 0.12^\circ$  for humerus position and orientation, respectively.

### Introduction

Biomechanical testing of human joints is commonly performed using universal testing machines [1]. While providing precise position and force measurements, the related protocols are often limited to only one or two degrees of freedom (DoF) [2]. To overcome this issue, several studies have been oriented toward the use of robotic manipulator with multiple DoFs [1,3,4]. However, to the best of our knowledge, these protocols remain performed in extra-corporal conditions by fixing a bony segment and mobilizing another one. In the context of the shoulder complex, such an approach may produce results quite far from physiological bone movements of this kinematic chain with various DoFs. The aim of this study was to assess the reliability and validity of a robotic manipulator to reproduce quasi-static humerus motions based on operator-induced movements on cadaveric specimens.

### Methods

Five female cadaveric specimens ( $77.4 \pm 9.99$  years) were obtained for the study. None of the 10 shoulders had degenerative joint disease or previous ligamentous injury. Specimens were placed on and attached to a vertical support to ensure that the thorax was held rigidly to the table. Each humerus was cut approximately 15.5 cm distal to the humeral head centre, potted in a custom 3d-printed cylinder by use of the bone cement (Palacos LV, Heraeus, Germany), and rigidly fixed to the end-effector of a robotic manipulator (KUKA LBR iiwa 14 R820, KUKA, Germany). The 3D trajectories of a set of cutaneous reflective markers placed on thorax and upper limb [5] were previously recorded using a 11-camera optoelectronic system sampled at 100 Hz (Oqus5, Qualisys, Sweden) during operator-induced humerus motions (flexion-extension, abduction-adduction, internal-external rotation at  $0^\circ$  of flexion, horizontal flexion-extension, vertical traction

and horizontal compression). These trajectories were gap-filled, filtered (2<sup>nd</sup> order Butterworth filter, 6 Hz cut-off) and used to compute the position and orientation of a segment coordinate system defined on the humeral 3d-printed cylinder. The resulting trajectory and quaternion were sent to ROS (Robot Operating System, version 16.04.6 “Kinetic”) and the manipulator motion planning was computed by inverse kinematics. Finally, the manipulator reproduced the humeral motions (27 cycles per motion) and the reliability and validity of the humerus position and orientation were assessed. As the motion velocity was not constrained, a dynamic time warping approach was used to map the compared time-series and the RMSD was then computed between the resulting mapped data for each humerus motion cycle. The reliability of the robotic manipulator was then quantified by the RMSD between a motion cycle and the related average across all cycles. Similarly, the validity of the robotic manipulator was quantified by the RMSD between a motion cycle and the related operator-induced motion. This protocol was approved by the Cantonal Commission for Research Ethics (2020-00598).

### Results and Discussion

Concerning the humerus position, the average RMSD related to reliability and validity were respectively  $0.28 \pm 0.13$  mm and  $0.58 \pm 0.56$  mm across specimens, motions and cycles. Concerning the humerus orientation, the average RMSD related to reliability and validity were respectively  $0.15 \pm 0.08^\circ$  and  $0.22 \pm 0.12^\circ$  across specimens, motions and cycles. The reliability of the humerus (i.e. the manipulator end-effector) position and orientation agrees with the manufacturer values ( $\pm 0.1^\circ$ ).

### Conclusions

Regarding the present reliability and validity of the robotic manipulator to reproduce quasi-static physiological humerus motions, the proposed methodology will now allow to develop various experimental cadaveric protocols to robustly assess joint kinematics in quasi-static conditions.

## Foot health technology for the diabetic high risk foot – A systematic Review

Claire Saliba Thorne MSc<sup>1</sup>, Alfred Gatt PhD<sup>1</sup>, Clifford DeRaffaele PhD<sup>1</sup>, Abdurahman Azena<sup>2</sup>, Cynthia Formosa PhD<sup>1</sup>

<sup>1</sup> Faculty of Health Sciences, University of Malta

<sup>2</sup> Middlesex University, Malta

Email: [claire.saliba-thorne.08@um.edu.mt](mailto:claire.saliba-thorne.08@um.edu.mt)

### Summary

This systematic review analyzed the existing literature on technologies used to read and measure both in-shoe pressures and skin temperatures. All studies have shown excellent index test validity and only a few tested for the reliability of the device. None of the studies tested for responsiveness of the device. Quality assessment results scored high-risk in ‘applicability’, and low risk in view of ‘use if index test’. The data outlined in this review confirms that further improvement, reliability testing and clinical validation of the developed systems is required despite the results of excellent performance in detecting changes of in-shoe skin temperature and pressure.

### Introduction

When the skin is subjected to continuous plantar stresses in the diabetic high-risk foot, the skin temperature at the area of stress rises, weakening the ability of the surrounding tissues to resist biomechanical abnormalities. To date, monitoring of skin temperature and plantar pressure mapping measurement, can only be obtained separately using a thermographic camera and an in-shoe pressure device, a technique which can result as both expensive and time consuming. In view of this, researchers have been attempting to develop and validate innovative in-shoe devices that can serve as an alternative to the current impractical technologies that are currently available. The aim of this systematic review is to provide a more rigorous analysis of existing literature related to the technologies used to read and measure both in-shoe plantar pressures and skin temperature.

### Methods

A systematic review of the literature related to the topic was searched in database sources such as Medline OVID, Cochrane Library, PubMed, CONAHL, PROSPERO, and Elsevier. Outcome measures of interest included validity, reliability and responsiveness of in-shoe temperature and/or pressure mapping device used, and characteristics and quantity of sensors used, anatomical landmarks and statistical analysis used to interpret the data. Quality of evidence and risk of bias was evaluated using the QUADAS-2.

### Results and Discussion

This study was first to provide a comprehensive understanding of the currently available technologies developed to measure in-shoe plantar pressures and temperature. Nineteen studies were included in this review. The majority of studies used a small sample and recruited healthy participants. All studies have shown index test validity and only a few tested for the reliability of the device. None of the studies tested for responsiveness of the device. Quality assessment results scored high-risk in view of ‘patient selection’, ‘use of reference standard’ and ‘applicability’, and low-risk in view of ‘use if index test’ and ‘flow and timing’. In-shoe technologies are generally developed to monitor only one of these parameters. Current evidence is not robust enough to confirm the reliability and validity of a such an innovative device vis-à-vis the early identification of ulcer development. By confirming valid and reliable measurement of peak plantar pressures and skin temperature, the clinician can have an objective risk assessment on which to base his/her clinical reasoning [1] which is highly commended by health care guidelines [2] and is proven to reduce ulcer development by 70% [3].

### Conclusions

The data outlined in this review confirms that further improvement, reliability testing and clinical validation of the developed systems is required. The type of information gathered from this review, can be useful in identifying functioning characteristics of mentioned devices to develop an innovative, low cost, reliable and valid, in-shoe pressure and temperature measuring device that can be used as an alternative to current technology to predict the risk of ulceration prior to tissue breakdown.

### Summary

We investigated movement quality in terms of symmetry, complexity, smoothness, and stability in hip or knee osteoarthritic and non-arthritic people and following total knee arthroplasty (TKA), using linear and non-linear measures assessed by a single lower trunk accelerometer. We detected differences in gait pattern between arthritic and non-arthritic subjects that surpassed the minimal detectable change. We observed normalisation of most symmetry measures after TKA. Further, the initial deterioration in movement complexity did not recover over time. Moreover, a less stable gait pattern was detected at one-year post-TKA compared to asymptomatic controls. These results show that a single trunk worn accelerometer can characterise movement quality before and after a total joint arthroplasty.

### Introduction

Hip and knee osteoarthritis (OA) are common, disabling musculoskeletal disorders. They are a leading cause of lower extremity disabilities [1]. Symptomatic OA is characterised by pain, stiffness, physical disabilities, and difficulties in performing daily life activities [1]. Patient-reported outcome measures are frequently used to assess daily functionality in arthritic subjects; however, they lack biomechanical insight [2]. Inertial measurement units have shown the ability to measure functionality in terms of gait symmetry, complexity, smoothness, and stability in a natural environment. However, the discriminant ability of these parameters in arthritic versus non-arthritic subjects is still mostly unexplored. The purpose was to evaluate which movement quality variables derived from a single trunk worn IMU can distinguish the gait pattern of arthritic compared to non-arthritic subjects. Second, we evaluated these variables' sensitivity to capture changes in gait properties during one year following total knee arthroplasty.

### Methods

Twenty patients with hip OA, 18 patients with knee OA and 20 asymptomatic controls participated in this study. Seventeen of the 18 subjects with knee OA were followed for one year postoperatively. The participants were equipped with a single trunk worn IMU (MVN BIOMECH Awinda, Xsens Technologies, 60 Hz) and were instructed to walk back and forth along a 10m walkway at a self-selected speed. During pre-processing, sensor tilt was corrected, and the left-right steps were recognised using the anteriorposterior and mediolateral acceleration signal. The separate walking trials were concatenated to one long time trial. The movement

quality parameters: gait symmetry (step-stride regularity and Harmonic Ratio), complexity (sample entropy), smoothness (Spectral Arc Length), and stability (Maximum Lyapunov Exponent) were calculated from the raw acceleration signal in three directions. We established the parameters' minimal detectable change using test-retest data from the asymptomatic controls to determine if measured differences surpassed naturally occurring measurement variability. We used the Mann-Whitney U test for group differences between asymptomatic controls and hip or knee OA subjects. To assess how the parameters evolve after a TKA, Friedman's chi-square ANOVA was conducted. When a significant difference was found ( $\alpha < 0.05$ ), a Wilcoxon signed-rank test with a Bonferroni correction ( $\alpha < 0.005$ ) was calculated to test for differences between time-point.

### Results and Discussion

We found that both arthritic groups had a more asymmetrical gait pattern than non-arthritic subjects. Furthermore, hip OA subjects had a more intermittent movement pattern than asymptomatic controls. At one year post-TKA, we see an initial deteriorating followed by improvement in gait symmetry—and an initial deterioration in movement complexity that does not recover over time. Moreover, at one-year post-TKA, patients display a more unstable gait pattern in long-term stability measure compared to asymptomatic individuals.

### Conclusions

A single lower back accelerometer can be used to characterise movement quality before and after a total joint arthroplasty. We see a recovery of most symmetry measures, but a more unstable and less complex gait pattern at follow-up. These results show the ability to monitor these variables in a free-living environment to inform personalised rehabilitation of gait symmetry, stability, complexity, and smoothness.

Email: thomas.robert@univ-eiffel.fr

### Summary

Short-term maximum Lyapunov exponent (LyE) has been proven useful in identifying gait instability in fall-prone aged adults. This study aims at demonstrating the feasibility of estimating LyE using very simple set-up (smartphone – simple walking protocol) which could be used to monitor the LyE evolution for elderly adults.

### Introduction

It is essential to identify falling risks and instability measures to reduce falls within the elderly population. The LyE has gained increasing interest in the present literature. In the context of gait stability, the LyE quantifies the motor system's ability to recover from small perturbation and maintain dynamic stability in the presence of kinematic variability which increases with age. LyE has been successfully measured by [1] using a non-aligned inertial measurement unit (IMU). To date, LyE has not been measured using smartphone IMU. Smartphone IMUs have been proved to be practical in terms of gait analysis. There is no restriction in terms of smartphone IMU signal's quality for LyE calculation. Measuring gait instability during a simple walking protocol, 6-minute walk test (6MWT), using smartphone accelerometer data can greatly benefit clinicians and individuals in terms of affordability and accessibility. Therefore, in this study, we aim at demonstrating the feasibility of estimating LyE using very simple set-up (smartphone – 6MWT) which could be used to monitor the LyE evolution for elderly adults.

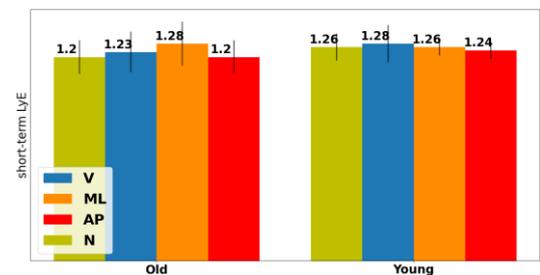

### Methods

Six elderly ( $72 \pm 6$  y, 6 men,  $89 \pm 23$  kg,  $170 \pm 6$  cm) and six young adults ( $26 \pm 6$  y, 4 women and 2 men,  $66 \pm 7$  kg,  $168 \pm 9$  cm) volunteered for this study. The participants had no history of falls. Each participant signed an informed consent. Participants walked in a corridor back and forth for 6 minutes with a smartphone, One plus 7, placed in a sport's belt at the waist. The acceleration signal was recorded at 100 Hz using a customized application. Because of the phone power-dependent sampling frequency, the recorded acceleration signal is resampled to 100 Hz. The LyE is calculated on the mediolateral (ML), anterior-posterior (AP), and vertical (V) acceleration components and on the acceleration norm (N). Pre-processing methods before LyE calculation of the four signals are similar to those found in [2]. No filtration was done because of the unwanted effects of filtering nonlinear signals. 150 consecutive strides are analyzed for each case. Signals are time-normalized to contain 15,000 samples. The chosen time delay is 10 samples and, the embedding dimension selected is

5. The LyE is estimated on 0 to 50 samples using the Python package nolds [3] and the Rosenstein et al. algorithm.

### Results and Discussion

Average LyE calculated on the V, ML, AP, and N signals for old and young adults are shown in figure 1. The LyE showed no difference between elderly and young adults and no difference between signal types.

**Figure 1:** Short-term Lyapunov (Lye) exponent calculated on vertical (V), mediolateral (ML), anterior-posterior (AP) components of acceleration, and acceleration norm (N) for old and young adults.

Due to the lack of standardized methodology, disparate LyE values for young and elderly adults are present in the literature [4]. Still values of LyE obtained in this study are within the range found in the literature [4]. Moreover, the findings that young and elderly with no history of falls present similar LyE is in line with the previous study [5] where negligible differences between healthy old and young adults were found.

The feasibility study is the first to show that it is possible to assess the LyE using a smartphone and a simple over-ground walking protocol. This evaluation, that can be either performed by a clinician or by the person himself at home, represents an interesting possibility to monitor the risk of fall. Further investigations are on-going on a larger database including elderly with a history of falls. A follow-up of elderly fall occurrences is also considered. Future results will provide additional information regarding the validity of this measure to detect an early increase risk of fall.

Email: [bt@ethz.ch](mailto:bt@ethz.ch)

### Summary

A passive strain sensor was developed using novel flexible electronic technologies with the aim to wirelessly measure *in vivo* human Achilles Tendon (AT) strain. Mechanical testing performed on the sensor in air and submerged in a saline bath at different temperatures demonstrated high performance and wireless data transmission under replicated *in vivo* conditions. The calibration curve remained linear and distinct signal changes were observed for strain steps of 0.1% in all conditions.

### Introduction

Early loading rehabilitation following AT rupture appears key to restoring the healthy tendon length and stiffness necessary for a full functional recovery. We developed a highly compliant implantable strain to monitor AT healing and inform data driven rehabilitation. For the sensor to reach this goal, it must achieve the necessary strain resolution and range to accurately capture AT elongation under dynamic *in vivo* conditions.

### Methods

A stretchable capacitive sensor was fabricated by embedding two conductive AuTiO<sub>2</sub> nanowire layers in series with a coil antenna in PDMS, allowing the whole unit to work as an inductor-capacitor-resistor circuit. A readout system was developed to wirelessly measure the sensor resonance frequency (RF) at 1024 Hz. Stretching the sensor reduces the distance between the two nanowire layers, and thus the capacitance and RF, allowing an indirect strain measurement. One sensor was stretched in a tensile machine (Zwick Roell ZDO-F0.5TS) while the RF was wirelessly measured (Figure 1A). Tests were performed under four conditions: the sensor in air or submerged in Phosphate-buffered saline (PBS) water, and the wireless data transfer across air or PBS water. Calibration and resolution tests were performed under displacement control in the four conditions after 50 cycles of pre-conditioning (0-25%):

**Calibration:** To characterize the relationship between the applied strain and the measured RF (Fig 1C), each sensor was stretched from 0% to 25% strain in 1% steps maintained for 30s. The RF value was averaged on 3 seconds.

**Resolution:** The smallest measurable strain variation was established by performing 10 cycles of 3 steps of ± 0.1%, 0.2% and 0.5% strain around the 5%, 10% and 15% strain levels (Fig 1C).

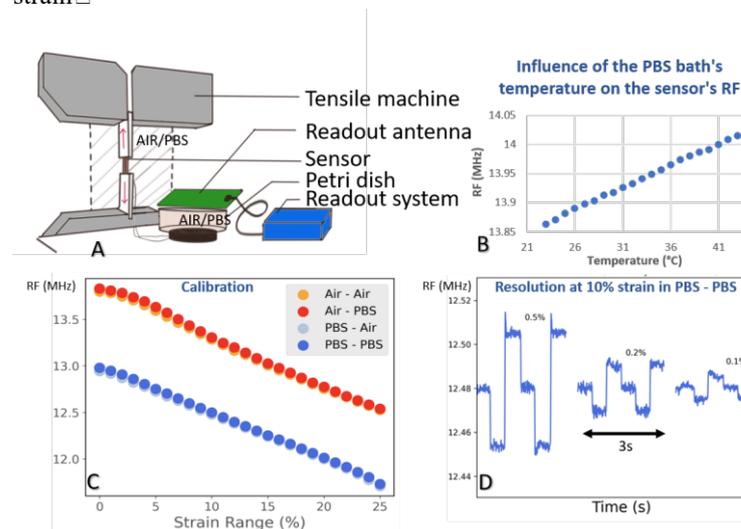

**Temperature:** One sensor was then set at a fixed length and the RF was measured while the PBS was heated from 22 to 45°C.

### Results and Discussion

**Calibration:** The slope of the sensor remained almost perfectly linear between 0% and 25% in all conditions ( $R^2=0.99$ ), a range that exceeds expected *in vivo* AT strains. However, submerging the sensor in PBS caused a shift in the baseline RF, likely due to swelling.

**Resolution:** The strain steps of 0.1% were observable in all conditions and at all strain levels. This resolution exceeds the necessary threshold to capture clinically relevant *in vivo* strain variations in the human AT during dynamic activities.

**Temperature:** The sensor RF increased linearly with temperature ( $R^2=0.99$ ): a 2°C increase leads to a sensor signal change equivalent to 0.1% strain.

**Figure 1:** A. Experimental setup. B. Influence of the temperature on the sensor RF. C. Calibration curves of the sensor in 4 conditions. D. Resolution for 3 different strain steps.

### Conclusions

Our novel sensor demonstrated in a saline environment with representative *in vivo* conductivity properties that it has the strain range and resolution needed to perform *in vivo* AT measurements. Upcoming implantations in sheep will demonstrate *in vivo* sensor function and biocompatibility over a two-month period.

## A NOVEL METHOD FOR EQUINE GAIT EVENT DETECTION

Eloise V. Briggs<sup>1</sup>, Claudia Mazza<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering and INSIGNEO Institute for in silico Medicine,  
University of Sheffield, Sheffield, United Kingdom  
Email: evbriggs1@sheffield.ac.uk

### Summary

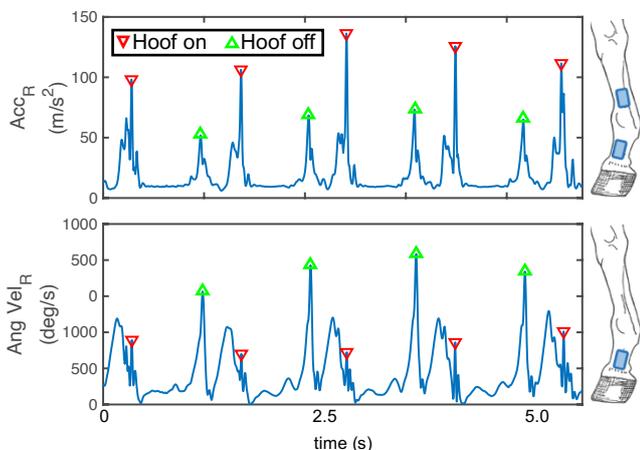

Accurate detection of hoof on and off events is essential to equine gait assessment. This study aimed to propose and validate inertial sensor-based methods of gait event detection, exploring different sensor placement and signal processing methods. A mixed cohort of eleven horses wore sensors on the left hooves, pasterns and canons. Walk and trot strides were recorded on asphalt. Gait events detected from pastern and cannon sensors were compared to reference, hoof-detected events. Pastern-based methods were the most accurate and precise, incurring mean errors of 1ms to 6ms, depending on the limb, gait and event. No horse-dependent effects were seen. Thus, developed methods were validated to enable reliable gait event detection from a mixed cohort of horses.

### Introduction

As interest in analysing equine gait in real world conditions increases, so too does demand for validated quantification methods which use portable measuring systems [1]. Consequently, several methods based on inertial measurement units (IMUs) have now been proposed for detecting gait as an alternative to traditional force plate-based methods [2,3,4,5]. However, these have been restricted to validation under lab conditions, often with a limited cohort of horses. This research aimed to propose and validate methods of gait event detection using IMUs attached to the pasterns and canons.

### Methods

Eleven horses (eight geldings, three mares; 154(21)cm; 12(8)years) were recruited to wear IMUs attached to the left hooves, pasterns and canons (Fig 1). Shimmer3 IMUs (Dublin, Ireland) collected data (200Hz) using triaxial gyroscopes ( $\pm 2000$  deg/s), magnetometers ( $\pm 49$  Ga) and accelerometers ( $\pm 16g$  m/s<sup>2</sup> canons;  $\pm 200g$  m/s<sup>2</sup> hooves, pasterns). Horses were led in a 25m straight line at walk and trot, three passes per gait on asphalt.

**Figure 1:** illustration of the two novel data processing methods to detect hoof on and off

Timing of gait events were detected from cannon IMUs using two state of the art methods [3,4] and from canons and pasterns using two novel methods, based on identification of peaks in the resultant angular velocity (pasterns; Fig 1, bottom) or resultant acceleration (pasterns or canons; Fig 1, top). The hoof on and off timings obtained using these methods were compared to event timings detected by a hoof-based, reference method [5]. The performance of each method for detecting events was assessed in terms of the mean error (*accuracy*) and distribution of these errors (*precision*). Results were investigated for significance using repeated measures ANOVA techniques.

### Results and Discussion

Novel cannon methods consistently outperformed application of literature methods, incurring mean errors (standard deviations) ranging from magnitudes of 1(19)ms to 15(33)ms, compared to 4(27)ms to 161(412)ms. Novel methods may be more robust than the alternatives for use in the field as they use only resultant data streams so exact IMU orientation is less important, reducing inter-user variability and effects of IMU movement during data collection. Pastern methods (Table 1) proved superior to novel cannon methods, with errors of 2(9)ms to 5(11)ms compared to 1(19)ms to 15(33)ms for forelimbs; and 1(12) to 6(14)ms compared to 1(15) to 7(14) hindlimbs. Differences were significant ( $p < 0.001$ ) for all events except forelimb events at walk. Furthermore, no horse-dependent effects were revealed by statistical analysis, suggesting the developed methods were consistent across the highly varied range of horses.

**Table 1:** Errors (ms) incurred by the most accurate and precise pastern methods to detect gait events

Gait	Forelimb		Hindlimb	
	Hoof on	Hoof off	Hoof on	Hoof off
Walk	-5(11)	3(16)	2(10)	6(14)
Trot	-2(9)	4(34)	1(12)	2(9)

### Conclusions

Methods have been developed which are able to accurately and precisely detect gait events from a varied cohort of horses using pastern mounted IMUs. This will facilitate future studies under field conditions.

### Summary

Older adults participating in an eight-week intervention with guided physical activity two times per week improved physical activity (PA) and reduced sedentary behaviour (SB) measured with accelerometers. The result of this study may contribute valuable knowledge in designing of proper public health strategies targeting healthier physical activity patterns in older adults.

### Introduction

Many beneficial health outcomes are associated with SB and PA in older adults.<sup>1</sup> However, research is scarce or lacking regarding supervised exercise-interventions with accelerometer measured SB and PA including reliability assessments in older adults. The aim of this study was to determine if eight-weeks of regular supervised exercise would have any effect on physical activity patterns in older adults. For comparison, a control group, not receiving supervised exercise, performed similar pre- and end-tests intervals. Reliability of the accelerometer with two separate pre-tests measures was also investigated.

### Methods

Seventy-eight older adults exercised (65-91yrs, 61,5% women) and 43 participated in a control group (65-88yrs, 69,8% women). The exercise group performed combined aerobic and strength-training, twice/w à 1 h. Accelerometer assessments (GT3X+, Actigraph) for the exercise group were performed three times, two times before the intervention (Pre-1 and Pre-2) and one test in the last week of the 8-week-exercise-period (End).<sup>2</sup> The control group performed one pre-test and one end-test at corresponding intervals, without receiving any supervised physical activity. Accelerometer data was analyzed using the vector magnitude (VM) of all three-axis in 60s epochs, with previously validated cut-points for physical activity intensities related to METs.<sup>3,4</sup>

### Results

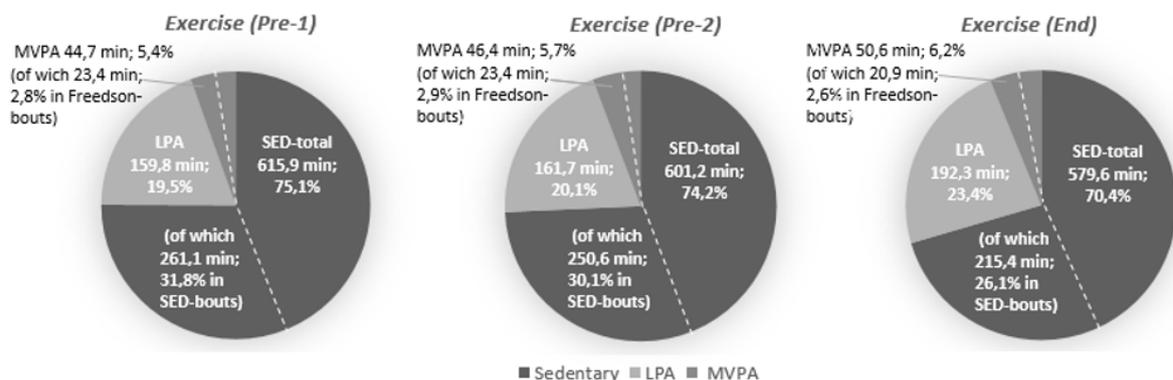

There was a significant difference in the exercise-group from Pre-1 to End-test in both absolute minutes (min/w) and relative to daily wear time (%); in moderate-to-vigorous-PA (MVPA +41 min/w and 8% of-total-daily-wear-time), light-intensity (LPA+228 min/w and 3.9% of-total-daily-wear-time), Sedentary (SED) -time (-254 min/w and -4.7% of-total-daily-wear-time) and SED-bouts-à-10 min (-320 min/w and -5.7% of-total-daily-wear-time), (see Figure 1). The control group showed only significant differences from pre-1-to-End-test in % of-total-daily-wear-time for LPA (+2.3%) and SED-time (-2.7%). Total-daily-counts in the End-test increased for controls (+6,7%) but significantly more for the exercise group (+17,3%). Between the exercise groups' two pre-tests, no significant difference was observed, except for percent of wear time in total-PA (+4.6%) and SED-total (-2.4%).

### Conclusions

Older adults participating in supervised exercise increased light and moderate- to vigorous PA and decreased time in SB, which is of importance because elderly being less sedentary and more physically active reduce risks of disease and morbidity. Furthermore, a good repeatability was shown from the two pre-tests.

### Summary

Tracking players' movements is important for monitoring and optimization of training load. A novel LiDAR-based system purports to accurately measure velocity and acceleration of player movements. The study examined the validity of this system against a 3D motion analysis system. Two competitive football players completed nine sport-specific movements trials, recorded concurrently by the LiDAR and 3D systems. Instantaneous velocity and acceleration, and time spent within key performance indicator (KPIs) bands were compared between systems. RMSE and  $R^2$  assessed agreement and goodness of fit, respectively. T-tests compared time within each KPI band. Velocity and acceleration RMSE values were low, while  $R^2$  showed high agreement across all movements. Differences in time spent within each KPI band were mostly trivial. These results show that the LiDAR-based system can provide valid measures of velocity and acceleration in football-specific tasks, thus providing accurate tracking of players and calculation of relevant KPIs.

### Introduction

Recent advances in electronic performance and tracking systems (EPTS) have allowed tracking football players' movements in training and competition [1], avoiding injuries and overload by monitoring and optimising training load and progression [2]. Additionally, live tactical changes are facilitated by in-game physical and tactical performance assessment. A new LiDAR-based system (Sportlight<sup>®</sup> LiDAR) purports to provide accurate velocity and acceleration metrics derived from player movements, with little set up time, no markers and high portability.

The aim of the study was to examine the validity of LiDAR against a 'gold standard' 3D motion analysis system (Icon).

### Methods

Two competitive football players (age: 18 years, height: 1.74 ± 0.01m, mass: 66.5 ± 7.8kg, playing experience at this level: 3 years) completed nine trials each of six sport-specific movements, consisting of straight-line sprints, cuts, and curved runs. Trials were recorded concurrently by four LiDAR units and a 64-camera Icon system. Instantaneous velocity and acceleration, and time spent within key performance indicator (KPI) bands (defined by velocity and acceleration thresholds) were compared between systems. Agreement and goodness of fit were evaluated by root mean

square error (RMSE) and coefficient of determination ( $R^2$ ), respectively. Time spent within each KPI band, as an indicator of work volume, was assessed with t-tests for statistical significance and Cohen's d for effect size.

### Results and Discussion

Velocity RMSE ranged from 0.04m s<sup>-1</sup> to 0.14m s<sup>-1</sup> across all movements and acceleration RMSE ranged from 0.16m s<sup>-2</sup> to 0.7m s<sup>-2</sup>, showing small deviation of the LiDAR system values from the Icon ones.  $R^2$  values for velocity and acceleration ranged from 0.88 to 1.00 across all movements, indicating high agreement between the two systems. Finally, differences between systems in time spent within each KPI were trivial, except for Sprint and High deceleration where small differences were found (Table 1).

**Table 1.** Key performance indicators (KPIs) for velocity and acceleration. Velocity thresholds: slow ( $\geq 0.3$  m·s<sup>-1</sup> and  $< 1.6$  m·s<sup>-1</sup>); moderate ( $\geq 1.6$  m·s<sup>-1</sup> and  $< 4.2$  m·s<sup>-1</sup>); fast ( $\geq 4.2$  m·s<sup>-1</sup> and  $< 5.5$  m·s<sup>-1</sup>); very fast ( $\geq 5.5$  m·s<sup>-1</sup> and  $< 6.9$  m·s<sup>-1</sup>); and sprint ( $\geq 6.9$  m·s<sup>-1</sup>). High acceleration threshold:  $\geq 3$  m·s<sup>-2</sup>. High deceleration threshold:  $< 3$  m·s<sup>-2</sup>. 3D and LiDAR data presented as mean ± SD. p: significance value ( $\alpha = 0.05$ ). Cohen's d: effect size. RMSE: root mean square error.

	3D	LiDAR	p	Cohen's d	RMSE
<i>Velocity KPI</i>					
<b>Slow</b>	9.70 ± 2.94	9.42 ± 2.78	0.024	0.098 (trivial)	0.545
<b>Moderate</b>	24.97 ± 5.08	24.77 ± 5.13	0.005	0.04 (trivial)	0.33
<b>Fast</b>	6.19 ± 1.37	6.20 ± 1.33	0.908	0.005 (trivial)	0.25
<b>Very fast</b>	3.01 ± 0.92	2.97 ± 0.90	0.315	0.044 (trivial)	0.164
<b>Sprint</b>	0.21 ± 0.21	0.16 ± 0.23	0.119	0.264 (small)	0.158
<i>Acceleration KPI</i>					
<b>High acceleration</b>	19.79 ± 4.87	19.52 ± 4.82	0.002	0.057 (trivial)	0.413
<b>High deceleration</b>	4.95 ± 1.27	4.54 ± 1.25	< 0.001	0.325 (small)	0.488

### Conclusions

The present results suggest that practitioners and coaches can use the LiDAR-based system to monitor workload through KPIs derived from velocity and acceleration, with no trade-off between portability and accuracy.

## Step count is related to habitual weight bearing asymmetry in the workplace: An occupational study in hotel employees

Alison N. Agres, Sónia A. Alves, Georg N. Duda  
 Julius Wolff Institute, Charité –Universitätsmedizin Berlin, Berlin, Germany  
 Email: alison.agres@charite.de

### Summary

Although standing is often suggested to promote health in the sedentary workplace, extensive standing results in accumulated joint load from prolonged weight bearing and can consequentially lead to musculoskeletal pain. Weight bearing asymmetries apply asymmetric loads, which can exacerbate this problem, but could also serve as an indicator for imbalanced musculoskeletal loading. Here, we analyzed weight bearing asymmetry in an occupational setting and found that hotel workers that took more steps during a work shift exhibited improved overall weight bearing symmetry. These results imply that periods of dynamic movement can improve weight bearing asymmetry, which can break up extended static periods in active and sedentary workplaces.

### Introduction

In the workplace, standing is typically recommended in order to avoid long sedentary periods. These static postures offer increased muscle activity versus sitting [1], yet prolonged standing still leads to detrimental musculoskeletal symptoms [2]. Longer periods of weight bearing (WB) lead to the accumulation of excessive joint loads that can precede occupational injury [3], which can accelerate when WB is asymmetric. It remains unclear how an individual's relative activity level, as determined by steps, affects overall WB asymmetries. Thus, the aim of this study was to determine the relationship between step count and side-to-side differences in weight bearing during a typical workday. In order to achieve this, instrumented insoles measured WB during shift work in active hotel employees.

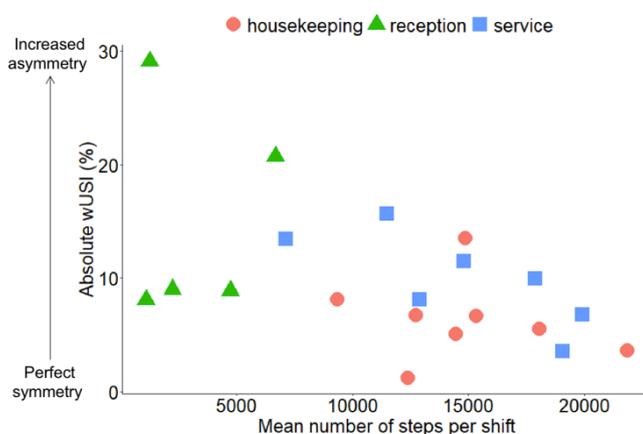

### Methods

Twenty participants (14 females, 31.9±7.9 years, 24.8±4.2 kg.m<sup>2</sup>) employed at five local hotels in reception, service, and housekeeping departments were recruited. The local ethics committee approved protocols and participants gave written informed consent. Each participant received an iPod and a pair of instrumented insoles (loadsol, novel GmbH), then instructed on data collection. Participants wore insoles for a minimum of one work shift within two weeks. Insoles recorded the overall plantar force from each foot, transmitted via Bluetooth to the iPod for local storage. Upon equipment recovery, raw data was downloaded. A custom-step recognition script (RStudio Inc.) identified periods of static and dynamic loading. The weighted Universal Symmetry Index (wUSI) [4] determined overall side-to-side load asymmetry over the entire measurement for each participant, where 0% indicates perfect symmetry and 100% indicates total asymmetry. After normality tests, one-way analyses of variance examined the effect of group on step count and wUSI values (p=0.05). A Pearson correlation examined the

relationship between the mean number of steps per shift and overall wUSI across all participants.

### Results and Discussion

In an average shift, reception workers took fewer steps (3210±2424, p<0.01) compared to service and housekeeping (14729±4597 and 14874±3783, respectively). The overall proportion of dynamic loading was 14% in the reception group, compared to 40% in service, and 39% in housekeeping. A negative correlation was found between overall wUSI and mean number of steps taken per shift (Figure 1;  $r = -0.540$ ;  $p = 0.014$ ).

**Figure 1:** Absolute weighted universal symmetry index (wUSI) versus mean steps per shift for participant from the housekeeping (pink circles) reception (green triangles) and service (blue squares).

Of note, many participants exceeded a wUSI of 10%, which corresponds to levels of asymmetry measured during crutch-assisted gait in healthy participants in a gait laboratory [4]. These results further underline the disparity between laboratory measurements and real-life workplace settings. Further work in expanded cohorts should aim to understand weight bearing symmetry and its relationship to physical activity and musculoskeletal health.

### Conclusions

Increased dynamic activity, measured by steps taken, corresponds to improved WB symmetry during a shift in active hotel workers. Prolonged static WB activity, such as standing, correlates to decreased WB symmetry or increased WB asymmetry.

## An Automatic Inertial Measurement Unit Alignment Pipeline in Human Motion Measurement

### Summary

This study presents an automatic pipeline to detect and correct misalignment in the Inertial Measurement Unit (IMU) - based human motion measurement. Novel algorithms were proposed and tested to successfully reduce IMU misalignment errors with great potential to an easy and reliable calibration.

### Introduction

Movement injury is increasingly recognized as a global public health concern as ageing occurs worldwide in recent years, which calls for accurate and timely medical diagnosis and well-designed rehabilitation scheme for patients. (IMU)-based human motion tracking system, characterized by considerable accuracy, friendly costing, and low dependency on utilizing occasion, plays a more and more significant role in the clinical treatment process. However, misalignment could be caused by magnetic distortion during measurement, resulting in inaccurate joint angle estimation and failure in motion reconstruction. This study aims to develop a pipeline integrated with novel algorithms to automatically detect motion phase and correct IMU misalignment.

### Methods

The experiment was conducted using a wireless IMU system (Trigno Avanti, Delsys, USA) and an electronic compass. Six IMUs were attached to a plane with corresponding axes pointing to the same direction (Y-axis to the global south). After keeping IMUs still for 5 to 10 seconds, the plane was rotated around the global up axis with a pitch motion in a range of  $-60^\circ$  to  $60^\circ$ .

An algorithm based on the Riemannian distance on  $SO(3)$  space was developed for the motion phase detection. The Riemannian distance is considered to be an intrinsic representation of rotation [1] to quantify relative motions between two adjacent frames and is calculated as

$$d = \frac{1}{\sqrt{2}} \log(\|R_1^T R_2\|_F)$$

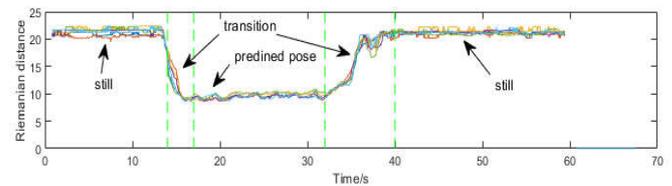

where  $\|\cdot\|_F$  denotes the Frobenius norm of the matrix. In addition, a high-order median average filter was utilized to smooth the processed signal to improve the threshold-based motion phase detection.

An algorithm to correct the IMU misalignment was also proposed: first, the projection of Y-axis was calculated with a reference to the global coordinate frame; next, an average projection was calculated which was a considerable rotation standard; finally, a rotation around the global Up axis was

performed on the direction cosine matrix of each frame to ensure the Y-axis pointing to the same direction.

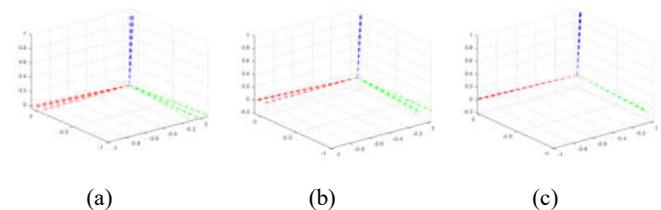

### Results and Discussion

Fig. 1 gives a visualization of different motion phase during a representative experiment. By calculating the Riemannian distance between adjacent frames, the motion phases were detected. The algorithm could be applied to detect the still-to-move transition and simplify a calibration procedure in human motion tracking which often requires a manual segmentation of a static anatomical position.

**Figure 1:** A representative result of motion phase detection. Green dash lines represent the boundary of motion phases.

As shown in the Fig. 2 (a), the IMU misalignment error decreased from  $13^\circ$  to  $5.0^\circ$  after the application of predefined pose and correction algorithm. The reduction was lower than 32.9% reduction as reported in the other study [2]. The repeatability test of ten experiments showed that the error was decreased from  $13^\circ \pm 18^\circ$  to  $5^\circ \pm 5^\circ$  (Fig. 2b); the correction algorithm further improved the precision with a variation of  $0^\circ$  (c), which was best when compared to the other algorithms [3].

**Figure 2:** IMU coordinate frame with reference to global frame (a) before correction (b) after predefined pose (c) after correction algorithm.

### Conclusions

The pipeline has shown to successfully improve the accuracy and precision in the IMU-based misalignment correction.

### Summary

A global health emergency based on the COVID-19 outbreak was declared on the 30th of January 2020. Countries more susceptible to the COVID-19 situation included those with compromised, weak or vulnerable healthcare systems. During the COVID-19 global pandemic it became apparent that the lives of the citizens of the world would be affected from a public health, lifestyle and economy perspective. As a consequence, the spread of the COVID-19 pandemic continued to grow which gave rise to observing quarantine measures, social distancing measures, hospitalisation / bed rest measures and risks of physical inactivity brought about by immobilisation. This study aims to evaluate the effect of COVID-19 on leisure physical activity among 10,121 participants using a validated COVISTRESS questionnaire.

### Introduction

The COVISTRESS network recently published a COVID-19 study associated with physical activity, sedentary action and psychological emotion [1]. Research in this area remains ongoing and continues to broaden. New COVISTRESS (<http://www.covistress.org/index-en.html>) questionnaires are developed ever so often to meet the demands of society in response to the changes brought about by the COVID-19 pandemic. On a global scale the impact of the COVID-19 pandemic continues to affect the lives of white-collared and blue-collared workers in our communities. Majority of these workers become emotionally distressed. In view of the first and second waves of the coronavirus, stringent lockdowns have been stipulated and as a consequence has led to reductions in physical activity levels and a rise in depression. This abstract highlights the impact COVID-19 has had on number of hours performed by the COVISTRESS questionnaire participants in terms of physical activity per week.

### Methods

Participants were recruited via the application of the convenience and snowball sampling technique. All participants that satisfied the recruitment criteria were granted online access to the COVISTRESS questionnaire. 10,121 participants (Male: 2850, Female: 6292) completed the questionnaire. Of the 10,121 participants 979 did not indicate their sex. Two observational study scenarios were evaluated namely “Prior” to COVID-19 pandemic and “Currently”, i.e., during the COVID-19 period. Specific

information requested included number of hours of leisure physical activity per week “Prior” to the Coronavirus Pandemic and “Currently”. All these components were evaluated using a Spearman correlation ( $r$ ) and the MAS with an intensity scale ranging from 0–100.

**Table 1** Descriptive statistics showing the “Prior” and “Currently” dataset summary of the MAS intensity scale

Physical Activity Measurement	Assessment "Before" COVID-19 (Mean $\pm$ SD)	Assessment "Now" during COVID-19 (Mean $\pm$ SD)
Female: Number of hours of leisure physical activity per week	8.32 $\pm$ 7.29	5.99 $\pm$ 6.08
Male: Number of hours of leisure physical activity per week	10.39 $\pm$ 8.61	7.75 $\pm$ 7.61

### Results and Discussion

Both males and females displayed similar output measures (Table 1). A stronger correlation between “Prior” COVID-19 and “Currently” was also observed among the Males ( $r = 0.720$ ) in comparison to the Females ( $r = 0.639$ ). The results presented in this abstract provide insightful information pertaining to physical activity using the COVISTRESS MAS intensity scale. On completion of the current dataset analyses, a 90% compliance was achieved with respect to completed COVISTRESS questionnaires.

### Conclusions

A detailed assessment and report on the impact of physical activity has been presented. The aim of this study was achieved through the effective use and interpretation of the COVISTRESS questionnaire. These findings from the COVISTRESS questionnaire are encouraging and provide a platform from which future studies and collaborations across different countries can be fostered.

### Acknowledgments

The authors would like to thank the COVISTRESS Network and all the participants involved in the study.

## Effect of total contact cast on lower limb kinematics and kinetics during walking gait

Aoife Healy<sup>1</sup>, Ilias Theodorakos<sup>2</sup>, Panagiotis Chatzistergos<sup>1</sup> and Nachiappan Chockalingam<sup>1</sup>

<sup>1</sup>Centre for Biomechanics and Rehabilitation Technologies, Staffordshire University, Stoke on Trent, UK

<sup>2</sup>Univ Lyon, Univ Gustave Eiffel, LBMC UMR\_T9406, F69622, Lyon, France

Email: a.healy@staffs.ac.uk

### Summary

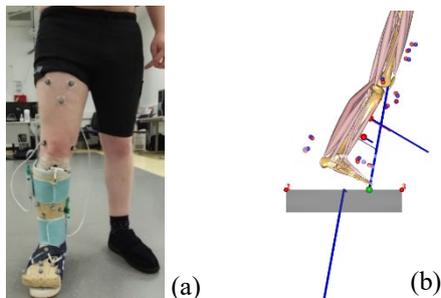

This study examined the effect of the use of total contact cast (TCC) on the range of motion and loading of the ankle, knee and hip joints during walking. While wearing the TCC, ankle kinematics and loading were significantly reduced and altered knee and hip kinematics were observed. The effect of a TCC on internal joint loading was quantified.

### Introduction

TCC is widely used in the management of diabetic foot ulceration by offloading the foot and ankle. Wearing a TCC is known to significantly change the biomechanics of gait but its effect on internal joint loading is not fully understood. A possible increase in knee or hip joint loading could have a detrimental effect on comfort and increase the risk for injury. In this context, the aim of this study is to quantify the changes in lower limb joints caused by the use of a TCC.

### Methods

Twelve participants were selected based on sex (6 males, 6 females), height (short, average, tall) and BMI (healthy, obese) with no known medical conditions, participated in the study. Participants performed walking trials with TCC (Figure 1a) and without TCC. Casting was done using a novel wood and biodegradable plastic casting material (Woodcast®, Onbone Oy, Espoo, Finland) [1,2].

**Figure 1:** (a) Lower limb casted with TCC; (b) AnyBody musculoskeletal model.

Two force plates (AMTI, USA), a Vicon motion capture system (Vicon, OMG, Oxford, UK), and F-Scan pressure measurement system (Tekscan Inc., Boston, USA) provided measurements that served as inputs to subject specific musculoskeletal models that were developed in the AnyBody Modelling System (AMS) v 6.1.0, based on the "MoCap\_LowerBody" model (Figure 1b). Simulations were performed to obtain joint kinematics and joint reaction forces.

### Results and Discussion

One way (cast condition) repeated measures ANOVA with two between subject factors (sex, BMI) revealed a significant reduction for the TCC trials for talocrural plantarflexion, subtalar eversion and hip flexion, while knee flexion was significantly increased (Table 1). For the kinetic variables, the TCC resulted in significantly reduced talocrural proximodistal and mediolateral, and subtalar anteroposterior and mediolateral reaction forces, and a reduction in the peak vertical ground reaction force. Hip loading was not significantly affected by the TCC. A significant interaction was observed between the TCC and BMI for the knee proximal force; knee proximal force decreased for the obese participants when they wore the TCC (No TCC 4.7 BW vs. With TCC 4.1 BW), while it increased for the healthy participants (No TCC 4 BW vs. With TCC 5.4 BW). The healthy participants used a more upright posture with a less flexed knee and hip, which resulted in significantly increased knee proximal force.

**Table 1:** Significantly different variables ( $p < 0.05$ ) between conditions (Mean (SD)).

Variable	p	No TCC	With TCC
Vertical ground reaction force (BW)	0.002	1.13 (0.06)	1.08 (0.07)
Talocrural plantarflexion angle (°)	0.002	23.8 (6.6)	17.2 (5.0)
Subtalar eversion angle (°)	0.037	-6.1 (8.5)	-12.4 (8.2)
Knee flexion angle (°)	0.011	11.6 (8.3)	28.4 (17.6)
Hip flexion angle (°)	0.047	18.8 (14.3)	9.3 (19.4)
Talocrural proximodistal force (BW)	0.017	-7.7 (2.1)	-5.9 (1.5)
Talocrural mediolateral force (BW)	0.040	1.7 (0.6)	1.3 (0.4)
Subtalar anteroposterior force (BW)	0.004	6.1 (1.8)	4.0 (1.4)
Subtalar mediolateral force (BW)	0.048	-0.6 (0.7)	-0.0 (0.7)

### Conclusions

Participants used different movement strategies based on their BMI to overcome the restricted ankle movement imposed by the TCC. While results support the use of TCCs where a reduced foot and ankle loading is required, longitudinal studies are needed to understand the effect of altered knee and hip kinematics and knee loading on individuals using a TCC.

Email: [dbenoit@uottawa.ca](mailto:dbenoit@uottawa.ca)

### Summary

The objective of this study was to determine the optimal limb symmetry index (LSI) cut-off threshold for classifying anterior cruciate ligament (ACL) deficient and uninjured paediatric patients. Forty-two ACL injured patients (ACLi) and 69 matched uninjured controls (CON) performed isometric strength and hopping tasks. Classification trees (CT) were then trained according to different LSI cut-off thresholds. A LSI threshold of 89% had the highest Mathew's Correlation Coefficient (MCC) with 0.662, a specificity of 93%, and a sensitivity of 70%. Thus, based on our analysis, it appears the 89-90% LSI cut-off is an appropriate threshold for separating the hopping and strength performance of ACL injured paediatric participants.

### Introduction

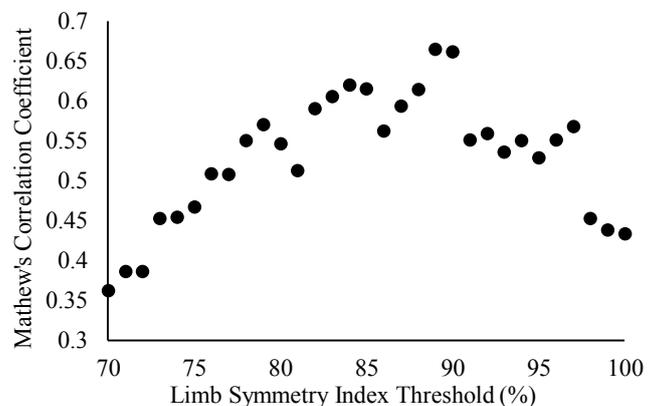

Following a paediatric ACL reconstruction the risk for a subsequent ACL injury is extremely high, with approximately 17-30% of paediatric patients sustaining a second ACL injury within two years [1]. Despite the high rate of re-injury, no consensus exists for what performance thresholds should be reached prior to return-to-activity (RTA). In adult populations, most contemporary RTA guidelines recommend a >90% LSI for single-leg hopping and strength tests; however, there is limited evidence supporting the >90% threshold in paediatric patients. In fact, research suggests that LSIs used by paediatric orthopaedic surgeons can range from 75-95% [2]. Therefore, the purpose of this study was to determine which LSI cut-off threshold should be used when classifying ACL deficient and uninjured paediatric patients.

### Methods

Forty-two ACLi patients (30 females; 10-18 years old) and 69 CON (36 females; 10-18 years old) were recruited for this study. Participants performed isometric knee extension and flexion tasks on an isokinetic dynamometer. Jump distance and time were also recorded during series of single-leg hopping tasks. LSIs were calculated as injured/uninjured limb for ACLi and non-dominant/dominant limb for CON. LSIs with significant between group (ACLi vs CON) differences (independent *t*-tests), were used in a machine learning algorithm. LSIs were then converted from percentage to categorical 'pass/fail' grades according to cut-off thresholds ranging from 70-100%. CTs were then fit to the converted categorical data at each cut-off threshold. Ten-fold cross-validation was used to determine the optimal tree complexity. Model performance was evaluated according to Mathew's Correlation Coefficients (MCC), sensitivity and specificity.

### Results and Discussion

Statistically significant differences ( $p < 0.05$ ) were identified in the maximum anterior, lateral and triple hop distances, timed 6m hop, and knee extension strength LSIs. These variables were then included in a machine learning algorithm. When the data was converted from percentage to categorical 'pass/fail' grades using LSI cut-off thresholds, a plateau in the MCCs occurred between LSIs thresholds of ~85-90%. A LSI threshold of 89% had the highest MCC with 0.662, as well as a specificity of 93% and a sensitivity of 70%.

**Figure 1:** The classification tree MCCs according to different limb symmetry index cut-off thresholds.

### Conclusions

By applying a machine learning model at different LSI cut-off thresholds we were able to determine that LSI thresholds in the 85-90% range provided the most accurate classification of paediatric ACL injury status (Figure 1). Thus, based on our analysis, it appears the 90% LSI cut-off is an appropriate threshold for separating the hopping and strength performance of ACLi and CON paediatric participants. Finally, considering that assigning LSI cut-off thresholds improves the interpretability of the functional tests while also offering an accurate classification for injury status, our findings suggest that LSI thresholds are viable in a clinical environment.

### Summary

In-silico models are essential for understanding the biomechanics of the human ankle joint. However, prior to their use, validation against experimental data is required. The goal of this study was to further develop one of these models to include artificial articular surfaces designed to mimic the natural geometries of one anatomical specimen and to validate it against corresponding experimental data via a dynamic simulation approach. The loading conditions for the dynamic simulations were obtained from the in-vitro experiment on the corresponding anatomical specimen. Model predictions, in terms of angular displacements of the ankle joint complex (AJC), compared well with the experimental results, thus demonstrating that such model is a good reproduction of the anatomical specimen. When provided with the same physiological loading conditions, all artificial surfaces were able to reflect the mechanics of the joint with natural surfaces.

### Introduction

The difficulty in accessing the internal parts of the AJC during in-vitro experiments is being overcome by the introduction of in-silico models with the potential to improve the surgical techniques and clinical outcomes of Total Ankle Replacement. In particular, an image-based model including three-dimensional bone geometries, cartilage compensation, and ligament fibre recruitment was developed [1,2] and validated against experimental data [3,4] using standard sinusoidal curves.

In the present study, the model was extended to include artificial articular surfaces and its predictions were compared to experimental data using the corresponding loading curves from the experiments.

### Methods

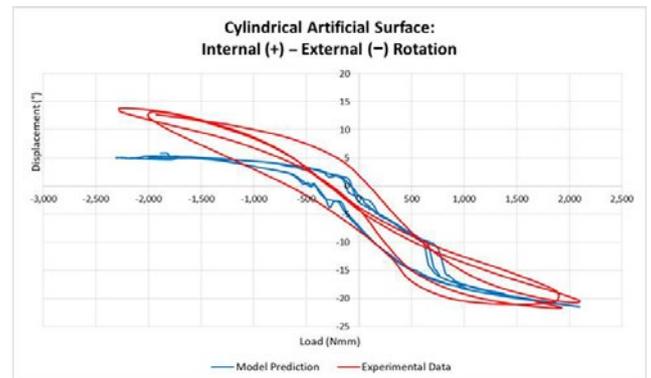

Morphological details of the ankle bones were obtained from medical imaging of an anatomical specimen and cartilage compensations were added at the articulations. The 3D bone geometries were imported in ADAMS (MSC Software Corporation, California, USA), where the ligaments were modelled as tension-only force elements with non-linear strain [1,2]. Artificial articular surfaces (a cylindrical surface, a standard cone with medial apex, and a skewed cone with lateral apex) designed to replace the natural shapes were virtually implanted on the model.

The loading conditions used to run the dynamic simulations were extracted from the corresponding experimental internal-external rotation and inversion-eversion torques [3,4]. Model predictions, in terms of angular displacement of the AJC, were compared to the experimental kinematics.

### Results and Discussion

The application of the corresponding loading conditions in the model produced load-displacement curves that were very similar to the experimental ones (Figure 1). Moreover, the model predictions reflected the pattern depicted by the experimental results, according to which the joint with standard conical surfaces allows the greatest internal-external rotation and inversion-eversion range of motion (29° and 30°), closely followed by the joint with cylindrical surfaces (27° and 29°) and skewed conical surfaces (26° and 29°). On the other hand, the joint with natural surfaces is characterised by the smallest range of motion, suggesting that such surfaces, together with the ligaments, provide a more constraining effect.

The application of the physiological loading conditions from the natural joint to the joint with three different artificial surfaces showed that all surfaces are good at replicating the motion of the natural joint, which was found to be smaller by just 0-3° depending on the type of surface and torque applied.

**Figure 1:** A typical load-displacement graph comparing experimental data (red) and model prediction (blue).

### Conclusions

This study has shown that experimental data can be used to further validate the model, whose predictions with artificial surfaces were found to be better than those with natural surfaces. The results presented suggest that this model can be used for future works on prosthetic devices for total ankle replacement with various articular surface geometries.

Attend our workshops  
at ISB2021

**1** **Generating automated reports with Xsens, bridging the gap between data and analysis**

**JULY 27<sup>TH</sup>**  
**3:30PM-4:00PM**

This report is automatically generated on the Xsens MotionCloud platform. The data is processed in the unique 'Xsens Sensor Fusion Engine, providing accurate and validated data. All that's required is an Xsens MVN motion capture setup and access to Xsens MotionCloud.

During this workshop, we would like to give you an insight in the functionalities of MVN Reports and the reports roadmap. Also, we would like to give you an in-depth introduction to the Gait Analysis report specifically.

With MVN Reports you can easily generate automated reports for Health, Ergonomics and Sports. Powered by the new Xsens MotionCloud platform, MVN Reports instantly present complex movement data in an accessible, easy-to-read report. In this workshop we will show you how you can easily generate an automated Gait Analysis report with MVN Reports.

In as little as a few minutes, a full standardized report with relevant data for that specific application is created. Also, the motion data is visualized as a 3D avatar.

**2** **Sneak peek: ACL patient tracking platform generates immediate objective results**

**JULY 28<sup>TH</sup>**  
**12:15PM-12:45PM**

Objective measurements can now be visualized in automated reports as part of a new platform aimed at improving the rehabilitation phase of an ACL patient. Xsens MotionCloud generates a Knee Assessment Report which contains objective results of nine knee stability tests like 'single hop for distance' or a 'drop vertical jump'. Joint angles, distances, symmetries and automated LESS are visualized in the report.

The MotionCloud report is integrated into a patient tracking platform, where it is combined with the results of patient surveys (IKDC, Tegner, etc.) training specific programs and other measurement. This platform aids a physiotherapist to monitor a patient through the rehab phases, keeping the patient motivated. A dashboard displays the criteria that need to be met to elevate a patient to the next phase.
